The previous history of a case is important, and leading questions must often be asked. The history of swallowing a corrosive or caustic or excessively hot fluid, or of an impacted foreign body, especially a tooth-plate, leads the clinician to doubt the existence of a true syphilitic lesion even in the presence of positive serological tests, and is more suggestive of a simple cicatricial stricture. The same is true of dysphagia following closely upon diphtheria or typhoid fever.

The duration of the dysphagia and its mode of onset is not of great value as an aid to an accurate diagnosis except when there is a definite history. Nevertheless, certain general facts should be borne in mind. Dysphagia in a case of syphilitic stenosis has usually lasted from four to twelve months before a careful examination reveals the true nature of the lesion. During this time the patient may or may not have been treated by his own medical practitioner for "indigestion," "gastritis," "gastric ulcer," "globus hystericus" or "nerves." Dysphagia of many years' standing, in the absence of a history indicative of simple stricture, is more suggestive of cardiospasm, but can be produced by a pharyngeal pouch, an œsophageal pouch, a fibrosis in the region of the crico-pharyngeal sphincter, a congenital stenosis of the œsophagus, or even by a syphilitic lesion. The onset of specific dysphagia is almost invariably gradual. Sudden difficulty in swallowing is more suggestive of an impacted foreign body or even of a malignant growth.

When syphilitic stenosis of the œsophagus is present there is usually nothing to distinguish it from any other variety of stricture except direct local examination. General examination will frequently reveal that the patient is suffering from syphilis, and there will be no clinical signs of malignancy, such as Virchow's glands. Especial attention should be paid to the mouth and throat, as signs of leukoplakia of the tongue or inner side of the cheek are rarely absent in long-standing cases. Scars are often found on the legs, and bilateral enlargement of the epitrochlear lymphatic glands, with no local condition to account for it, is always present.

Radioscopy.—After a complete general examination of the patient radioscopy is employed in order to exclude the presence of an aneurysm or other intrathoracic cause of extrinsic pressure upon the œsophagus, and to determine the level of the lesion.

Œsophagoscopy should next be resorted to, and great difficulty may be met with in making a purely visual diagnosis. This is especially so in the [illegible] ulcerated variety of gumma, which [illegible] an infiltrating carcinoma. At other times [illegible] readily diagnosed, and a portion removed for microscopical examination may reveal the true nature of the disease. The diagnostician must not be led astray by a negative Wassermann reaction of the blood, which is given by a very [illegible] sufferers from tertiary syphilis. [illegible] examination of the cerebro-spinal fluid [illegible] almost invariably confirm the clinical diagnosis of syphilis in this stage. On the other hand, a positive Wassermann reaction must not be taken to indicate that the condition is non-malignant, and therefore biopsy must always be performed. If in a doubtful case this fails to prove suspected malignant disease, it should be repeated. After two or more microscopic examinations have failed to reveal the true cause, and in the absence of a history indicative of a simple stricture, syphilis is to be strongly suspected. The diagnosis is usually confirmed by appropriate treatment.

become carcinomatous, and thus the improvement in the results of operation for carcinoma of the stomach lies in operating upon the ulcer in its still benign period. In the United States of America this relationship is well recognised, but unfortunately in this country there has been a tendency of late to belittle the relationship between the two lesions; probably this has in part been due to the fact that in the past it was claimed that the majority of cases of carcinoma commenced as chronic ulcers, a view which wider experience could not support, and hence there is a tendency for the pendulum to swing in the opposite direction. The denial of such a relationship has, however, gone hand in hand with extravagant claims for the value of medical treatment, and this of necessity, for if chronic ulcers may become carcinomatous it will clearly be inadvisable to subject them to prolonged periods of such treatment. It is also unfortunate that the lay press has widely circulated the view that all chronic ulcers can be cured by medical treatment, for there is now a tendency for patients to postpone operation and to undertake a prolonged course of medical treatment, a procedure which I feel convinced will lead to an increase in the number of cases of carcinomata of the stomach, and will undo much of the preventive treatment for which surgeons have striven so long.

In my own series of cases there has been very definite evidence that a certain number of cases of carcinoma have started as chronic ulcers. I have only placed in this group those that have fulfilled the following requirements:—

1. They must all have had a history of many years' standing in which the earliest symptoms were periodic.
2. They must all at the time of operation have had a relatively high test-meal.
3. The appearances of the lesion at operation must have suggested the presence of a chronic ulcer. In some cases, indeed, the diagnosis of chronic ulcer to the naked eye appeared to be definite.
4. The pathological report must have shown that the carcinoma was almost certainly secondary to an ulcer.

In my own series of 229 cases there were 25 examples which conformed with these requirements, and these, of course, do not include any examples which had progressed so far that a radical operation was not possible, or those which had led to a complete achlorhydria. Hence, this figure probably much underestimates the frequency. They are of special importance, for it is in such cases that a radical cure is most to be expected. My patient, who is alive and well seven years after operation, was only recognised to be a case of carcinoma after the microscopic examination, but a partial gastrectomy was carried out on suspicion owing to a slight alteration in the symptoms. She was therefore treated at the earliest possible stage. Of equal importance with this group are those cases which are definitely but erroneously diagnosed as simple chronic ulcers before operation, for it is these cases especially in which medical treatment is likely to be continued and the opportunities of early operation are lost. I have elsewhere pointed out that since the recent vogue for medical treatment four such cases have come to me when the carcinoma was hopelessly advanced. In my own series there were 55 such cases, a percentage of nearly 25 of the total. These had been definitely diagnosed by physicians of wide experience and repute as simple chronic ulcers, and it was only at operation that the evidence of carcinoma was forthcoming. To my mind, therefore, there can be no question whatever that the hope of greater success in the future lies not only in a wider recognition of the early symptoms of carcinoma, but also in the acceptance of the belief that chronic ulcers in patients between the age of 40 and 60 should be subjected to early operative treatment, and should not be treated medically for a long period of time. It is probably owing to such a course of action that my figures show no increase but rather a definite relative decrease in the frequency of carcinoma of the stomach, and every effort must be made not to lose this advantage.

Early Symptoms and Early Treatment.

In the recognition of the important early symptoms, special stress must be laid upon the fact that after a perfectly clear past history the majority of patients have developed a dyspepsia persisting for two or three weeks. I have always taught, and I am confident that it is correct, that if there is no definite error of diet to account for such a group of symptoms, those patients should be regarded as carcinomatous unless definite evidence can be produced to show that they are suffering from some other lesion. It is perfectly true that occasionally, if such a dictum is accepted, a patient will be operated upon and will be found to be suffering only from a gastritis, possibly of an atonic type due to overwork and worry; a careful investigation will, however, often eliminate such a condition. In the few remaining cases it has been my experience, much as I deprecate the use of an exploratory laparotomy, that such patients are so pleased to find that they are not suffering from a carcinoma that they will only too willingly put up with the drawbacks of an unnecessary laparotomy. I have been honoured by having been asked to operate upon a large number of medical men, and these patients, who are those best able to realise the drawbacks of operation, have been only too willing to face the possibility of an unnecessary laparotomy if in the end they can be assured that no carcinoma is present, and it would seem self-evident that the line of conduct which a medical man would choose for himself is the one which he can best advise his patients to follow. Of the individual symptoms of the different varieties of carcinoma I shall say but little, for these have been described upon so many occasions that they should now be well recognised. To briefly sum them up, they are the constancy and often the mild degree of the pain, which, although increased by the taking of food, does not completely disappear in the course of the day, the steady and progressive loss of appetite, the increased feeling of lassitude, weakness, and the loss of the usual feeling of well-being, the presence of frequent regurgitation rather than of actual vomiting, and the failure of relief to be given to the pain thereby. It is especially the supervention of such symptoms upon a case presenting a typical history of gastric ulcer which would lead us to infer that the ulcer has become carcinomatous, but one would hope that in the future this change will be seen less and less as the long-persistent ulcers are more frequently treated by operation. It is well, also, to point out here that cases are seen where there is severe pain, and where there is vomiting of the obstructive type, or where there is hæmatemesis which may be sudden and severe, and that the presence of such symptoms, which are usually regarded as more definite evidence of a gastric ulcer, are no counter-indication of the presence of carcinoma. It is also well to remember that although a test-meal and X ray investigation are of very great value, a high test-meal does not of necessity eliminate the possibility of carcinoma, and neither does a negative X ray.

Such symptoms occurring in a patient over 40 must always be regarded with the most grave suspicion, and it is by the recognition of their importance that one must hope to obtain better results in the treatment of this most dangerous and depressing variety of carcinoma. Although at present but few cases have been cured by operative treatment, there can be no question but that a small percentage are so cured, and of this benefit every patient must be given the advantage at the earliest opportunity, for all other methods known to us at present, such as the use of radium and deep X ray therapy, are—useful though they may be—no more than palliative procedures. It must also be remembered that whereas cases which are not operated upon have an average expectation of life of only three to six months, those who are treated by partial gastrectomy not infrequently live for three or four years in happiness and comfort. In my own series, 15 cases showed evidence of recurrence only between the second and third year, five between the third and fourth year, and two after four years. My chief reason for putting these figures before you, however, is to impress upon you my belief that in this, as in other branches of medicine, the greatest progress has been and is still to be made by the use of preventive measures. An understanding of the cause of carcinoma implying, as I believe it does, a knowledge as to why a cell reverts from its unipotential character to a totipotential phase, still seems far from us, and until that time arrives, the greatest hope of preventing carcinoma of the stomach lies in the free surgical removal of all chronic ulcers. If the lay press, altering their present views, will help us with the great weight of their authority to teach the public that the majority of such ulcers should be excised, much will be accomplished in diminishing the frequency of this dread disease.

SYPHILIS OF THE ŒSOPHAGUS.

WITH A REPORT OF TWO CASES.

BY A. LAWRENCE ABEL, M.S. LOND.,
F.R.C.S. ENG.,
SURGEON TO THE KENSINGTON GENERAL AND LONDON LOCK HOSPITALS; ASSISTANT SURGEON TO THE WOOLWICH WAR MEMORIAL HOSPITAL, ETC.

SYPHILIS of the œsophagus is only diagnosed in one or two of every 1000 cases presenting themselves with an œsophageal lesion. It occurs, however, in all cases of acute syphilis which remain untreated until the so-called "secondary" stage is established, but only as a part of the general inflammation of all mucous membranes, and usually there is a complete absence of any œsophageal syndrome. It is not until a secondary œsophagitis is present, or a spasmodic or organic stenosis appears, that cases of syphilis of the œsophagus come to the hands of the œsophagoscopist for diagnosis and treatment. I shall confine these remarks, therefore, to a description of syphilis of the œsophagus accompanied by the cardinal symptom of dysphagia.

Pathology.

Syphilis of the œsophagus occurs rarely in the congenital form of the disease. More commonly, in the so-called "secondary" stage, it may give rise to an œsophagitis, of such severity as to be manifested by dysphagia. The condition rapidly responds to appropriate treatment, and is very seldom followed by stenosis.

During the so-called "tertiary" period syphilis of the œsophagus is still more common, and takes the form of localised gummata. The gumma usually arises in either the upper or lower third of the canal, and on rupture produces a typical gummatous ulcer with a clearly cut edge and an unhealthy yellow base. There is considerable local induration, which, together with the concomitant spasm, is the main cause of the obstruction to the lumen. Leukoplakic patches may occur in the neighbourhood; some local non-specific œsophagitis may be present, together with a little hypertrophy of the wall and dilatation of the œsophagus above the level of the lesion.

Diagnosis.

The symptoms are those of painless dysphagia, together with those of any other syphilitic lesion which may coexist. If, however, there is any pharyngeal lesion, painful dysphagia occurs, together with some local spasm and regurgitation.

The previous history of a case is important, and leading questions must often be asked. The history of swallowing a corrosive or caustic or excessively hot fluid, or of an impacted foreign body, especially a tooth-plate, leads the clinician to doubt the existence of a true syphilitic lesion even in the presence of positive serological tests, and is more suggestive of a simple cicatricial stricture. The same is true of dysphagia following closely upon diphtheria or typhoid fever.

The duration of the dysphagia and its mode of onset is not of great value as an aid to an accurate diagnosis except when there is a definite history. Nevertheless, certain general facts should be borne in mind. Dysphagia in a case of syphilitic stenosis has usually lasted from four to twelve months before a careful examination reveals the true nature of the lesion. During this time the patient may or may not have been treated by his own medical practitioner for "indigestion," "gastritis," "gastric ulcer," "globus hystericus" or "nerves." Dysphagia of many years' standing, in the absence of a history indicative of simple stricture, is more suggestive of cardiospasm, but can be produced by a pharyngeal pouch, an œsophageal pouch, a fibrosis in the region of the crico-pharyngeal sphincter, a congenital stenosis of the œsophagus, or even by a syphilitic lesion. The onset of specific dysphagia is almost invariably gradual. Sudden difficulty in swallowing is more suggestive of an impacted foreign body or even of a malignant growth.

When syphilitic stenosis of the œsophagus is present there is usually nothing to distinguish it from any other variety of stricture except direct local examination. General examination will frequently reveal that the patient is suffering from syphilis, and there will be no clinical signs of malignancy, such as Virchow's glands. Especial attention should be paid to the mouth and throat, as signs of leukoplakia of the tongue or inner side of the cheek are rarely absent in long-standing cases. Scars are often found on the legs, and bilateral enlargement of the epitrochlear lymphatic glands, with no local condition to account for it, is always present.

Radioscopy.—After a complete general examination of the patient radioscopy is employed in order to exclude the presence of an aneurysm or other intrathoracic cause of extrinsic pressure upon the œsophagus, and to determine the level of the lesion.

Œsophagoscopy should next be resorted to, and great difficulty may be met with in making a purely visual diagnosis. This is especially so in the non-ulcerated variety of gumma, which closely simulates an infiltrating carcinoma. An actual ulcer is more readily diagnosed, and a portion removed for microscopical examination may reveal the true nature of the disease. The diagnostician must not be led astray by a negative Wassermann reaction of the blood, which is given by a very large proportion of sufferers from tertiary syphilis. The pathological examination of the cerebro-spinal fluid will, however, almost invariably confirm the clinical diagnosis of syphilis in this stage. On the other hand, a positive Wassermann reaction must not be taken to indicate that the condition is non-malignant, and therefore biopsy must always be performed. If in a doubtful case this fails to prove suspected malignant disease, it should be repeated. After two or more microscopic examinations have failed to reveal the true cause, and in the absence of a history indicative of a simple stricture, syphilis is to be strongly suspected. The diagnosis is usually confirmed by appropriate treatment.

I wish most strongly to emphasise that syphilis of the œsophagus must not be diagnosed by symptoms and serological tests alone, because many patients who have carcinoma of the œsophagus have also active syphilis. As I have shown elsewhere,[1] it is most important that cancer of the œsophagus should be treated at the earliest possible moment; direct œsophagoscopic examination must, therefore, be made in all cases with symptoms of an œsophageal disease.

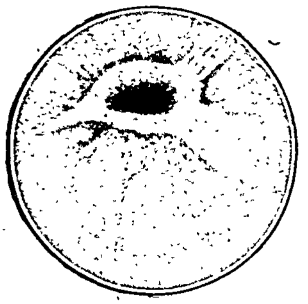

FIG. 2.

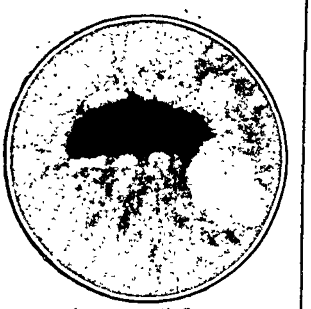

FIG. 1 (Case 1).—Syphilitic stricture of the œsophagus (cervical region) as seen through the œsophagoscope before treatment.
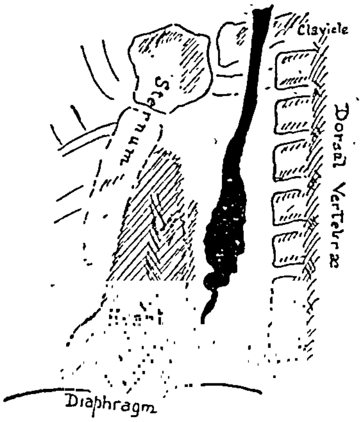
FIG. 2 (Case 1).—Seven days after dilatation with bougies.

Treatment.

Treatment is undertaken along two lines: (1) Antisyphilitic treatment; (2) œsophageal treatment to combat the actual or potential stenosis.

1. In acute syphilis, arsenic is administered intravenously for eight weeks, provided it has not been previously used in large quantities in the same patient. If it has, then only a shorter course of arsenic should be given. The dose varies from 0·45 to 0·6 g. in the female, and from 0·6 to 0·9 in the male, at weekly intervals. At the same time as the arsenical injection an intramuscular injection of mercurial cream or bismuth is given. At about the middle, and at the end of this course of treatment, an intramuscular injection of 0·25 g. of contramine should be given. After the last injection of contramine the patient is allowed four weeks' rest from injections and given potassium iodide grs. 5 in plenty of water, three times a day by the mouth. After this, intramuscular injections should be recommenced, and continued once a week for eight weeks. They may consist of either gr. 1 of mercury as a mercurial cream given each week, or 0·2 g. of an oily suspension of bismuth. By far the best preparation of bismuth in my experience is iodo-bismuthate of quinine (Fraisse), and this may be used with benefit alternately with the injections of mercury. After eight injections the patient is given four weeks' treatment by medicine—either potassium iodide as before, or collosol sulphur, 1 drachm three times a day; then eight weeks on a heavy metal and four weeks on a non-metal, and so on. The arsenical treatment should not be repeated.

FIG. 5.



Fi dio-
of
dio-
opaque emulsion.

In secondary syphilis this treatment should be continued for at least three years, and no notice whatever need be taken of the Wassermann reaction, whether positive or negative, during this time. In tertiary syphilis arsenic may be used, but its effect is not so good as in the early stages of the disease, and in my experience it is inferior to bismuth given as iodo-bismuthate of quinine (Fraisse). In tertiary and congenital lesions I strongly advise continuing injections of bismuth for at least four years, with four weeks' rest after each two months' injections; or alternate courses of injections may consist of bismuth for one course, mercury for the next, and so on.

FIG. 3.

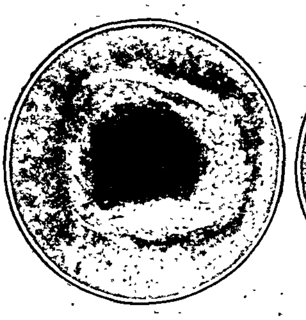


FIG. 4.

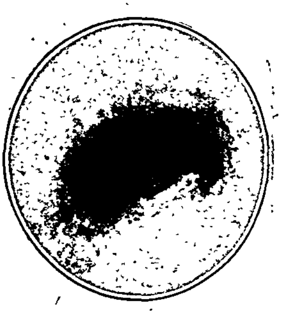

FIG. 3 (Case 1).—Two months later.
FIG. 4 (Case 1).—Eleven months later. (Since then no abnormality has been seen on œsophagoscopy.)

Œsophageal Treatment.

Every healed and healing gumma of the œsophagus is accompanied by fibrosis and contraction; therefore the œsophagus must be subjected to frequent dilatations during the early months of the treatment, but later this need only be done at rare intervals, in order to be quite sure that no further active contraction is taking place. In the first instance it should be done under direct vision and, if no contra-indication such as excessive dilatation or diverticulum is present, may subsequently be performed blindly.

Report of Two Cases of Syphilis of the Œsophagus.

CASE 1.—Female, aged 48. First attended at the Cancer Hospital, London, on June 30th, 1925, under Mr. Percival Cole, who kindly allowed me to undertake her investigation and treatment. This patient first noticed difficulty in swallowing in December, 1923, when she began to get occasional attacks of choking after taking solid food, and sometimes brought up food that had been swallowed. The symptoms became progressively worse until September, 1924, when she could only swallow liquid. She said she had been admitted to another hospital where the stricture was dilated. At that time the Wassermann reaction of her blood was positive, and she was given a course of N.A.B. (novarsenobenzol) injections, after which the Wassermann was negative. She was then free of symptoms until two months before I saw her at the Cancer Hospital, during which time the dysphagia became progressively worse. On admission she could only take very soft solids. Solid food appeared to stop at the lower part of the neck. There was no history of any previous illness or accident of any kind. She had one child, aged 19 years, and no miscarriages.

FIG. 6.

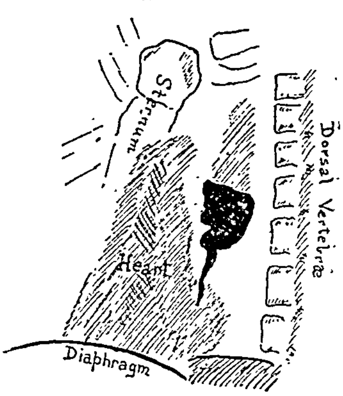

FIG. 6 (Case 2).—Diagram of radiogram of same case as Fig. 5 taken one hour later.

Physical Examination.—The patient was thin, but not cachectic. She said she had lost a little weight. Colour good. Complete artificial dentures. Both epitrochlear glands were enlarged, but otherwise there were no clinical signs of any abnormality.

---

[1] Abel, A. L.: The Treatment of Cancer of the Œsophagus, Brit. Jour. Surg., 1926, xiv., 53, p. 131.

Radioscopy, July 2nd, 1925.—Patient could only swallow a teaspoonful or two of thin bismuth emulsion, which passed very slowly from the pharynx into the œsophagus. No other abnormality was detected.

Œsophagoscopy was performed on July 3rd. Immediately the end of the œsophagoscope had passed the cricopharyngeal sphincter a dense white fibrous stricture was seen, almost completely obliterating the lumen of the œsophagus. A large patch of leukoplakia was present on the right posterior wall of the œsophagus at the level of the stricture. A bougie was passed and the fibrous constriction seen to split. Three small bougies were left in situ for one hour. Four days later the patient was able to swallow easily. The appearance as seen by the œsophagoscope before instrumentation is shown in Fig. 1; as seen a week later in Fig. 2.

Bougies were passed, using gradually increasing sizes, every week or two. Fig. 3 shows the condition present in September, 1925. For the following nine months bougies were passed on an average once every two months. The appearance on June 7th, 1926, is shown in Fig. 4. Her antisyphilitic treatment has been carried out on the lines indicated above, and is still being continued. A large bougie was passed twice in 1927, and met with no obstruction. The patient has had no difficulty in swallowing since July 7th, 1925.

CASE 2.—Male, aged 55. First attended the Cancer Hospital on July 15th, 1925, and was kindly handed over to my care by Mr. Ernest Miles. The patient complained of dysphagia, which had been gradually increasing for three months. He brought up solid foods immediately, but fluids were retained unless swallowed quickly. He said he frequently brought up a great deal of "phlegm." He had been losing weight and was a little constipated. He had had attacks of vomiting lasting for two or three days every three or four months for six years, and had been treated by his doctor for "indigestion." He admitted having syphilis 30 years previously, when he was treated with one bottle of medicine only. There was no history of swallowing a corrosive or foreign body, or of any other serious illness.

FIG. 7.

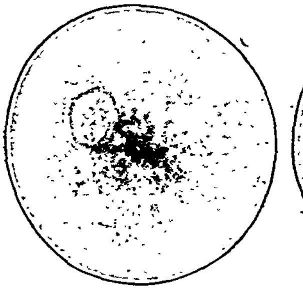

FIG. 8.

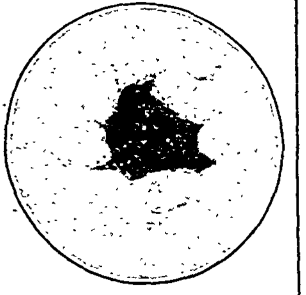

FIG. 7 (Case 2).—Syphilitic stenosis of the œsophagus (thoracic region as seen by endoscopy.

FIG. 8 (Case 2).—Two years later.

On examination he was well covered but somewhat anæmic. There was well-marked leukoplakia on the inner aspects of both cheeks, with enlarged epitrochlear glands. No other abnormality was detected on ordinary physical examination. His Wassermann reaction was found to be positive.

X ray examination with a bismuth emulsion on July 15th showed an irregular contraction of the œsophagus about four inches above the diaphragm, with some dilatation above (Figs. 5 and 6).

Œsophagoscopy was performed on July 21st, and the appearance was as shown in Fig. 7. The stenosis was 13 inches from the incisor teeth, and would admit only a very small sound. The mucosa was very red and inflamed, and bled easily. Patches of leukoplakia were seen on the inflamed surface with a small area of actual ulceration, which was thought to be malignant, and a portion was removed for microscopy. The stenosis was dilated, and a Symonds' tube left *in situ*. This was vomited two days later. Microscopic examination failed to show the presence of any malignancy, and the patient improved with occasional dilatation.

Two months later œsophagoscopy was again performed, and a second portion of the suspected growth removed for biopsy. The appearances were so strongly suspicious of malignancy that two tubes, each of 50 mg. of radium, were left *in situ* for six hours by means of an œsophageal catheter. As the second microscopic examination was also negative radium was abandoned; antisyphilitic treatment, together with regular dilatation by bougies, was commenced, and the patient improved rapidly. His antisyphilitic treatment has been continued ever since. Bougies were passed at first once a week, then once a fortnight, and then monthly, for nearly two years. The œsophagoscopic appearances as seen on July 14th, 1927, are shown in Fig. 8, and a radiogram taken at the same time is shown in Fig. 9. The patient still has a bougie passed about once every three months, and has no trouble with swallowing unless he gulps very large particles.

FIG. 9.

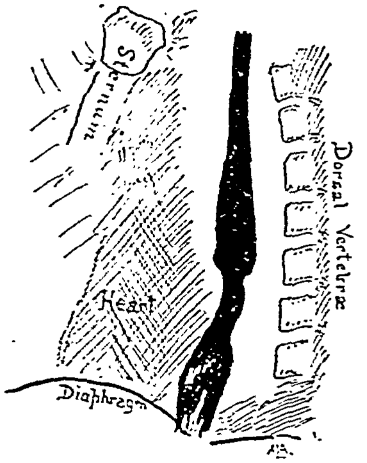

FIG. 9 (Case 2).—Diagram of radiogram of same case as Figs. 5 and 6 taken 18 months later.

The points which I wish to emphasise are: (1) Syphilis of the œsophagus is probably not so rare as a study of the literature would lead one to suspect. (2) Syphilis of the œsophagus is difficult to diagnose by vision alone, either from simple stricture or from a malignant growth. (3) One or more microscopical examinations must be made before pronouncing a case free from malignancy. (4) The patient or his relatives should not be told that he is about to die of cancer when only a specific stricture is present. Conversely, a patient with cancer of the œsophagus should not be given antisyphilitic treatment and energetic bouginage, and told that he will soon be quite normal. (5) Treatment must be by dilatation, as for any simple stricture of the œsophagus, and, in addition, very prolonged antisyphilitic treatment must be undertaken.

SKIN ANTISEPSIS WITH IODINE AND SOME NEW SOLVENTS.

By R. A. MACDONALD, M.B. EDIN., D.P.H.,
ASSISTANT PATHOLOGIST AND RESEARCH FELLOW, HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET;
AND
J. WICLIFFE PECK, F.C.S., PH.C.,
PHARMACEUTIST TO THE HOSPITAL.

TINCTURE of iodine has long been employed for disinfecting the skin, and its uses as a skin dressing and before operation are almost universal.

Until recently rectified spirit has been the only solvent available as the chemical action of iodine on certain other solvents renders them unsuitable in every way. The extremely irritating vapours produced by the small amounts of methyl alcohol in methylated spirit make this solvent unusable. Methyl alcohol becomes oxidised by the iodine to formaldehyde and formic acid, which attack the eyes and nasal mucous membrane. It is even probable that acetic acid and other products are in course of time formed by the decomposition of ethyl alcohol with iodine, and it has been stated that old tincture of iodine has been known to burn the skin. Rectified spirit bears a very heavy duty, although the Customs and Excise grant a considerable rebate when it is used for medicinal preparations. It is on account of the heavy annual cost to hospitals that we have searched for a solvent that would replace it.

Any new solvent had to comply with the following conditions: (1) It should itself be antiseptic; (2) it should have penetrative powers when applied;

I wish most strongly to emphasise that syphilis of the œsophagus must not be diagnosed by symptoms and serological tests alone, because many patients who have carcinoma of the œsophagus have also active syphilis. As I have shown elsewhere,[1] it is most important that cancer of the œsophagus should be treated at the earliest possible moment; direct œsophagoscopic examination must, therefore, be made in all cases with symptoms of an œsophageal disease.

FIG. 1.

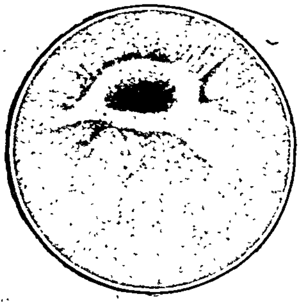

FIG. 2.

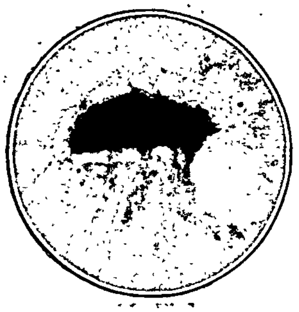

FIG. 1 (Case 1).—Syphilitic stricture of the œsophagus (cervical region) as seen through the œsophagoscope before treatment.
FIG. 2 (Case 1).—Seven days after dilatation with bougies.

Treatment.

Treatment is undertaken along two lines: (1) Antisyphilitic treatment; (2) œsophageal treatment to combat the actual or potential stenosis.

1. In acute syphilis, arsenic is administered intravenously for eight weeks, provided it has not been previously used in large quantities in the same patient. If it has, then only a shorter course of arsenic should be given. The dose varies from 0·45 to 0·6 g. in the female, and from 0·6 to 0·9 in the male, at weekly intervals. At the same time as the arsenical injection an intramuscular injection of mercurial cream or bismuth is given. At about the middle, and at the end of this course of treatment, an intramuscular injection of 0·25 g. of contramine should be given. After the last injection of contramine the patient is allowed four weeks' rest from injections and given potassium iodide grs. 5 in plenty of water, three times a day by the mouth. After this, intramuscular injections should be recommenced, and continued once a week for eight weeks. They may consist of either gr. 1 of mercury as a mercurial cream given each week, or 0·2 g. of an oily suspension of bismuth. By far the best preparation of bismuth in my experience is iodo-bismuthate of quinine (Fraisse), and this may be used with benefit alternately with the injections of mercury. After eight injections the patient is given four weeks' treatment by medicine —either potassium iodide as before, or collosol sulphur, 1 drachm three times a day; then eight weeks on a heavy metal and four weeks on a non-metal, and so on. The arsenical treatment should not be repeated.

FIG. 5.

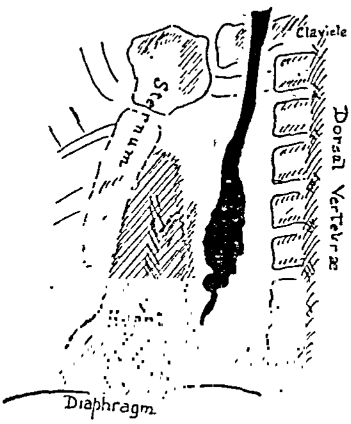

FIG. 5 (Case 2).—Diagram of radiogram of syphilitic stricture of œsophagus after swallowing radio-opaque emulsion.

In secondary syphilis this treatment should be continued for at least three years, and no notice whatever need be taken of the Wassermann reaction, whether positive or negative, during this time. In tertiary syphilis arsenic may be used, but its effect is not so good as in the early stages of the disease, and in my experience it is inferior to bismuth given as iodo-bismuthate of quinine (Fraisse). In tertiary and congenital lesions I strongly advise continuing injections of bismuth for at least four years, with four weeks' rest after each two months' injections; or alternate courses of injections may consist of bismuth for one course, mercury for the next, and so on.

Œsophageal Treatment.

Every healed and healing gumma of the œsophagus is accompanied by fibrosis and contraction; therefore the œsophagus must be subjected to frequent dilatations during the early months of the treatment, but later this need only be done at rare intervals, in order to be quite sure that no further active contraction is taking place. In the first instance it should be done under direct vision and, if no contra-indication such as excessive dilatation or diverticulum is present, may subsequently be performed blindly.

FIG. 6.

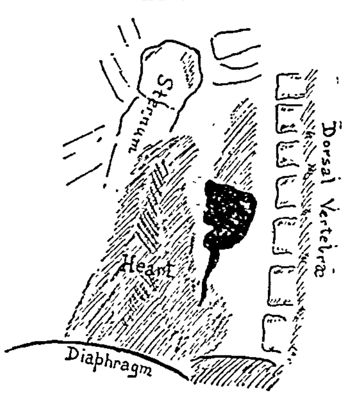

FIG. 6 (Case 2).—Diagram of radiogram of same case as Fig. 5 taken one hour later.

Report of Two Cases of Syphilis of the Œsophagus.

CASE 1. — Female, aged 48. First attended at the Cancer Hospital, London, on June 30th, 1925, under Mr. Percival Cole, who kindly allowed me to undertake her investigation and treatment. This patient first noticed difficulty in swallowing in December, 1923, when she began to get occasional attacks of choking after taking solid food, and sometimes brought up food that had been swallowed. The symptoms became progressively worse until September, 1924, when she could only swallow liquid. She said she had been admitted to another hospital where the stricture was dilated. At that time the Wassermann reaction of her blood was positive, and she was given a course of N.A.B. (novarsenobenzol) injections, after which the Wassermann was negative. She was then free of symptoms until two months before I saw her at the Cancer Hospital, during which time the dysphagia became progressively worse. On admission she could only take very soft solids. Solid food appeared to stop at the lower part of the neck. There was no history of any previous illness or accident of any kind. She had one child, aged 19 years, and no miscarriages.

Physical Examination.—The patient was thin, but not cachectic. She said she had lost a little weight. Colour good. Complete artificial dentures. Both epitrochlear glands were enlarged, but otherwise there were no clinical signs of any abnormality.

---

[1] Abel, A. L.: The Treatment of Cancer of the Œsophagus, Brit. Jour. Surg., 1926, xiv., 53, p. 131.

Radioscopy, July 2nd, 1925.—Patient could only swallow a teaspoonful or two of thin bismuth emulsion, which passed very slowly from the pharynx into the œsophagus. No other abnormality was detected.

Œsophagoscopy was performed on July 3rd. Immediately the end of the œsophagoscope had passed the cricopharyngeal sphincter a dense white fibrous stricture was seen, almost completely obliterating the lumen of the œsophagus. A large patch of leukoplakia was present on the right posterior wall of the œsophagus at the level of the stricture. A bougie was passed and the fibrous constriction seen to split. Three small bougies were left in situ for one hour. Four days later the patient was able to swallow easily. The appearance as seen by the œsophagoscope before instrumentation is shown in Fig. 1; as seen a week later in Fig. 2.

Bougies were passed, using gradually increasing sizes, every week or two. Fig. 3 shows the condition present in September, 1925. For the following nine months bougies were passed on an average once every two months. The appearance on June 7th, 1926, is shown in Fig. 4. Her antisyphilitic treatment has been carried out on the lines indicated above, and is still being continued. A large bougie was passed twice in 1927, and met with no obstruction. The patient has had no difficulty in swallowing since July 7th, 1925.

CASE 2.—Male, aged 55. First attended the Cancer Hospital on July 15th, 1925, and was kindly handed over to my care by Mr. Ernest Miles. The patient complained of dysphagia, which had been gradually increasing for three months. He brought up solid foods immediately, but fluids were retained unless swallowed quickly. He said he frequently brought up a great deal of "phlegm." He had been losing weight and was a little constipated. He had had attacks of vomiting lasting for two or three days every three or four months for six years, and had been treated by his doctor for "indigestion." He admitted having syphilis 30 years previously, when he was treated with one bottle of medicine only. There was no history of swallowing a corrosive or foreign body, or of any other serious illness.

FIG. 7.

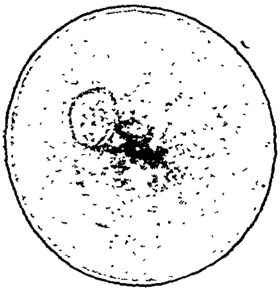

FIG. 8.

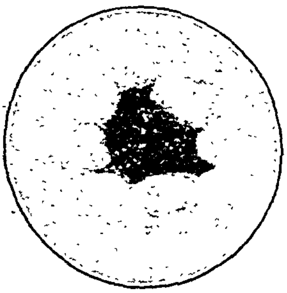

FIG. 7 (Case 2).—Syphilitic stenosis of the œsophagus (thoracic region as seen by endoscopy.
FIG. 8 (Case 2).—Two years later.

On examination he was well covered but somewhat anæmic. There was well-marked leukoplakia on the inner aspects of both cheeks, with enlarged epitrochlear glands. No other abnormality was detected on ordinary physical examination. His Wassermann reaction was found to be positive.

X ray examination with a bismuth emulsion on July 15th showed an irregular contraction of the œsophagus about four inches above the diaphragm, with some dilatation above (Figs. 5 and 6).

Œsophagoscopy was performed on July 21st, and the appearance was as shown in Fig. 7. The stenosis was 13 inches from the incisor teeth, and would admit only a very small sound. The mucosa was very red and inflamed, and bled easily. Patches of leukoplakia were seen on the inflamed surface with a small area of actual ulceration, which was thought to be malignant, and a portion was removed for microscopy. The stenosis was dilated, and a Symonds' tube left *in situ*. This was vomited two days later. Microscopic examination failed to show the presence of any malignancy, and the patient improved with occasional dilatation.

Two months later œsophagoscopy was again performed, and a second portion of the suspected growth removed for biopsy. The appearances were so strongly suspicious of malignancy that two tubes, each of 50 mg. of radium, were left *in situ* for six hours by means of an œsophageal catheter. As the second microscopic examination was also negative radium was abandoned; antisyphilitic treatment, together with regular dilatation by bougies, was commenced, and the patient improved rapidly. His antisyphilitic treatment has been continued ever since. Bougies were passed at first once a week, then once a fortnight, and then monthly, for nearly two years. The œsophagoscopic appearances as seen on July 14th, 1927, are shown in Fig. 8, and a radiogram taken at the same time is shown in Fig. 9. The patient still has a bougie passed about once every *three months*, and has no trouble with swallowing unless he gulps very large particles.

The points which I wish to emphasise are: (1) Syphilis of the œsophagus is probably not so rare as a study of the literature would lead one to suspect. (2) Syphilis of the œsophagus is difficult to diagnose by vision alone, either from simple stricture or from a malignant growth. (3) One or more microscopical examinations must be made before pronouncing a case free from malignancy. (4) The patient or his relatives should not be told that he is about to die of cancer when only a specific stricture is present. Conversely, a patient with cancer of the œsophagus should not be given antisyphilitic treatment and energetic bouginage, and told that he will soon be quite normal. (5) Treatment must be by dilatation, as for any simple stricture of the œsophagus, and, in addition, very prolonged antisyphilitic treatment must be undertaken.

FIG. 9.

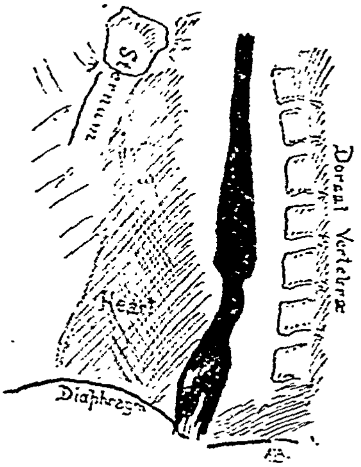

FIG. 9 (Case 2).—Diagram of radiogram of same case as Figs. 5 and 6 taken 18 months later.

SKIN ANTISEPSIS WITH IODINE AND SOME NEW SOLVENTS.

By R. A. MACDONALD, M.B. EDIN., D.P.H.,
ASSISTANT PATHOLOGIST AND RESEARCH FELLOW, HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET;
AND
J. WICLIFFE PECK, F.C.S., PH.C.,
PHARMACEUTIST TO THE HOSPITAL.

TINCTURE of iodine has long been employed for disinfecting the skin, and its uses as a skin dressing and before operation are almost universal.

Until recently rectified spirit has been the only solvent available as the chemical action of iodine on certain other solvents renders them unsuitable in every way. The extremely irritating vapours produced by the small amounts of methyl alcohol in methylated spirit make this solvent unusable. Methyl alcohol becomes oxidised by the iodine to formaldehyde and formic acid, which attack the eyes and nasal mucous membrane. It is even probable that acetic acid and other products are in course of time formed by the decomposition of ethyl alcohol with iodine, and it has been stated that old tincture of iodine has been known to burn the skin. Rectified spirit bears a very heavy duty, although the Customs and Excise grant a considerable rebate when it is used for medicinal preparations. It is on account of the heavy annual cost to hospitals that we have searched for a solvent that would replace it.

Any new solvent had to comply with the following conditions: (1) It should itself be antiseptic; (2) it should have penetrative powers when applied;

(3) it should not be harmful to the skin; (4) it should be stable; and (5) it should evaporate readily when painted on the skin.

Doubt has recently been expressed amongst surgeons as to whether iodine is an efficient antiseptic, and whether in the solution in general use the more important agent is not the spirit. It seemed advisable therefore to carry out some experiments to find out the actual bactericidal value of iodine in various solvents, as well as considering the relative merits of these solvents. The solvents used were as follows: Rectified spirit and ethyl alcohol, 70 per cent.; isopropyl alcohol, 90 per cent.; isopropyl alcohol, 70 per cent.; ethylene-glycol-mono-ethyl ether (for convenience hereafter called E.G.E.E.) and water with potassium iodide.

Method of Investigation.

In our investigation we made a number of solutions of iodine in other solvents, such as ether, petroleum ether, diacetone alcohol, sextone, sextol, as well as isopropyl alcohol and E.G.E.E., but it was decided that only the last two could possibly be used. Isopropyl alcohol is made from the gases emanating from petroleum wells by absorption in sulphuric acid and subsequent steam distillation. E.G.E.E. is made in the United States from ethylene obtained by "cracking" petroleum oils; the precise method does not seem to be known here. It is stated that ethyl alcohol is germicidal to *Bacillus coli* in 70 per cent. strength in two and a half minutes, and isopropyl alcohol in 30 per cent. strength in the same time. Iodine is said to kill *B. coli* in two and a half minutes in a strength of 1 in 50,000.[1] Ethyl alcohol is more active as a germicide in a strength of 70 per cent. than in any other concentration, being 30 times more powerful than 60 per cent., and 40 times more powerful than 80 per cent.[2] In our investigation the antiseptic properties of the solutions mentioned above were tested as follows: One series of experiments was made in vitro, using cultures of *B. coli* and staphylococci and the other directly on the skin to reproduce as nearly as possible the conditions obtaining at operation.

In vitro.—A measured quantity of each solution was added to an equal quantity of a 24-hour broth culture of each organism, and two drops of the mixture were abstracted by means of a sterile capillary pipette at the end of 1, 2, 3, 4, and 5 minutes. These were at once transferred to tubes containing approximately 3 c.cm. of broth and incubated over night. At the same time controls were put up containing two drops of culture and two drops of the antiseptic added separately. In the case of those solutions containing iodine this was neutralised by adding subsequently some sodium thiosulphate, in order to avoid any inhibition of growth of any organisms not killed by their period in contact with the antiseptic. (It was found later that the organisms grew perfectly in a medium containing two drops of iodine, although this gives a concentration of not less than 1 in 5000.)

On the Skin.—Areas of skin on the front of the forearm were selected, and marked off into segments with a grease pencil. As the majority of the antiseptics used had been found to be lethal to staphylococci and *B. coli* in one minute by the tube test, this period of time only was used. In each case an ordinary sterile throat swab was moistened in sterile broth and then rubbed hard on *part* of the selected area of skin. It was then transferred to a tube of broth and the latter incubated overnight. This served as a control to ensure that there were organisms on that particular piece of skin, before the addition of the antiseptic. The area of skin was then gently swabbed all over with the antiseptic in question. After one minute this area was again rubbed *all over* very thoroughly with a throat swab moistened in broth. The swab was again transferred to a tube of broth and this was incubated overnight. (N.B.—The amount of antiseptic carried over into the broth by this means must have been considerably less than the two drops used in the test-tube controls, and so in this case no further controls were added.)

Results of the Tests.

In the *tube test* growth was present in all the control tubes, but not in any case where one of the solutions had been in contact with the organisms, except ethyl alcohol 70 per cent. with staphylococci, where growth was present in all four tubes, and E.G.E.E. with staphylococci where growth was present in the first three tubes. In the *skin test* growth was present in all the control tubes, and also in all cases where the solvents had been used alone, without iodine. With none of the solutions containing iodine was any growth observed.

Isopropyl alcohol proved to be the most bactericidal of the solvents used, and no trace of irritation was noticed by either of us, after long periods of vigorous swabbing with this fluid. It is said to be twice as toxic as ethyl alcohol, but it is not absorbed to any appreciable extent by the skin or lungs.[3] The penetrative powers were tested along with the other solvents as follows:—

Areas of skin on the forearm, which had not been washed for six hours were sectioned off with grease pencil and well painted with the solution of iodine in the solvent in question, using a new camel-hair brush for each area. After the lapse of 30 minutes the forearm was swabbed with cotton-wool soaked in a 5 per cent. watery solution of sodium thiosulphate. The stains from iodine in 70 per cent. alcohol and 70 per cent. isopropyl alcohol were the most difficult to remove, the next being iodine in 90 per cent. alcohol, and the easiest being watery iodine, iodine in E.G.E.E., and iodine in isopropyl alcohol.

We had further to consider whether any decomposition would take place between iodine and the approved solvent. Isopropyl alcohol is $CH_3.CH.OH.CH_3$ and on oxidation yields acetone. We have failed to discover even a trace of acetone in our solutions of iodine in isopropyl alcohol, in bottles half full, that have been opened many times during a month. We think it would be advisable, however, in view of the possibility of oxidation, to recommend the use of comparatively recent solutions. Lastly, there is little difference between the evaporation rate of isopropyl alcohol and that of ethyl alcohol, the boiling point of the former being only 2–3 degrees higher than the latter.[3] Isopropyl alcohol, moreover, has quite a pleasant smell.

The relative costs of the solvents used in this investigation are as follows:—

Rectified spirit, after deducting the rebate allowed by the Customs and Excise, £2 13*s.* per gallon.

Isopropyl alcohol, in 10-gallon quantities, 13*s.* 6*d.* per gallon.

E.G.E.E., in 10-gallon quantities, 11*s.* 6*d.* per gallon.

Isopropyl alcohol 70 per cent. would be approximately 10*s.* 6*d.* per gallon, and if used generally in hospital would produce a saving of about 85 per cent.

Conclusions.

Our conclusions, therefore, are: (1) that iodine in the strength of 1·25 per cent. is in itself an efficient antiseptic; (2) that isopropyl alcohol is the most antiseptic of the solvents used in this experiment; (3) that iodine 1·25 per cent. in isopropyl alcohol is not harmful to the skin; (4) that its penetrative powers and evaporation rate are equal to those of ethyl alcohol; and (5) that its cost is very much less than that of rectified spirit. We therefore strongly recommend iodine 1·25 per cent. in 70 per cent. isopropyl alcohol as a substitute for the commonly used iodine in rectified spirit.

We wish to thank Dr. D. N. Nabarro, director of the pathological department, for permission to carry out this work, and for his kind interest and assistance.

THE RATING OF HOSPITALS.—The County Valuation Committee for Cornwall has decided to assess hospitals at a uniform rate of 7*s.* 6*d.* per bed, but the Truro Rural Rating Committee has resolved not to demand rates from hospitals and similar institutions.

NEW HOSPITALS FOR EGYPT.—The Egyptian Government has adopted a scheme for the provision, at a cost of £1,500,000, of 100 hospitals in various towns and villages, to be completed within the next five years. These institutions will be open to all classes of the population, but especially to the fellaheen, who will thus no longer be compelled to travel long distances to the nearest hospital.

Clinical and Laboratory Notes.

A NOTE ON THE SO-CALLED WHITE LINE OF ADRENAL INSUFFICIENCY.

By A. Muir Crawford, M.D., F.R.F.P.S. Glasg.,
ASSISTANT PHYSICIAN, GLASGOW ROYAL INFIRMARY.

In certain individuals, if the skin is lightly stroked with the pad of the finger or the smooth rounded end of a fountain pen, a band of pallor is produced in the area of skin corresponding to the part stimulated. This phenomenon was closely studied by Sergent,[1] who regarded it as a valuable clinical test. He considered it to be pathognomonic of adrenal insufficiency and termed it "the white line of adrenal insufficiency" (*la ligne blanche surrénale*). Considerable interest has been shown in the reaction, notably among French clinicians, and reference to the subject is to be found frequently in French literature. In this country and in America, several workers have investigated the reactions produced by cutaneous stimulation, with results which apparently show that the reaction is of no clinical value as a sign of adrenal insufficiency. Thus, Cotton, Slade, and Lewis,[2] in an elaborate investigation on the phenomena of dermatographism carried out on soldiers affected with "irritable heart," refer to the remarkably sharp outline of a white band produced by stroking the skin with the end of a flat ruler in a susceptible subject. Their observations were made with special reference to the effects of pressure of a blunt point drawn firmly over the skin. This invariably demonstrated the appearance of a red tache of varying intensity, with or without borders of distinct pallor, and they concluded that the variations in the type of reaction could be attributed to differences in the grade of pressure. In many of their cases light pressure produced a simple white line, whereas, in other cases, light pressure was either without effect or produced a transitory red band. Wright,[3] working in the Physiological Department of the Middlesex Hospital Medical School, has investigated the significance and value of Sergent's white line by applying the test to healthy subjects. He carried out the test on 100 young medical students and in each case recorded the systolic and diastolic blood pressures. A positive result was obtained in 66 per cent. of the tests, and his observations led him to the conclusion that the white line of Sergent is a phenomenon occurring in a large proportion of normal subjects, that it is not related to adrenal insufficiency or to abnormally low systolic or diastolic blood pressure, and is, in fact, without pathological significance.

Personal Observations.

In order to test further the value of the phenomenon I thought it might be of interest to carry out the test on hospital patients of different ages and affected with different types of disease. Tests were, therefore, carried out on 100 ward patients in the Glasgow Royal Infirmary. The patients were affected with the usual diseases seen in a general medical ward, and no selection was made of either patient or type of disease. The test was carried out by lightly stroking the skin of the anterior abdominal wall with the smooth rounded end of a fountain pen, due attention being paid to the details of the Sergent technique. After a few preliminary observations it was decided to record the results as follows:—

1. *Negative*, where there was either no result or where the stroking was followed by a red line.
2. *Positive* +, where there appeared a definite but not marked band of pallor.
3. *Positive* + +, where there appeared a very marked white band with clear-cut edges.

This method of recording the results is very similar to that employed by Wright. Although accurate time observations were not made, it was generally found that a positive reaction appeared in about 20 to 30 seconds and lasted for one to two minutes. The following tables show the results obtained. Of 100 cases examined, 49 per cent. gave a positive reaction (14 per cent. were positive + +, and 35 per cent. positive +), while 51 per cent. were negative.

TABLE I.—*Showing Results in Relation to Age and Sex.*

Age in years.	Sex.	P. + +	P. +	N.
10 to 20 ..	M.	0	5	3
	F.	3	6	4
21 to 35 ..	M.	6	7	3
	F.	2	8	3
36 to 50 ..	M.	1	3	12
	F.	2	2	4
Over 50 ..	M.	0	4	16
	F.	0	0	6

P. = Positive. N. = Negative.

An examination of Table I. shows that a positive reaction was obtained far more frequently under 35 years of age than over. This is in accordance with the results obtained by other observers. Thus, Kay and Brock[4] state that the white line occurs most frequently in young adults of either sex. In my series, in 29 patients between the ages of 21 and 35 years, 79·3 per cent. gave a positive reaction, while in 50 patients between the ages of 36 and 74 years, only 24 per cent. were positive.

TABLE II.—*Showing Results in Relation to Type of Disease.*

Disease.	P. + +	P. +	N.	Disease.	P. + +	P. +	N.
Gastro-intestinal	1	9	14	Diabetes m. ..	1	3	2
Respiratory ..	2	7	15	Blood	0	0	4
Exophthalmic goitre	4	0	1	Renal	2	5	4
Rheumatic ..	0	2	2	Cardiac	2	4	3
				Nervous ..	2	4	3
				Miscellaneous	0	1	3

Diabetes m. = Diabetes mellitus.

The only criticism I have to offer on these results given in Table II. is that in four cases of exophthalmic goitre the reaction was obtained in a very marked degree; in fact, they showed a white band more intense than that obtained in any other disease. This tends to support the hypothesis formulated by Tracy[5] that the white line is a manifestation of sympatheticotonia.

TABLE III.—*Showing Results in Relation to Blood Pressure.*

—	P. + +	P. +	N.
Average systolic pressure ..	119	117	122
Average diastolic pressure ..	69	72	73
Average pulse pressure	50	45	49

A glance at Table III. shows that no definite relationship can be demonstrated between blood pressure or pulse pressure and type of reaction.

Conclusions.

As a result of these observations and from the reports published by other investigators it would appear that (1) the white line of Sergent is a phenomenon which may be readily demonstrated in a large percentage of young adults; (2) it bears no relationship to the sex of the individual; (3) it bears no relationship to the blood pressure and is not pathognomonic of adrenal insufficiency; (4) it bears no relationship to any particular type of disease, although

(3) it should not be harmful to the skin; (4) it should be stable; and (5) it should evaporate readily when painted on the skin.

Doubt has recently been expressed amongst surgeons as to whether iodine is an efficient antiseptic, and whether in the solution in general use the more important agent is not the spirit. It seemed advisable therefore to carry out some experiments to find out the actual bactericidal value of iodine in various solvents, as well as considering the relative merits of these solvents. The solvents used were as follows: Rectified spirit and ethyl alcohol, 70 per cent.; isopropyl alcohol, 90 per cent.; isopropyl alcohol, 70 per cent.; ethylene-glycol-mono-ethyl ether (for convenience hereafter called E.G.E.E.) and water with potassium iodide.

Method of Investigation.

In our investigation we made a number of solutions of iodine in other solvents, such as ether, petroleum ether, diacetone alcohol, sextone, sextol, as well as isopropyl alcohol and E.G.E.E., but it was decided that only the last two could possibly be used. Isopropyl alcohol is made from the gases emanating from petroleum wells by absorption in sulphuric acid and subsequent steam distillation. E.G.E.E. is made in the United States from ethylene obtained by "cracking" petroleum oils; the precise method does not seem to be known here. It is stated that ethyl alcohol is germicidal to *Bacillus coli* in 70 per cent. strength in two and a half minutes, and isopropyl alcohol in 30 per cent. strength in the same time. Iodine is said to kill *B. coli* in two and a half minutes in a strength of 1 in 50,000.[1] Ethyl alcohol is more active as a germicide in a strength of 70 per cent. than in any other concentration, being 30 times more powerful than 60 per cent., and 40 times more powerful than 80 per cent.[2] In our investigation the antiseptic properties of the solutions mentioned above were tested as follows: One series of experiments was made in vitro, using cultures of *B. coli* and staphylococci and the other directly on the skin to reproduce as nearly as possible the conditions obtaining at operation.

In vitro.—A measured quantity of each solution was added to an equal quantity of a 24-hour broth culture of each organism, and two drops of the mixture were abstracted by means of a sterile capillary pipette at the end of 1, 2, 3, 4, and 5 minutes. These were at once transferred to tubes containing approximately 3 c.cm. of broth and incubated over night. At the same time controls were put up containing two drops of culture and two drops of the antiseptic added separately. In the case of those solutions containing iodine this was neutralised by adding subsequently some sodium thiosulphate, in order to avoid any inhibition of growth of any organisms not killed by their period in contact with the antiseptic. (It was found later that the organisms grew perfectly in a medium containing two drops of iodine, although this gives a concentration of not less than 1 in 5000.)

On the Skin.—Areas of skin on the front of the forearm were selected, and marked off into segments with a grease pencil. As the majority of the antiseptics used had been found to be lethal to staphylococci and *B. coli* in one minute by the tube test, this period of time only was used. In each case an ordinary sterile throat swab was moistened in sterile broth and then rubbed hard on *part* of the selected area of skin. It was then transferred to a tube of broth and the latter incubated overnight. This served as a control to ensure that there were organisms on that particular piece of skin, before the addition of the antiseptic. The area of skin was then gently swabbed all over with the antiseptic in question. After one minute this area was again rubbed *all over* very thoroughly with a throat swab moistened in broth. The swab was again transferred to a tube of broth and this was incubated overnight. (N.B.—The amount of antiseptic carried over into the broth by this means must have been considerably less than the two drops used in the test-tube controls, and so in this case no further controls were added.)

Results of the Tests.

In the *tube test* growth was present in all the control tubes, but not in any case where one of the solutions had been in contact with the organisms, except ethyl alcohol 70 per cent. with staphylococci, where growth was present in all four tubes, and E.G.E.E. with staphylococci where growth was present in the first three tubes. In the *skin test* growth was present in all the control tubes, and also in all cases where the solvents had been used alone, without iodine. With none of the solutions containing iodine was any growth observed.

Isopropyl alcohol proved to be the most bactericidal of the solvents used, and no trace of irritation was noticed by either of us, after long periods of vigorous swabbing with this fluid. It is said to be twice as toxic as ethyl alcohol, but it is not absorbed to any appreciable extent by the skin or lungs.[3] The penetrative powers were tested along with the other solvents as follows:—

Areas of skin on the forearm, which had not been washed for six hours were sectioned off with grease pencil and well painted with the solution of iodine in the solvent in question, using a new camel-hair brush for each area. After the lapse of 30 minutes the forearm was swabbed with cotton-wool soaked in a 5 per cent. watery solution of sodium thiosulphate. The stains from iodine in 70 per cent. alcohol and 70 per cent. isopropyl alcohol were the most difficult to remove, the next being iodine in 90 per cent. alcohol, and the easiest being watery iodine, iodine in E.G.E.E., and iodine in isopropyl alcohol.

We had further to consider whether any decomposition would take place between iodine and the approved solvent. Isopropyl alcohol is $CH_3.CH.OH.CH_3$ and on oxidation yields acetone. We have failed to discover even a trace of acetone in our solutions of iodine in isopropyl alcohol, in bottles half full, that have been opened many times during a month. We think it would be advisable, however, in view of the possibility of oxidation, to recommend the use of comparatively recent solutions. Lastly, there is little difference between the evaporation rate of isopropyl alcohol and that of ethyl alcohol, the boiling point of the former being only 2–3 degrees higher than the latter.[3] Isopropyl alcohol, moreover, has quite a pleasant smell.

The relative costs of the solvents used in this investigation are as follows:—

Rectified spirit, after deducting the rebate allowed by the Customs and Excise, £2 13*s.* per gallon.

Isopropyl alcohol, in 10-gallon quantities, 13*s.* 6*d.* per gallon.

E.G.E.E., in 10-gallon quantities, 11*s.* 6*d.* per gallon.

Isopropyl alcohol 70 per cent. would be approximately 10*s.* 6*d.* per gallon, and if used generally in hospital would produce a saving of about 85 per cent.

Conclusions.

Our conclusions, therefore, are: (1) that iodine in the strength of 1·25 per cent. is in itself an efficient antiseptic; (2) that isopropyl alcohol is the most antiseptic of the solvents used in this experiment; (3) that iodine 1·25 per cent. in isopropyl alcohol is not harmful to the skin; (4) that its penetrative powers and evaporation rate are equal to those of ethyl alcohol; and (5) that its cost is very much less than that of rectified spirit. We therefore strongly recommend iodine 1·25 per cent. in 70 per cent. isopropyl alcohol as a substitute for the commonly used iodine in rectified spirit.

We wish to thank Dr. D. N. Nabarro, director of the pathological department, for permission to carry out this work, and for his kind interest and assistance.

These institutions will be open to all classes of the population, but especially to the fellaheen, who will thus no longer be compelled to travel long distances to the nearest hospital.

Clinical and Laboratory Notes.

A NOTE ON THE SO-CALLED WHITE LINE OF ADRENAL INSUFFICIENCY.

BY A. MUIR CRAWFORD, M.D., F.R.F.P.S. GLASG.,
ASSISTANT PHYSICIAN, GLASGOW ROYAL INFIRMARY.

IN certain individuals, if the skin is lightly stroked with the pad of the finger or the smooth rounded end of a fountain pen, a band of pallor is produced in the area of skin corresponding to the part stimulated. This phenomenon was closely studied by Sergent,[1] who regarded it as a valuable clinical test. He considered it to be pathognomonic of adrenal insufficiency and termed it "the white line of adrenal insufficiency" (*la ligne blanche surrénale*). Considerable interest has been shown in the reaction, notably among French clinicians, and reference to the subject is to be found frequently in French literature. In this country and in America, several workers have investigated the reactions produced by cutaneous stimulation, with results which apparently show that the reaction is of no clinical value as a sign of adrenal insufficiency. Thus, Cotton, Slade, and Lewis,[2] in an elaborate investigation on the phenomena of dermatographism carried out on soldiers affected with "irritable heart," refer to the remarkably sharp outline of a white band produced by stroking the skin with the end of a flat ruler in a susceptible subject. Their observations were made with special reference to the effects of pressure of a blunt point drawn firmly over the skin. This invariably demonstrated the appearance of a red tache of varying intensity, with or without borders of distinct pallor, and they concluded that the variations in the type of reaction could be attributed to differences in the grade of pressure. In many of their cases light pressure produced a simple white line, whereas, in other cases, light pressure was either without effect or produced a transitory red band. Wright,[3] working in the Physiological Department of the Middlesex Hospital Medical School, has investigated the significance and value of Sergent's white line by applying the test to healthy subjects. He carried out the test on 100 young medical students and in each case recorded the systolic and diastolic blood pressures. A positive result was obtained in 66 per cent. of the tests, and his observations led him to the conclusion that the white line of Sergent is a phenomenon occurring in a large proportion of normal subjects, that it is not related to adrenal insufficiency or to abnormally low systolic or diastolic blood pressure, and is, in fact, without pathological significance.

Personal Observations.

In order to test further the value of the phenomenon I thought it might be of interest to carry out the test on hospital patients of different ages and affected with different types of disease. Tests were, therefore, carried out on 100 ward patients in the Glasgow Royal Infirmary. The patients were affected with the usual diseases seen in a general medical ward, and no selection was made of either patient or type of disease. The test was carried out by lightly stroking the skin of the anterior abdominal wall with the smooth rounded end of a fountain pen, due attention being paid to the details of the Sergent technique. After a few preliminary observations it was decided to record the results as follows:—

1. *Negative*, where there was either no result or where the stroking was followed by a red line.
2. *Positive* +, where there appeared a definite but not marked band of pallor.
3. *Positive* + +, where there appeared a very marked white band with clear-cut edges.

This method of recording the results is very similar to that employed by Wright. Although accurate time observations were not made, it was generally found that a positive reaction appeared in about 20 to 30 seconds and lasted for one to two minutes. The following tables show the results obtained. Of 100 cases examined, 49 per cent. gave a positive reaction (14 per cent. were positive + +, and 35 per cent. positive +), while 51 per cent. were negative.

TABLE I.—*Showing Results in Relation to Age and Sex.*

Age in years.	Sex.	P. + +	P. +	N.
10 to 20 ..	M.	0	5	3
	F.	3	6	4
21 to 35 ..	M.	6	7	3
	F.	2	8	3
36 to 50 ..	M.	1	3	12
	F.	2	2	4
Over 50 ..	M.	0	4	16
	F.	0	0	6

P. = Positive. N. = Negative.

An examination of Table I. shows that a positive reaction was obtained far more frequently under 35 years of age than over. This is in accordance with the results obtained by other observers. Thus, Kay and Brock[4] state that the white line occurs most frequently in young adults of either sex. In my series, in 29 patients between the ages of 21 and 35 years, 79·3 per cent. gave a positive reaction, while in 50 patients between the ages of 36 and 74 years, only 24 per cent. were positive.

TABLE II.—*Showing Results in Relation to Type of Disease.*

Disease.	P. + +	P. +	N.	Disease.	P. + +	P. +	N.
Gastro-intestinal	1	9	14	Diabetes m. ..	1	3	2
Respiratory ..	2	7	15	Blood	0	0	4
Exophthalmic goitre	4	0	1	Renal	2	5	4
Rheumatic ..	0	2	2	Cardiac	2	4	3
				Nervous ..	2	4	3
				Miscellaneous	0	1	3

Diabetes m. = Diabetes mellitus.

The only criticism I have to offer on these results given in Table II. is that in four cases of exophthalmic goitre the reaction was obtained in a very marked degree; in fact, they showed a white band more intense than that obtained in any other disease. This tends to support the hypothesis formulated by Tracy[5] that the white line is a manifestation of sympatheticotonia.

TABLE III.—*Showing Results in Relation to Blood Pressure.*

—	P. + +	P. +	N.
Average systolic pressure ..	119	117	122
Average diastolic pressure ..	69	72	73
Average pulse pressure	50	45	49

A glance at Table III. shows that no definite relationship can be demonstrated between blood pressure or pulse pressure and type of reaction.

Conclusions.

As a result of these observations and from the reports published by other investigators it would appear that (1) the white line of Sergent is a phenomenon which may be readily demonstrated in a large percentage of young adults; (2) it bears no relationship to the sex of the individual; (3) it bears no relationship to the blood pressure and is not pathognomonic of adrenal insufficiency; (4) it bears no relationship to any particular type of disease, although

(3) it should not be harmful to the skin; (4) it should be stable; and (5) it should evaporate readily when painted on the skin.

Doubt has recently been expressed amongst surgeons as to whether iodine is an efficient antiseptic, and whether in the solution in general use the more important agent is not the spirit. It seemed advisable therefore to carry out some experiments to find out the actual bactericidal value of iodine in various solvents, as well as considering the relative merits of these solvents. The solvents used were as follows: Rectified spirit and ethyl alcohol, 70 per cent.; isopropyl alcohol, 90 per cent.; isopropyl alcohol, 70 per cent.; ethylene-glycol-mono-ethyl ether (for convenience hereafter called E.G.E.E.) and water with potassium iodide.

Method of Investigation.

In our investigation we made a number of solutions of iodine in other solvents, such as ether, petroleum ether, diacetone alcohol, sextone, sextol, as well as isopropyl alcohol and E.G.E.E., but it was decided that only the last two could possibly be used. Isopropyl alcohol is made from the gases emanating from petroleum wells by absorption in sulphuric acid and subsequent steam distillation. E.G.E.E. is made in the United States from ethylene obtained by "cracking" petroleum oils; the precise method does not seem to be known here. It is stated that ethyl alcohol is germicidal to *Bacillus coli* in 70 per cent. strength in two and a half minutes, and isopropyl alcohol in 30 per cent. strength in the same time. Iodine is said to kill *B. coli* in two and a half minutes in a strength of 1 in 50,000.[1] Ethyl alcohol is more active as a germicide in a strength of 70 per cent. than in any other concentration, being 30 times more powerful than 60 per cent., and 40 times more powerful than 80 per cent.[2] In our investigation the antiseptic properties of the solutions mentioned above were tested as follows: One series of experiments was made in vitro, using cultures of *B. coli* and staphylococci and the other directly on the skin to reproduce as nearly as possible the conditions obtaining at operation.

In vitro.—A measured quantity of each solution was added to an equal quantity of a 24-hour broth culture of each organism, and two drops of the mixture were abstracted by means of a sterile capillary pipette at the end of 1, 2, 3, 4, and 5 minutes. These were at once transferred to tubes containing approximately 3 c.cm. of broth and incubated over night. At the same time controls were put up containing two drops of culture and two drops of the antiseptic added separately. In the case of those solutions containing iodine this was neutralised by adding subsequently some sodium thiosulphate, in order to avoid any inhibition of growth of any organisms not killed by their period in contact with the antiseptic. (It was found later that the organisms grew perfectly in a medium containing two drops of iodine, although this gives a concentration of not less than 1 in 5000.)

On the Skin.—Areas of skin on the front of the forearm were selected, and marked off into segments with a grease pencil. As the majority of the antiseptics used had been found to be lethal to staphylococci and *B. coli* in one minute by the tube test, this period of time only was used. In each case an ordinary sterile throat swab was moistened in sterile broth and then rubbed hard on *part* of the selected area of skin. It was then transferred to a tube of broth and the latter incubated overnight. This served as a control to ensure that there were organisms on that particular piece of skin, before the addition of the antiseptic. The area of skin was then gently swabbed all over with the antiseptic in question. After one minute this area was again rubbed *all over* very thoroughly with a throat swab moistened in broth. The swab was again transferred to a tube of broth and this was incubated overnight. (N.B.—The amount of antiseptic carried over into the broth by this means must have been considerably less than the two drops used in the test-tube controls, and so in this case no further controls were added.)

Results of the Tests.

In the *tube test* growth was present in all the control tubes, but not in any case where one of the solutions had been in contact with the organisms, except ethyl alcohol 70 per cent. with staphylococci, where growth was present in all four tubes, and E.G.E.E. with staphylococci where growth was present in the first three tubes. In the *skin test* growth was present in all the control tubes, and also in all cases where the solvents had been used alone, without iodine. With none of the solutions containing iodine was any growth observed.

Isopropyl alcohol proved to be the most bactericidal of the solvents used, and no trace of irritation was noticed by either of us, after long periods of vigorous swabbing with this fluid. It is said to be twice as toxic as ethyl alcohol, but it is not absorbed to any appreciable extent by the skin or lungs.[3] The penetrative powers were tested along with the other solvents as follows:—

Areas of skin on the forearm, which had not been washed for six hours were sectioned off with grease pencil and well painted with the solution of iodine in the solvent in question, using a new camel-hair brush for each area. After the lapse of 30 minutes the forearm was swabbed with cotton-wool soaked in a 5 per cent. watery solution of sodium thiosulphate. The stains from iodine in 70 per cent. alcohol and 70 per cent. isopropyl alcohol were the most difficult to remove, the next being iodine in 90 per cent. alcohol, and the easiest being watery iodine, iodine in E.G.E.E., and iodine in isopropyl alcohol.

We had further to consider whether any decomposition would take place between iodine and the approved solvent. Isopropyl alcohol is $CH_3.CH.OH.CH_3$ and on oxidation yields acetone. We have failed to discover even a trace of acetone in our solutions of iodine in isopropyl alcohol, in bottles half full, that have been opened many times during a month. We think it would be advisable, however, in view of the possibility of oxidation, to recommend the use of comparatively recent solutions. Lastly, there is little difference between the evaporation rate of isopropyl alcohol and that of ethyl alcohol, the boiling point of the former being only 2–3 degrees higher than the latter.[3] Isopropyl alcohol, moreover, has quite a pleasant smell.

The relative costs of the solvents used in this investigation are as follows:—

Rectified spirit, after deducting the rebate allowed by the Customs and Excise, £2 13*s.* per gallon.

Isopropyl alcohol, in 10-gallon quantities, 13*s.* 6*d.* per gallon.

E.G.E.E., in 10-gallon quantities, 11*s.* 6*d.* per gallon.

Isopropyl alcohol 70 per cent. would be approximately 10*s.* 6*d.* per gallon, and if used generally in hospital would produce a saving of about 85 per cent.

Conclusions.

Our conclusions, therefore, are: (1) that iodine in the strength of 1·25 per cent. is in itself an efficient antiseptic; (2) that isopropyl alcohol is the most antiseptic of the solvents used in this experiment; (3) that iodine 1·25 per cent. in isopropyl alcohol is not harmful to the skin; (4) that its penetrative powers and evaporation rate are equal to those of ethyl alcohol; and (5) that its cost is very much less than that of rectified spirit. We therefore strongly recommend iodine 1·25 per cent. in 70 per cent. isopropyl alcohol as a substitute for the commonly used iodine in rectified spirit.

We wish to thank Dr. D. N. Nabarro, director of the pathological department, for permission to carry out this work, and for his kind interest and assistance.

THE RATING OF HOSPITALS.—The County Valuation Committee for Cornwall has decided to assess hospitals at a uniform rate of 7*s.* 6*d.* per bed, but the Truro Rural Rating Committee has resolved not to demand rates from hospitals and similar institutions.

NEW HOSPITALS FOR EGYPT.—The Egyptian Government has adopted a scheme for the provision, at a cost of £1,500,000, of 100 hospitals in various towns and villages, to be completed within the next five years. These institutions will be open to all classes of the population, but especially to the fellaheen, who will thus no longer be compelled to travel long distances to the nearest hospital.

Medical Societies.

ROYAL INSTITUTE OF PUBLIC HEALTH.

DUBLIN CONGRESS, AUGUST 14TH–20TH, 1928.

MEMBERS were received at the Mansion House by the President, General R. Mulcahy, Minister for Local Government and Public Health, President Cosgrave being among the hosts. At the inaugural meeting a further welcome was given by Mr. Seamus Murphy, the Chief Commissioner of Dublin, who was supported by the Vice-Provost of Trinity College, the President of the National University College, Dublin, and the Presidents of the Royal College of Physicians, the Royal College of Surgeons, and the Apothecaries' Hall, Ireland. General Mulcahy, in his opening address, referred to the problems in front of the Free State, remarking that they were watching with interest the results of the English inquiry into maternal mortality. He also acknowledged the generosity of the Rockefeller Foundation in aiding the establishment of efficient county public health services. General Mulcahy was presented with the Honorary Fellowship of the Institute by Sir Thomas Oliver, and the opening session terminated with greetings from many overseas delegates.

SECTION OF BACTERIOLOGY, PATHOLOGY, AND BIOCHEMISTRY.

Prof. **JAMES M. BEATTIE** gave a presidential address entitled Public Authorities and Research, which was printed in THE LANCET last week (pp. 430–31).

Prof. **W. D. O'KELLY** (University College, Dublin), who followed, while agreeing in general with Prof. Beattie, thought the problem was how to convince the local authorities that this was going to be an economic proposition.

Prof. **J. W. BIGGER** (Trinity College, Dublin) had something to say in favour of institute research, for the individual was able to consult at any stage with experts in other lines. Further, he himself favoured pure research and did not think Dr. Beattie distinguished sufficiently between research and investigation. It would be difficult in Ireland, he thought, to persuade the local authorities to spend money on research. Dr. Bigger went on to read a paper entitled the Expectation of Life and the Bacteriological Laboratory (which also led up to the question of the endowment of research). He compared the deaths in Ireland from 20 groups of diseases in 1875 and 1925 respectively. He showed that in 15 groups there had been a fall in the death-rate and in 5 a rise. In 13 of the 15 cases the falls were in bacteriological diseases, whereas in only 1 of the 5 "rises" was the disease a bacterial one. Bacteriology had saved very many lives and would in time save very many more. In Ireland, however, the public health authorities had not even applied the incomplete knowledge which we possessed at present. Ireland lagged behind in the provision of laboratory facilities for diagnosis and for the detection of carriers, and had made no use of recent advances in diphtheria and scarlet fever.

Dr. **NORAH H. SCHUSTER** (pathologist, Royal Chest Hospital, London) read a paper on primary carcinoma of the lung. She produced evidence that there was a real increase in this disease in London and stated that a similar increase had occurred in various foreign cities.—Dr. **BEATTIE** pointed out that in a large experience he had never seen this disease associated with the pneumoconioses of the Sheffield grinder.—Prof. **W. BOXWELL** (Dublin) stated that primary carcinoma of the lung was very rare in Dublin.—Prof. **J. T. WIGHAM** (Dublin) suggested that an investigation as to why this disease was rare in one place and increasingly prevalent in another might lead to interesting results.

sometimes it may be specially marked in certain pathological states not connected with adrenal insufficiency.

NON-SPECIFIC PROTEIN THERAPY IN ERYSIPELAS.

By Henry C. Semon, M.D. Oxf., M.R.C.P. Lond.,

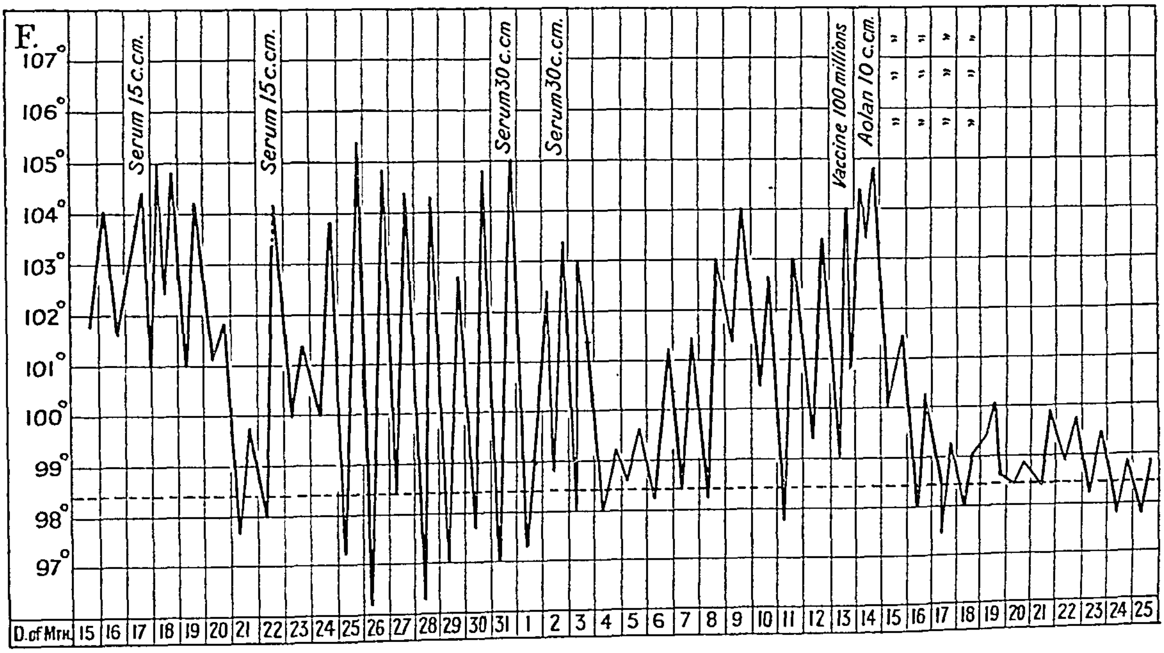
PHYSICIAN, DISEASES OF THE SKIN, ROYAL NORTHERN HOSPITAL.

THE respective potencies of specific as opposed to non-specific protein therapy, both of acute and chronic infections, are still sub judice, and the adherents of the former doctrine could doubtless produce examples in support of their contentions as striking as the one here submitted. The writer holds no fixed views in the controversy; his object is merely to call attention to a very harmless and sometimes exceedingly effective means of stimulating to their utmost capacity the natural protective mechanisms against disease.

A middle-aged married lady had suffered from an aural furunculosis for about three months. On May 15th last, on her return from the seaside, she appeared to have caught a chill, and on the following day at noon she went to bed with a temperature of 102° F. She complained of deafness and a feeling of fullness over the right ear and cheek. On the 17th an erysipelatous eruption appeared in those situations, and during the course of her illness in the following weeks wandered over the scalp and the rest of the face in an irregular manner. Each extension appears to have been associated with rigors and increase in the temperature.

An injection of antistreptococcal serum was given on May 17th, but there was no fall in temperature until May 21st. A second injection, given on the following day, appeared to have some effect, but doubled doses on the third and fourth days produced no result. Two attempts to grow the organisms from the blood were unsuccessful, and the injection of a stock vaccine on June 13th appears to have been followed by an even higher temperature, almost 105°.

The patient was very ill indeed when I was asked to see her in consultation on June 14th, the thirty-first day of her infection. She had a running pulse of 130, a temperature of 105°, and was almost comatose. It was very difficult to rouse her, and there was complete loss of control of the sphincters. The erythematous rash on the scalp and face was slightly œdematous in places, but had not the typical sharply defined raised edge of text-book descriptions. Nevertheless, the rest of the picture left no doubt of the nature of her infection. My first suggestion, to give an intravenous injection of gr. 1/16 of perchloride of mercury, was opposed by one of the consultants on the ground that she had mitral stenosis and probably some valvular vegetations, which he believed he had seen detached by this procedure in another case. No objections were raised to the intramuscular injection of 10 c.cm. of aolan, a germ- and toxin-free derivative of cow's milk, which is put up in 5 and 10 c.cm. ampoules by the firm of Beiersdorf, in Hamburg. The injection was made into the buttocks, 5 c.cm. intramuscularly, and another 5 c.cm. into the fascial planes over the glutei. No harmful effects were observed at the time, and that same evening the temperature fell to 101°. 10 c.cm. were given on the three following days, and 5 c.cm. on June 17th and 18th. The effects on the temperature are well illustrated by the chart, and the improvement in the general condition proceeded pari passu with the fall of temperature. The eruption on the scalp and forehead did not appear to be influenced to the same extent, but this was at no time a very striking feature of the case, and gradually involuted under local applications of a weak solution of ichthyol and lead.



Temperature chart of a case of erysipelas, showing improvement under the influence of aolan.

The recovery was so striking that the case seems worthy of record.

A NEW CULTURE MEDIUM.

By C. Y. Wang, M.D., F.R.C.P. Edin.

(From the School of Pathology, University of Hong-Kong.)

THE following preparation is the outcome of a series of experiments I have had occasion to conduct, whilst studying certain aspects of the biological properties of bacteria, for the purpose of raising early and abundant growth :—

Trypsinised defibrinated ox blood	10 parts.
,, plain bouillon	8 ,,
,, plain milk medium	4 ,,
Beaten whole egg	10 ,,

Preparation of the Medium.

The defibrinated blood should be fresh, but need not be obtained with aseptic precautions. For trypsinisation, to every 10 c.cm. of blood add 0·2 c.cm. of liquor pancreaticus (Benger's). The treated blood is left overnight (18–24 hours) at 37° C., but should be occasionally shaken during the first few hours of incubation. The bouillon is the ordinary peptone broth made with meat extract and adjusted to the usual reaction. Trypsinisation is effected by adding 0·16 c.cm. of liquor pancreaticus to every 8 c.cm. of broth, leaving to stand overnight at body temperature. Strict aseptic precautions are to be observed in this procedure, at the end of which the broth should remain clear. The milk medium is similarly prepared and should show practically no change in reaction. After being trypsinised the three fluids are well mixed with the beaten egg, and the whole mixture is strained through gauze or muslin and distributed in tubes. These are sloped in an inspissator, so heated as to take 3½–4 hours to reach 75° C., at which temperature they remain for 15–30 minutes before being autoclaved at 120° C. for 20 minutes.

Growth of Various Organisms.

On this medium the growth of the tubercle bacillus is rapid at body heat. In subculture the minute colonies, somewhat raised above the surface and plainly visible to the naked eye, soon become confluent and nodular in appearance. Examined microscopically the organisms present marked pleomorphism, some appearing as beaded bodies 15–20 μ in length, a few of them so disposed as to give the appearance of a chain of streptococci. Here and there, at one or both ends of the organism, detached beads appear as minute cocci. Other organisms are seen as irregularly disposed rounded bodies, as small as *B. melitensis*.

The pneumococcus grows very rapidly on the medium. When sown from a loopful of a thin emulsion, scarcely turbid to the naked eye, it yields in 12–16 hours an abundant growth of colonies which in 24–36 hours become flattened out, appearing as glossy patches. The organism tends to retain its viability for many weeks, if evaporation is prevented. The growth far surpasses that obtained on other media, such as blood-agar or solidified serum.

The streptococcus thrives extremely well. Unlike those of the pneumococcus, the colonies do not tend to flatten out.

The diphtheria bacillus develops readily; at 12–24 hours after incubation the colonies are more numerous than those seen on Löffler's serum.

The medium has also been found favourable for the growth of other bacteria, such as the meningococcus, hæmophilic bacilli, and the organisms of glanders and plague.

ROYAL NATIONAL ORTHOPÆDIC HOSPITAL.—The annual report states that the new buildings at the country branch at Brockley Hill, Stanmore, are now occupied and provide 90 additional beds, with an operating theatre and other accommodation. There are now 214 beds at Stanmore, and the King's Fund has promised a further £1000 towards the provision of another 50 beds there. An additional 70 acres of land have been purchased which will not only provide for future extensions, but will ensure the maintenance of the rural character of the hospital.

FLORENCE NIGHTINGALE FUND.—The annual report of the Florence Nightingale Fund School at St. Thomas's Hospital states that last year there were 156 probationer nurses under training. Of these, 70 were taken on as extra nurses to complete their training, 37 completed their term and received certificates, and only 13 resigned or were discharged as unsuitable. The fund was raised after the Crimean war in recognition of Miss Nightingale's services and has an income of £2000 a year. It claims to give the best training a nurse can receive, and, owing to the demands upon the staff for important outside posts, the matron has been compelled for the moment to refuse to allow further drafts to be made upon it.

Medical Societies.

ROYAL INSTITUTE OF PUBLIC HEALTH.

DUBLIN CONGRESS, AUGUST 14TH–20TH, 1928.

MEMBERS were received at the Mansion House by the President, General R. Mulcahy, Minister for Local Government and Public Health, President Cosgrave being among the hosts. At the inaugural meeting a further welcome was given by Mr. Seamus Murphy, the Chief Commissioner of Dublin, who was supported by the Vice-Provost of Trinity College, the President of the National University College, Dublin, and the Presidents of the Royal College of Physicians, the Royal College of Surgeons, and the Apothecaries' Hall, Ireland. General Mulcahy, in his opening address, referred to the problems in front of the Free State, remarking that they were watching with interest the results of the English inquiry into maternal mortality. He also acknowledged the generosity of the Rockefeller Foundation in aiding the establishment of efficient county public health services. General Mulcahy was presented with the Honorary Fellowship of the Institute by Sir Thomas Oliver, and the opening session terminated with greetings from many overseas delegates.

SECTION OF BACTERIOLOGY, PATHOLOGY, AND BIOCHEMISTRY.

Prof. JAMES M. BEATTIE gave a presidential address entitled Public Authorities and Research, which was printed in THE LANCET last week (pp. 430–31).

Prof. W. D. O'KELLY (University College, Dublin), who followed, while agreeing in general with Prof. Beattie, thought the problem was how to convince the local authorities that this was going to be an economic proposition.

Prof. J. W. BIGGER (Trinity College, Dublin) had something to say in favour of institute research, for the individual was able to consult at any stage with experts in other lines. Further, he himself favoured pure research and did not think Dr. Beattie distinguished sufficiently between research and investigation. It would be difficult in Ireland, he thought, to persuade the local authorities to spend money on research. Dr. Bigger went on to read a paper entitled the Expectation of Life and the Bacteriological Laboratory (which also led up to the question of the endowment of research). He compared the deaths in Ireland from 20 groups of diseases in 1875 and 1925 respectively. He showed that in 15 groups there had been a fall in the death-rate and in 5 a rise. In 13 of the 15 cases the falls were in bacteriological diseases, whereas in only 1 of the 5 " rises " was the disease a bacterial one. Bacteriology had saved very many lives and would in time save very many more. In Ireland, however, the public health authorities had not even applied the incomplete knowledge which we possessed at present. Ireland lagged behind in the provision of laboratory facilities for diagnosis and for the detection of carriers, and had made no use of recent advances in diphtheria and scarlet fever.

Dr. NORAH H. SCHUSTER (pathologist, Royal Chest Hospital, London) read a paper on primary carcinoma of the lung. She produced evidence that there was a real increase in this disease in London and stated that a similar increase had occurred in various foreign cities.—Dr. BEATTIE pointed out that in a large experience he had never seen this disease associated with the pneumoconioses of the Sheffield grinder.—Prof. W. BOXWELL (Dublin) stated that primary carcinoma of the lung was very rare in Dublin.—Prof. J. T. WIGHAM (Dublin) suggested that an investigation as to why this disease was rare in one place and increasingly prevalent in another might lead to interesting results.

In another paper Dr. Bigger dealt with the bacteriological control of shell-fish, describing a method adopted by him for determining the fitness of shell-fish for human consumption, which was essentially a modification of Klein's. He referred to the discordance between the results obtained by him acting for the Department of Fisheries and those obtained by Prof. J. W. Eyre for the Fishmongers' Company. He believed that the divergent results were chiefly due to chance in the selection of shell-fish and chance in the selection of the particular fraction of shell-fish fluid examined. He thought his own method gave more reliable and just as rapid results as the Houston-Eyre method.—The desirability of the adoption of a uniform standard was brought out by the discussion.

Dr. Geoffrey Bewley (Adelaide Hospital, Dublin), in a paper on the Schick test, showed that the mortality from diphtheria had always been smaller in Ireland than in England and Scotland. The rates in England and Scotland, however, had recently been greatly reduced, whilst that in the Free State had been practically stationary. The number of Schick reactors was probably proportionately greater in the Free State than in England. In the Adelaide Hospital 54 per cent. of the nurses were positive, as compared with an average figure of 25 per cent. for English hospitals. From this he inferred that the soil was prepared, and that diphtheria might at any time assume epidemic proportions in the Free State. The prophylactic inoculation of the children was, therefore, worthy of consideration.

Prof. Blair Bell (Liverpool) claimed that the clinical results of combination of the lead and X ray therapy for cancer is better than those obtained from either alone. He reviewed their 1925 statistics in the light of subsequent history. Of 31 cases which were believed to be cured 3 had since died, 2 from intercurrent disease, and 1 from recurrence. The remainder were alive and healthy.—Dr. Leslie Cunningham described the toxic effects of intravenous lead and emphasised the need for careful study of the variation in functions of the liver during the treatment.

Section of Child Welfare.

Prof. A. Louise McIlroy (London), in her presidential address on the Progress of Midwifery in the Present Century, referred to Dublin as the Mecca of obstetrics. Bedside teaching in the three great hospitals was given by experts. There had been much advance in antenatal work between 1900 and 1925. Obstetrics, once the Cinderella of medicine, raised to a science, would promote the dignity of motherhood and the saving of child life. She referred gratefully to the pioneer work of Ballantyne, of Edinburgh, and proceeded to deal with changes wrought by antenatal supervision. Disease in expectant mothers was now treated as disease complicated by pregnancy rather than pregnancy complicated by disease. Wonderful results had accrued from the work of a special heart clinic for pregnant women at the Royal Free Hospital. Rational treatment had been introduced for eclampsia to take the place of induction of labour and high forceps cases with their great mortality. To this change Dr. Hastings Tweedie, of Dublin, had contributed much. Research had been promoted as to the normal and the abnormal. Decayed teeth might give rise to eclampsia and toxic symptoms, therefore the work of a dental clinic for expectant mothers was extremely important. X ray examination was invaluable for removing doubt as to pregnancy, &c., though some might question the advantage to the mother of learning a few months beforehand of the advent of triplets, against which risk insurance companies had now refused to insure. Practice was taking the place of lectures in the teaching of medical students. There should be, now, few emergencies in homes unsuitable for complicated labour. The spreading of this knowledge would help the cause of better housing and the demand for more skilled attention for mothers. Hurried labours should become a thing of the past. She had found gas and oxygen the ideal anæsthetic for labour and, in reply to a question, mentioned that a portable apparatus for the purpose was being worked out with promise of success. Although there was as yet little improvement in sepsis mortality, septic morbidity was becoming less. For sepsis she used glycerine drainage with vaccines and open-air treatment. Hopeful research as to vaccines was in progress based on the Dick tests. She believed in serum rather than autogenous vaccine. Since the draining of the uterus by glycerine had been introduced, the douching of the uterus and vagina had been discarded, but in certain cases intestinal lavage was good. The treatment of venereal disease in pregnancy prevented the birth of syphilitic babies and gonorrhœal ophthalmia. Through postnatal clinics and preventive midwifery they would ultimately have more maternity and fewer gynæcological beds, as 50 per cent. of the gynæcological beds were at present filled by conditions due to bad or meddlesome midwifery. The sacrifice of the child by induction of labour was very seldom necessary. Hyperemesis and retroversion of the gravid uterus ought not to be, as formerly, common causes of abortion. In seven and a half years in the Royal Free Hospital they had had no case of craniotomy, owing to improved Cæsarean technique or antenatal work. Subsequent normal labour might occur after Cæsarean section with the scar still holding. The same antenatal care was good for both mother and child. Considering its aims, obstetrics was the greatest subject in medicine, and the new teaching must be spread to the Connemara mothers.

The claims made by Dr. McIlroy for antenatal treatment received ample confirmation in later papers.—Dr. Louis Cassidy (Master, Coombe Hospital) pointed out that 30 per cent. of pregnant women needed much care throughout pregnancy. Early abortion was preventable. In seven years at the Coombe they had only had two deaths from pernicious vomiting and both these cases were moribund on admission. By early treatment with rest in bed and a suitable vitamin-rich diet much could be done to avert fœtal death and trouble from kidney disease. Contraction of the pelvis was becoming rarer. In the prevention of autogenous sepsis attention to septic teeth, the nasopharynx, and the bladder were important. There should be no vaginal examination in normal cases. For the education of the medical student three months' residence in a maternity hospital should be required. Obstetricians should make a more determined effort to secure representation on the General Medical Council. Preventive midwifery would abolish craniotomies and make Cæsarean sections comparatively rare. Women must be persuaded to go early to the antenatal clinics.

Dr. N. Falkiner mentioned that at the Rotunda, breech presentations were only rectified if this could be done easily by external versions. They had had living babies in all their last breech deliveries.—Dr. A. W. Spain (National Maternity Hospital) considered that there were good antenatal facilities for the poor and, he believed, the rich also availed themselves of antenatal advice, but the middle class did not. They must educate the public through the medical officers of health.—Dr. Bethel Solomons (Rotunda) thought that antenatal clinics should only be held at maternity hospitals. Every woman should have antenatal care and the private practitioner's fee should include this. He criticised severely the rule of the Central Midwives Board making vaginal examinations by midwives compulsory. The rectification of breech presentations might result in the death of the baby by the twisting of the cord and give rise to the separation of the placenta. He believed that the results obtained in the maternity hospitals of Scandinavia and Dublin were the best in the world.—Dr. G. W. Fitzgerald (Manchester) advocated that part of the improved training of the medical student should be post-graduate. He emphasised the fact that the theory of autogenous infection was a dangerous doctrine. Other points made were that antenatal clinics, if not always held at maternity hospitals, should at any rate be conducted by experts, and that, if possible, the confinements should be conducted by those who had done the antenatal examinations.

The discussion brought out the fact that two-thirds of the births in Dublin were attended through the intern and extern departments of the three hospitals, and a resolution was passed requesting the masters to consider the preparation of statistics on a considerable scale which would establish the value of antenatal work.

School Medical Service.

Dr. J. A. Harbison (Kildare), after describing the aim of preventive medicine as medical "supervision from conception to corruption," went on to show what gaps needed to be filled. They wanted nursery schools like the McMillan to teach habits to the toddler, and they wanted health education for older scholars.—Dr. T. S. Fulton (Belfast) emphasised the unhygienic condition of many of the schools. In Belfast they had much leeway to make up. Out of 186 schools only seven were really good. They were endeavouring to renovate five every year at a cost of about £30,000, and expenditure on nursery schools was at present starved out in Belfast, though the need for them was recognised.—Both speakers deprecated hurried examinations and the undue importance attributed to statistics. The need for the education of the public and of education authorities in the wide difference between a nursery school and the ordinary infants' department of an elementary school was emphasised in the discussion.

Dr. A. Dingwall Fordyce described the beginning made in Liverpool in the supervision of the rheumatic school-child by means of a hospital clinic coöperating with the public medical services. Many more residential beds and convalescent homes were needed on Merseyside for this work. Head-teachers should be fully notified how to deal with each rheumatic child.—Dr. Catherine Chisholm (Manchester) from her experience said that rheumatic febrile attacks in the 1–5 age period could be discovered if sought for.—Dr. Letitia Fairfield described the scheme for rheumatic children carried out by the coöperation of Guy's Hospital. They had special classes in the "physically defective" schools for such cases and taught them a suitable trade from 12 years old onwards. An important point made in the discussion was that school medical officers, like tuberculosis officers, should be in some way attached to hospitals and thus given a wider clinical field. Dr. Fairfield gave an extremely interesting account of the working of the L.C.C. scheme for mentally defective children, and in replying to a vigorous discussion she said there had been no dull and backward in the London M.D. schools during the last ten years. She further said that mongols were admitted to the M.D. schools, but that their education was a waste of money. She wished something could be done to correct the impression that thyroid was beneficial to mongols, as absolutely fallacious hopes were aroused in parents. Modern opinion was dead against sterilisation. Those for whom sterilisation was justifiable also needed confinement.

OTHER SECTIONS.

Some 80 contributions, a large proportion of which were from representatives of the Free State, official and non-official, were discussed at the five sections and their various subsections.

Prof. P. Abercrombie (Liverpool) dealt with town and rural planning, and referred to the modern anti-social phenomenon of "ribbon" building. He advocated instead the grouping of houses on side roads at right-angles to the main artery, so as to secure compact communities.—Mr. J. Webb (President of the Royal Institute of Architects of Ireland) pressed the urgency of planning for all the towns and rural areas of Ireland.—Mr. George Beckett (Vice-President R.I.A.I.) said his institute has been pressing the Government during the last five years for planning measures. He believed that the city commissioners were quite alive to the importance of planning but that the Government was not.—Dr. W. C. Dwyer (one of the three Dublin commissioners) pointed out the urgent need for town planning in Dublin, and emphasised the disastrous effect of bad housing on education.—Mr. Manning Robertson, M.R.I.A.I., said that Ireland lagged hopelessly behind the Continent in town and regional planning, and that a comprehensive planning Act was needed. Fortunately for Ireland, he said, they had not inherited the legacy from uncontrolled industrialism that was the despair of England's housing reformers. He moved a resolution, which was accepted by the section, recommending the Government to set up a planning commission for the development of the Free State as a whole.—Mr. W. J. Byrne (Dublin Commercial Utility Society) showed how much could be done by utility societies if the local authorities throughout the Free State would grant to them the facilities provided for under the various housing acts.—Mr. H. T. O'Rourke (city architect) outlined the activities of the Dublin Corporation. Modern methods of dealing with the housing problem in the congested areas of old towns were so hopelessly uneconomic that he had practically reached the conclusion that free housing was as necessary as free education.—It was clear from the discussion that the spoiling of the country-side, although it had not reached so advanced a stage as in England, was quite sufficient of a menace in the Free State to provoke vigorous protests. In order to deal with this menace Mr. R. M. Butler (Professor of Architecture, University College, Dublin) urged that "committees of taste," composed of architects, artists, road engineers, and business men should be set up in every district.

Dr. Gerald Leighton (Scottish Board of Health) advocated a great extension of the fixing of standards for foodstuffs.—Mr. J. H. Norris (Director of Veterinary Research) estimated that 20 per cent. of the Irish dairy cattle were tuberculous and strongly supported the recommendations of the Free State Interdepartmental Committee, which included veterinary inspection of dairy cattle, the extension of the tuberculosis order, and the grading of milk.—That the Free State will be able to profit by our experience and secure a better nomenclature for graded milks was pointed out by Mr. J. McAllan (Chief Veterinary Inspector, Aberdeen).—A joint contribution from Dr. E. G. Gibb-Smith (M.O.H., Teddington) and Dr. F. Hobday (Principal, Royal Veterinary College) drew attention to the unsatisfactory form of bottle used for milk and to its inefficient capping. The authors also suggested the possibility of destructible containers for milk.

Dr. P. C. Varrier-Jones, in his presidential address, referred to the failure of sanatoriums to cure tuberculosis. Sanatorium treatment only touched the fringe of the matter. The crux of the question was the provision of suitable employment under sheltered conditions with facilities for treatment when required. Village settlements, such as Papworth, fulfilled these requirements.

A Tunbridge Wells Centenary.—The centenary of the Tunbridge Wells General Hospital was observed during the week ended August 18th, when funds were raised towards the £100,000 needed for the building of a new hospital at Great Culverden, Mount Ephraim. In 1926 the governors agreed to mark the centenary by beginning the erection of a new building, instead of spending many thousands of pounds in extensions. The new hospital, which will have 150 beds, will combine the eye and ear hospital, now in its fiftieth year, and a considerable portion of the £100,000 needed will accrue from the sale of the two sites. Building is to be started in a few months.

Reviews and Notices of Books.

FROM MAGIC TO SCIENCE.

By CHARLES SINGER, M.D., D.Litt. Oxf., F.R.C.P. Lond. London: Ernest Benn, Ltd. 1928. Pp. 253. *25s.*

THESE essays deal with what their author terms poetically "the scientific twilight," and have all been printed at various times during the last ten years. But as they are scattered through various publications, some of which are not easily accessible, and as they represent a continuous development of a single line of thought, Dr. Singer has been well advised to bring them together with such modifications from the original form as later publication warranted. We have thus set out what may be called the story of early accomplishment in natural philosophy, as human knowledge groped its way from myth to something of exactitude.

The first essay briefly describes science under the Roman Empire. The author shows the superficial nature of the resemblance of the Lucretian theory to modern atomic views, and gives proper credit to Pliny and Seneca as the two founts of ancient Roman learning whose written works were not lost during the dark ages. Pliny's credulity, however, in medical matters deserves the exposure which it receives. The position of Celsus is accurately described, with much interesting information on the Roman hospital system and the growth of hygienic ideas from prehistoric times. The "Dawn of Science," the subject of the second essay, receives no particular date, but Dr. Singer suggests that we may fix the end of Antiquity and the beginning of the Middle Ages for science at the end of the fourth or the beginning of the fifth century. The lowest degradation of the human intellect in Europe generally may be placed in the tenth century, after which a slow ascent can be discerned. By the thirteenth and fourteenth centuries there is considerable expansion of natural knowledge, and Dr. Singer places the limiting date of the mediaeval attitude towards nature as 1543, and gives his reasons in great detail, which should be read in connexion with an informing chronological pedigree of mediaeval science. Three hundred years earlier the first truly scientific wave which our comparatively modern world experienced marked the arrival of Roger Bacon, while it need hardly be said that Leonardo da Vinci, Paracelsus, and Vesalius are in the pedigree, the last named being contemporary with the critical year. A chapter on the Lorica of Gildas the Briton introduces a subject of medical interest which will be novel to most readers. The lorica was literally a coat of mail, but the word was used for religious spells or invocations of a protective character. The most famous of the loricæ was that attributed to St. Gildas, which is Celtic in character and of date about 600—there is doubt about the exact period. It appeals to the Trinity and to the Hosts of Heaven in 47 stanzas which form a catalogue of the various parts of the body, and lest the compiler should have omitted any part he asks that other members of the body should be held to cover the names of which he has perchance left out. As the chief interest in the Lorica of Gildas is the extraordinary vocabulary of foreign words, the origin of many of which are obscure, Dr. Singer adds very full notes on them which, as he explains, give an idea of how, at certain cultural stages, any phrase or idea that is foreign or strange can be enlisted by the magician for his purposes. An appendix to the chapter describes the six known manuscripts of the Lorica of Gildas, one of which is in the British Museum and forms mainly the text for the essay. In the last essay, which deals with some of the legends which gathered round the school of Salerno, Dr. Singer questions the suggestion that that centre of learning gave free access to women, and states how one of its alleged female celebrities, Trotula, was none other than a man—one Trottus—and that Trotula passed long ago into the fairy tales as Dame Trot. Thus fades into nothingness, he says, the first woman professor whose life a learned medical historian, Salvatore De Renzi, once essayed to write in his Collectio Salernitana.

We have to thank Dr. Singer for a learned, amusing, and suggestive book, and one of special interest to medical men inasmuch as from our science most of the examples of evolutionary knowledge are taken. The illustrations are an interesting feature of the volume.

SOME PRINCIPLES OF DIAGNOSIS, PROGNOSIS AND TREATMENT.

A Trilogy. By ROBERT HUTCHISON, M.D., F.R.C.P., Physician to the London Hospital. Bristol: John Wright and Sons, Ltd. 1928. Pp. 54. *2s. 6d.*

WHENEVER Dr. Robert Hutchison gives an address his audience may expect something interesting, witty and sound. This little book could be bought and read with profit by every specialist and general practitioner, young and old, in the land. In the specialist Dr. Hutchison's broad outlook should help to preserve a mental balance which is sometimes in danger; to the young general practitioner the practical principles he lays down are invaluable; while the older man will chuckle as he sees Dr. Hutchison put into pithy sentences the conclusions which he has himself arrived at by experience but has been unable to formulate. The book contains three addresses, two of which are reprinted from weekly medical journals, while the third is taken from the author's book on "The Elements of Medical Treatment."

In his preface Dr. Hutchison says that his object is to repeat and emphasise the elementary principles of diagnosis, prognosis, and treatment, which are in danger of being ignored through the rapid advances of modern medicine on the laboratory side. It is not that Dr. Hutchison despises modern methods, but he is anxious to show that medicine is and must remain an art, and that our duty is not finished when we have put an appropriate label on the symptoms. In diagnosis the author comments on the three faculties which are called into play—observation, knowledge, and judgment, and gives a list of "don'ts." Prognosis he characterises as the branch of medicine which has, perhaps, made least progress since the time of Hippocrates, and he discusses most admirably the vexed question of "What the patient should be told." Treatment is discussed under appropriate headings, and Dr. Hutchison emphasises the importance of paying attention to the patient's likes and dislikes, quoting Sydenham to the effect that "more importance is to be attached to the desires and feeling of the patient, provided that they are not excessive or dangerous, than to doubtful and fallacious rules of medical art."

CHILDBIRTH.

By WILLIAM GEORGE LEE, A.B., M.D. University of Chicago Press. 1928. Pp. 300. *15s.*

THE manuscript of this book was completed just before the death of the author. It consists of the personal views of a leading American obstetrician not only on the theory and practice of obstetrics, but also on what he considers to be the ideal method of organising the maternity service of a country. Some of his ideas on organisation are excellent; others will receive little sympathy in this country. The following passage is hardly likely to represent current American or British opinion. "The midwife still persists to-day as an evolutionary remnant in our midst, although, like the vermiform appendix, she is now of concern chiefly because of the great amount of harm she originates, her essential functions having long since been lost.” The author possesses the power of explaining difficult points in the simplest language. Only 50 pages are devoted to normal labour, but the whole process could be readily understood by an intelligent lay reader; yet few experienced obstetricians would fail to derive benefit from reading the account. A long and careful survey is given of the reasons for interfering with the course of labour; under this heading are grouped such various conditions as hæmorrhage, contracted pelvis, and malpresentations. This is a mistake from the student's point of view, since the characteristic features of each of these abnormalities are not clearly set out. The procedures recommended are in the main orthodox, but the author's recommendation of uterine tamponade as a routine after manual removal of the placenta is unusual. Dr. Lee gives a full account of the Kjelland forceps; he considers this instrument the best for general purposes.

The book will be of interest mainly to those who already have a fair amount of experience in obstetrics.

Gastro-intestinal Diseases.

Lectures delivered at the James Mackenzie Institute for Clinical Research. London: Humphrey Milford, Oxford University Press. 1928. Pp. 278. *10s. 6d.*

THE collection of articles which form this volume consists of lectures delivered at the James Mackenzie Institute at St. Andrews during the winter session of 1927. Containing as it does the views of 11 eminent British authorities, together with discussion of their opinion by no less eminent critics, the volume is more than readable; it becomes practically a treatise on many unusual problems in connexion with the alimentary canal. We would call attention particularly to the article by Dr. E. Matthew on hæmatemesis, and that by Prof. D. P. D. Wilkie on gallbladder disease as being models of what advanced lectures should be. The article by Prof. John Fraser on superficial pain as an aid in the differential diagnosis of abdominal disease is of the thoughtful and deeply informed nature which one is accustomed to expect from this authority.

The volume should receive a ready welcome from all practitioners whose interest in their profession is sufficient to persuade them not to neglect the use of books.

Neurobiology.

Handbuch der biologischen Arbeitsmethoden. Edited by Geh. Med.-Rat. Prof. Dr. EMIL ABDERHALDEN. *Neurobiologische Studien am menschlichen Fœtus.* By M. MINKOWSKI. Zürich. *Methoden der Reflexprüfung beim Menschen.* By ARTHUR BÖHME. Bochum. Abt. V., Teil 5B, Heft 5. With illustrations. Berlin and Vienna: Urban and Schwarzenberg. 1928. Pp. 511–692. Mk.10.

Prof. Minkowski deals with a hitherto relatively unexplored field of neurophysiology, the material for the study of which is bound to be meagre and difficult to come by. Most if not all of it has been obtained by the help of colleagues, who have given him living fœtuses procured during Cæsarean operations. The viability of such organisms being dubious and in the majority of instances certainly brief, Prof. Minkowski has found it essential to form beforehand a clear idea of the exact experiments to be made and the time limits to be imposed for these, in each particular case: full details of his technique are supplied. Working along these lines, he has been able to cover a surprising amount of the field of antenatal neurophysiology. His experiments have been directed towards investigation of the origination of movements in the fœtus; whether at the earliest stages neuromuscular activity is possible without intervention of the central nervous system. Reflexes and reflex movements of all kinds are examined, including those studied by Magnus and de Kleijn; the special senses, too, are not omitted. The electrical excitability of the fœtal musculature receives attention. Prof. Minkowski divides fœtal life somewhat schematically into “phases” described as embryonic or neuromuscular, early fœtal or spinal, middle fœtal or tegmentospinal, and late fœtal or pallido-rubrocerebello-tegmentospinal, respectively; his intention is to indicate, along the lines followed by Magnus, that at such and such an antenatal stage the fœtus is a “neuromuscular animal,” a “spinal animal,” and so forth. While this is doubtless correct enough in a physiological sense the discrimination is apt to lead to a rather artificial conception of neural activity. The monograph is peculiarly interesting and worth perusing by all those whose concern is with the nervous system.

Dr. Böhme's contribution is on clinical lines and deals comprehensively with reflexes in health and disease. In addition to those, both superficial and deep, with which the clinician has long been practically familiar, due attention is paid to the relatively novel reflexes and automatisms which in recent years have been elucidated by a number of workers, and which exhibit the activities of mechanisms at spinal and mesencephalic levels. The application of the researches of Magnus and de Kleijn to human pathological cases here receives full discussion and illustration. Altogether a very useful contribution to “reflexology.”

Rheumatic Diseases.

Being the Proceedings of a Conference on Rheumatic Diseases held at Bath on May 10th and 11th, 1928. *Published by the Hot Mineral Baths Committee of the Bath City Council.* Pp. 292. 5s.

THE proceedings at the important Conference on Rheumatic Diseases which was held at Bath under the presidency of Sir George Newman in May last were reported in these columns, several of the papers being published in full at the time or later. These proceedings have now been issued verbatim by the Hot Mineral Baths Committee of the Corporation of the City of Bath, and the volume forms a useful indication of the present state of our knowledge in regard to the incidence, causation, and treatment of many very common and obstinate pathological conditions. For convenience of reference the papers have been grouped under the headings of Social and General Aspects, Causation, and Treatment; a good index makes the record readily available for inquiry. On many important matters the papers show a diversity of opinion and consequently the need for further investigation, but along general lines the therapeutics represent the most recent work, and the book will be welcomed by medical practitioners as a help towards the elucidation of puzzling problems and a guide for routine treatment.

Botany.

A Practical Botany for Matriculation. By MARGARET A. SHUTTLEWORTH, Biology Mistress, Sydenham County Secondary School. London: University of London Press, Ltd. 1928. Pp. 272. *5s.*

Miss Shuttleworth is already known as author of “The Wonders of the Human Body.” Her aim has now been to supply a book, the subject matter of which will cover the matriculation syllabus in botany. It represents the minimum to be attempted in a two-years course and does not presuppose any previous course in nature study. In the experimental sections only the simplest apparatus has been described, pupils being encouraged to devise other methods of doing their practical work. The book is more than an examination manual, for it is interestingly written and excellently produced and illustrated. The author regards the relation between flowers and insects as the best basis for the study of the variety of flower forms, and the attention paid to pollination makes the manual of special interest.

HISTOLOGICAL TECHNIQUE.

A Guide for Use in a Laboratory Course in Histology. By B. F. KINGSBURY, Ph.D., M.D., and O. A. JOHANNSEN, Ph.D., Cornell University, Ithaca, N.Y. London: Chapman and Hall, Ltd.; New York: John Wiley and Sons, Inc. 1927. Pp. 142. 11*s*.

THIS book is designed as an introduction to laboratory methods and should prove of benefit to those who aspire to become laboratory assistants as well as to medical students. The authors, from their own experience, have made a conservative, and in many cases happy selection of the most applicable lines of procedure in histological investigations. Thus the inquirer is not faced with the problem of choosing from a bewildering number of alternative methods. Several notes on the difficulties commonly encountered in laboratory technique are given and a tabulated list of the causes of defects and difficulties in sectioning paraffin blocks should be of help to the beginner. Certain parts of the book may be criticised on the grounds that they are too sketchy to be of value, notably the section on the microscope and its accessories, which might well have been omitted. Figures depicting microscopes and accessories unaccompanied by descriptions are of little use.

HÆMATOLOGY OF CHILDHOOD.

Die Klinische Hämatologie des Kindesalters. By HEINRICH BAAR, Assistant at St. Anne's Hospital, Vienna; and EUGEN STRANSKY, General Assistant at the Imperial Institute for the Care of Mothers and Infants, Vienna. Leipzig and Vienna: Franz Deuticke. 1928. Pp. 481. 48*s*.

THIS work forms a useful pendant to the exhaustive monograph of A. Schittenhelm on blood diseases in general; pædiatricians and hæmatologists alike will find a great deal to interest them in these lucid pages. The hæmatology of childhood has quite legitimately been treated as a subject apart. It is regrettable that no two successive authors in this field can quite harmonise their nomenclature, but a liberal choice of synonyms is offered. An attractive feature is the full recognition of English-speaking authors in the excellent bibliography. The main sections of this work are on normal blood in childhood, the anæmias of childhood, "acute system-reactions," such as leukæmia, and the hæmorrhagic diatheses. A particularly valuable account of blood changes in infections of various types is included, and also clear discussions on the influence of faulty diet on the blood picture, and on the "anæmia pseudoleucæmica infantum" and Banti's disease.

The book is likely to become a standard work of reference. In subsequent editions the illustrations might well be more ample, and the inferior photomicrographs omitted.

SURGICAL ANATOMY.

By GRANT MASSIE, M.B., M.S., F.R.C.S., Senior Demonstrator of Anatomy and Surgical Tutor, Guy's Hospital Medical School. London: J. and A. Churchill. 1928. Pp. 413. 15*s*.

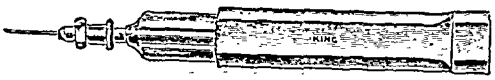
IT is difficult to break new ground in a subject like surgical anatomy; difficult, too, to keep the size of a volume within bounds and yet to include all that the ordinary student should know. There is nothing very original about this book, but the author has achieved the more important parts of his task with some success. He has given us a book easy to read and not too long, and yet sufficiently full for the needs of the student up for his finals. He states in his preface that his object has been to present anatomical facts attractively, and this also he has done. The illustrations are simple, clear, and informative, and the book should be popular.

New Inventions.

INJECTION TREATMENT OF VARICOSE VEINS.

(1) A NEW SYRINGE FOR INJECTING SCLEROSING SOLUTIONS INTO VARICOSE VEINS.

As is well known, it is essential for a successful injection that the sclerosing solution should come in intimate contact with the inner coat of the varicose vein in order to injure the endothelium; this injury will be greater the more concentrated the injected solution. On the other hand, it is necessary to make sure that the lumen of the vein has been entered, and this is done by aspirating some blood; the blood thus drawn into the syringe is apt to reduce the concentration of the sclerosing solution. It is therefore essential to aspirate as little blood as possible, and a syringe which allows the smallest quantity of blood to be clearly detected is indicated. I have used such a syringe for the last six months with most gratifying results. The essential part of it is the long fine nozzle made of polished glass, magnifying the extremely fine lumen. An infinitely small amount of blood is readily observed, which could not cause any dilution of the sclerosing liquid; a fine short bevelled needle is used with the syringe.

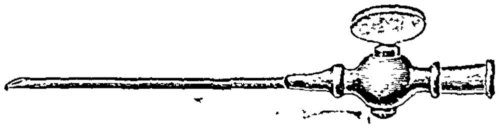


Messrs. Charles King, 34, Devonshire-street, London, are the manufacturers.

Harley-street, W. A. A. MILLER.

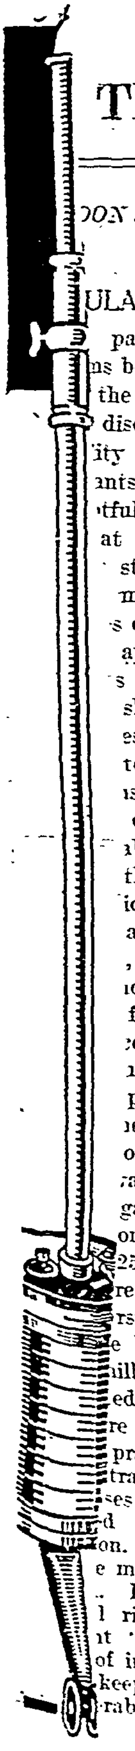
(2) NEEDLE FOR THE INJECTION TREATMENT OF VARICOSE VEINS.

THE needle here illustrated allows the syringe to be detached without causing undesirable effects while the patient is changing from the standing to the supine position, the prevention of loss of blood and of air entering the vein. Through the body of the needle head there is a hole into which a loosely fitting stop-cock is fitted. The stop-cock is "open" when the cross-bar is in line with the long axis of the needle. The stop-cock is fitted with a No. 17 needle, one inch in length. In use, the needle, attached to the syringe, is inserted into the vein while the patient is standing. The syringe is then detached allowing blood to flow from the needle and then the tap is closed by a quarter turn of the cross-bar. The patient then lies down and the needle will remain undisturbed in the vein. The limb is somewhat elevated and the nozzle of the syringe lightly approximated to the head of the needle, the cavity of which is gently filled with the fluid to be injected, so as to expel the air from it; the syringe is then firmly attached, the tap opened, and the injection made.



The needle is manufactured by Messrs. Allen and Hanburys, Ltd., Wigmore-street, London.

H. ARTHUR MURRAY, M.B., Ch.B. Edin.,
M.O., Colonial Medical Service (Basutoland).



THE LANCET.

ON: SATURDAY, SEPTEMBER 1, 1928.

ULATION AGAINST ENTERIC FEVERS.

paratyphoid outbreaks have put many ns before practitioners in the affected districts. the more important of these are the recognition disease in those who are unwell, and the ity of preventing infection of the healthy ants. Certain diagnosis of the enteric fevers tful cases owes more to the laboratory than at of any other group of diseases, since at stages of the disease either agglutination microscopic examination of blood, urine, s can be relied on to reveal infection. It is appropriate that the first of our new series s on the Clinical Interpretation of Aids to should deal with the topical subject of agglu-ests in enteric fevers, and we draw special to the detailed advice offered by Dr. A. B. s to the best methods of collection and of specimens of blood. The diagnosis ablished, the house-mates of the patient than likely to demand advice as to means ion since they have realised how extremely able an attack of paratyphoid fever may , therefore, worth while to consider the d nature of the vaccine which may be for protective purposes.

cess of anti-typhoid-paratyphoid (T.A.B.) ring the late war is familiar to everyone, preparation has been accepted as a con-eans of safeguarding persons likely to be o the enteric group of diseases. The army as made up to a strength of 1000 million ganisms per cubic centimetre—comprising on typhoid bacilli. 250 million paratyphoid 250 million paratyphoid B. Half a cubic re (or 500 million organisms in all) was given rst dose, after which 10 days were allowed e before giving the second dose of 1 c.cm. illion mixed organisms). These quantities edly produced a high degree of immunity, re is certainly no reason for exceeding them practice, as is sometimes recommended. On trary, it should be remembered that these ses of 500 and 1000 mixed organisms were d for healthy men in excellent physical on. They are probably too great for the e male civilian and undoubtedly excessive for .

In prophylaxis by vaccines the ideal is a l rise of immunity unaccompanied by un-t "reactions." Military life makes a long of injections inconvenient, because this would keeping the troops under observation for a rable time; the number of doses is, therefore, reduced to two. Similarly, there may be reasons in civil life why the resistance should be raised immediately rather than at leisure—e.g., the presence of an epidemic—but it is wrong to suppose that two large doses producing two strong reactions at a week or ten days' interval is the only means of securing immunity. When there is plenty of time before exposure to infection there is no reason why a feverish reaction should not be avoided altogether by starting with quite small doses—even as little as 10 millions at first—and gradually building up the patient's powers of resistance. The immunity thus induced would probably be stronger than that obtained from two large injections. No vaccines are calculated to save a person who incurs successive infection by large quantities of virulent organisms; to ask this is to ask too much. If enormous doses of enteric bacilli are taken, as sometimes happens, for example, among mental patients of unclean habits, even recent immunisation might not actually stave off the disease, though it would probably prevent its being fatal. The usual aim of prophylaxis is to arm us against small accidental contaminations of food, and it need be effective no longer than there is danger of these occurrences. Immunity is a purely relative term, but, judging by agglutination tests, that conferred by paratyphoid A vaccine in ordinary dosage tends to disappear after about a year; typhoid immunity may possibly last three years, whilst paratyphoid B occupies an intermediate position. In civil life relatively small amounts of vaccine—e.g., three doses of 100 millions, 200 millions, and 500 millions respectively might be tried with advantage. Probably these are somewhere near the minimal quantities for securing rapid immunity to moderate infection in a male adult. If immediate protection by a single dose is wanted 500 million T.A.B. organisms should prove sufficient for practical purposes, and half this amount can give a considerable reaction. Inoculation is believed to be followed by a "negative phase" in which the subject's resistance is somewhat lowered, and this might be regarded as endangering individuals who are given typhoid vaccine whilst exposed to infection. It is hard to say when this phase begins and ends, but its significance has probably been much exaggerated. It is said to come on shortly after the organisms have been administered and to cease as the febrile symptoms abate. The negative phase affords no good reason for abstaining from inoculation. Nor are there many other reasons provided that the dosage chosen is not too large. In estimating the quantities to be given to children a calculation may be made on the basis of body-weight, though this does not hold good for very small children; when in doubt it is better to give less rather than more than the calculated amount. Apart from this it is enough to say that alcoholics react rather strongly; that renal disease requires especial caution; and that care and judgment are naturally needed where patients are enfeebled by disease or any other cause.

At the beginning of the late war it was found that soldiers inoculated with pure typhoid vaccine readily contracted the paratyphoid fevers. This shows that the killed typhoid organism confers a specific immunity, being powerless to protect the patient against others of the enteric tribe; so the typhoid element in T.A.B. does not appreciably reinforce the action of the A and B elements. As paratyphoid A is almost unknown in this country, and typhoid is not a serious risk in most localities, it would be sufficient in face of a paratyphoid B outbreak to give a pure *paratyphosus* B vaccine. The total number of organisms given can thus be greatly reduced and the reaction—sometimes far from negligible—should also be diminished, though not perhaps in arithmetical proportion. To give the full anti-typhoid-paratyphoid vaccine for fear of a paratyphoid epidemic is like insuring against accidents by all means of transport when about to travel by aeroplane. Large doses of T.A.B., as now given with some freedom, are not likely to make inoculation popular, and it seems worth while to point out that they are seldom necessary.

◆

THE LEGAL LIABILITY OF HOSPITALS.

If a patient has some grave cause of complaint over the treatment he has received in hospital, it must surprise him to find how difficult it is to make the hospital liable in law for the actions of its expert staff. He may never have heard of the legal maxim *respondeat superior*, but he will know of frequent cases where an employer has been made to answer in damages for an employee's wrongful acts towards third parties. He will probably think of hospital and doctor as master and servant, for he will have an idea that the hospital exercises control over its expert staff by paying their salaries and by wielding the power of appointment and dismissal. But he will be wrong. These may be elements of the relationship between master and servant but—as Captain J. E. Stone makes clear in the careful analysis of the legal position which is concluded in our columns this week—these elements are not enough. The physician or surgeon on the staff of a hospital is nobody's servant. The hospital does not interfere with the prescriptions of the one or the operations of the other. The hospital's duty is to select a competent staff; it does not insure that the experts so selected will use that degree of care and skill which persons competent in that sphere may be expected to use. This limitation upon the doctrine of *respondeat superior* is by no means confined to the medical profession, but it happens to have been affirmed in three cases in which medical treatment was in question.

In the first of these (Hall *v.* Lees, 1904) a plaintiff complained that she had been injured by the negligence of a nurse provided by the defendants who were an association existing to supply duly qualified nurses. It was held that the association only undertook to supply a competent nurse for the patient, not to nurse the patient; the nurses had to follow the directions of the patient's doctor and the association was not responsible if a nurse failed to exercise due care and skill. Two years later, in Evans *v.* Liverpool Corporation, a jury found that the plaintiff's son had been discharged too soon from an infectious diseases hospital provided by the defendant corporation. He was sent home before he was completely recovered from scarlet fever, and consequently his brother and sisters were infected. Mr. Justice Walton held the defendants not liable. "They do not undertake the duties of medical men or to give medical advice, but they do undertake that the patients in their hospitals shall have competent medical advice and assistance." The doctor in charge was admittedly competent and so no blame attached to the corporation for employing him. Finally, in Hillyer *v.* St. Bartholomew's Hospital the Court of Appeal put the matter beyond doubt in 1909. A patient somehow received burns while under an anæsthetic on the operating table; he sued the hospital but his claim failed. Lord Justice Farwell said it was impossible to contend that the surgeon or the acting assistant surgeon, or the house surgeon, or the anæsthetist were servants of the hospital in the proper sense of the word. They were all professional men employed by the hospital to exercise their profession to the best of their abilities according to their own discretion; in exercising it they were in no way under the orders of the hospital or bound to obey its directions. A similar principle applied to the nurses. "The nurses and carriers assisting at an operation cease for the time being to be the servants of the defendants (the hospital), inasmuch as they take their orders during that period from the operating surgeon alone."

As Captain Stone is careful to point out, Lord Justice Kennedy, while concurring in the court's decision, added a qualification. "It may well be," he remarked, "that the hospital authority is legally responsible to the patients for the due performance by their servants within the hospital of their purely ministerial or administrative duties, such as, for example, attendances of nurses in the wards, summoning of medical aid in emergency, the supply of proper food, and the like." Hospitals, therefore, it appears, must distinguish between the matters of professional skill in which the hospital board will not interfere with physician, surgeon, or nurse, and the "purely ministerial or administrative duties" which the board is responsible for regulating. Presumably it would be for the jury to apply the distinction to the facts of a particular case. But a jury could hardly decide without giving due weight to the evidence of the medical profession on what would be largely a matter of professional practice. The same remark applies to those occasions where there is a question of the relative responsibility of nurse and medical practitioner as in a recent case where a patient was scalded by a hot-water bottle. If the profession can achieve unanimity in its evidence regarding the particular functions delegated by physicians or surgeons to nurses, the court and the jury are not likely to take a different view.

◆

DENGUE IN ATHENS.

An epidemic described as dengue fever has attacked the inhabitants of Athens and the Piræus during the last few days. The number of cases is reported to be between 160,000 and 200,000. All business is paralysed and many shops, offices, and factories have had to close down owing to the illness of their staffs. The leading bank, with a normal staff of 180, is now carrying on with only 20, while Government departments are quite disorganised. The epidemic is now spreading to the provinces, whither Athenians have fled to avoid contagion.

Dengue fever is best known as an endemic infection in the coastal regions of India, China, the East Indies, and throughout the Pacific islands. Many widespread epidemics have been recorded since Manson first described the virulent outbreak in Amoy in 1872, which completely paralysed the small European population of the town and attacked 95 per cent. of the Chinese population. The exact method of conveyance of the disease was at that time unsuspected; but Manson recorded with characteristic fidelity the sudden onset, the excruciating bone pains which have bestowed the synonym of "dandy" or "breakbone fever" on the affection. Other peculiar features—the double crisis of fever, the purpuric rash, and the post-febrile bradycardia—were also noticed in the Amoy cases. To show the sudden onset of symptoms it is recorded that victims attacked while shaving would drop a razor to the ground from a helpless hand. Since that period dengue has occurred at intervals of years in epidemic waves, mainly in the early autumn months. In Europe it has appeared in Southern Spain, Gibraltar, Malta, Turkey, and, notably in 1881, in the Ægean Islands. In Asia Minor serious epidemics have occurred in Smyrna, Cyprus, Beirut, Jaffa, and Jerusalem. While normally a coastal disease, in its pandemic form dengue spreads a considerable distance beyond its usual confines and may even, in Syria, ascend mountains to a height of 5000 feet. That the disease is spread solely by the agency of mosquitoes has been recognised since the original observations of H. GRAHAM in Beirut in 1903. At that time he suspected that the carrier was the common brown mosquito *Culex fatigans*, though since then the carefully conducted experiments of CLELAND, BRADLEY, and MCDONALD, in Australia, have incriminated the common "tiger mosquito," *Aëdes argenteus* (formerly known as *Stegomyia fasciata*) as the sole vector. The exact nature of the dengue virus is unknown, but the researches of CLELAND and his fellow workers have shown conclusively that the virus is attached or agglutinated to the red blood corpuscles and can pass through the pores of a Pasteur-Chamberland filter. J. F. SILER has demonstrated that the blood in dengue is infective to the mosquito for 18 hours before the onset to the end of the third day of the illness. The mosquito, after imbibing dengue blood, does not become infective for 11 to 14 days, but thereafter remains so for the rest of its life.

For the development of an epidemic the vector must be present in large numbers, and this implies defective sanitation and abundant opportunities, in the supply of stored water in close proximity to the houses, for the mosquito to breed; in short, the conditions which favour the spread of dengue are similar to those conducive to yellow fever. At the present moment conditions in Athens must be unusually favourable to the propagation of *Aëdes argenteus*. As regards potential disability during an attack dengue is serious enough, but as a rule it leaves no permanent serious sequelæ in its wake, and the mortality-rate is very low. Perhaps it is for this reason that no specific pathological lesions, gross or microscopic, have been discovered. Unfortunately the present epidemic at Athens appears to be exceptional in having a high mortality-rate, the attacks being often fatal. Probably, however, the infection is killing only those who are the subjects of grave heart or kidney disorders, where it acts as the immediate cause of death. If dengue is the sole cause it must be of an unprecedented virulence. Another possibility is that the epidemic may be due to some other infection. If it is dengue there is no prospect of abatement until the advent of the cool weather, which cannot be expected for another two months.

POST-VACCINAL ENCEPHALITIS.—The Small-pox and Vaccination Committee of the Health Committee of the League of Nations met at Geneva on August 22nd under the presidency of Dr. R. Jorge, of Portugal, to consider this among other questions. A report has been drawn up in which the rarity of these cases is emphasised, in comparison with the total number of vaccinations in any country. The committee points out that children between 3 and 13 years of age are particularly susceptible, whereas infants and adults are hardly ever affected; this age incidence suggests the inadvisability of postponing primary vaccination, which is the most powerful weapon available against small-pox, until after infancy. The appearance of encephalitis is not held to be associated with any particular strains of lymph or with accidents ir [illegible] mittee conclude, on the evidence [illegible] accinal encephalitis is distinct from [illegible]

Annotations.

"Ne quid nimis."

THE COPENHAGEN CONGRESS.

THE First International Congress of Oto-Rhino-Laryngology, which was held at Copenhagen at the opening of last month under the presidency of Prof. E. Schmiegelow, was fully attended. The meetings were held in the Christiansborg, the Danish Houses of Parliament, and the opening ceremony was honoured by the presence of the King of Denmark. The amount of material was so great that the Danes generously forwent the reading of their papers. There were four main subjects for discussion: (1) Septicæmia as a result of pharyngeal infection, opened by Prof. W. Uffenorde (Marburg) and G. Ferreri (Rome), the opening with excellent lantern slides showing invasion of vessels in the neck by organisms. (2) The conservative radical operation, by Prof. H. B. Neumann (Vienna), well illustrated by slides of microscopical sections to show bony changes going on in apparently healed radical operations. Mr. H. Barnett (Bath) followed, condemning the radical operation. Considerable discussion took place, but nothing really new emerged. (3) The influence of anatomical structure of the middle ear on the course of suppuration therein by Profs. F. J. Moure and G. Portmann (Bordeaux) and by Prof. K. Wittmaack (Hamburg). This is a subject on which otologists in this country have long held definite opinions, led by Mr. A. H. Cheatle. (4) Surgical diathermy for cancer of the pharynx, larynx, and œsophagus, opened by Dr. Dan McKenzie, followed by Mr. Norman Patterson (London); a strong case was made out for removal of growths by the diathermy knife instead of the cold knife. In the subsequent discussion papers were given by French and Spanish authors. The shorter papers read at the Congress dealt with practically every branch of the specialty. To mention one or two that were outstanding: Dr. A. Pohlman (St. Louis, U.S.A.) spoke on "minimal audition"; experiments on this subject had been made with an audiometer and many interesting observations emerged, notably that lengthened bone conduction is apparently not real. This property was, however, vigorously sponsored by clinical observers of the German school. It seems that the audiometer has not been given enough attention in this country. Dr. Wells Eagleton's (Newark, U.S.A.) study of sixth nerve involvement in connexion with the early diagnosis of meningitis called forth some interesting discussion. Dr. E. Huizinga and Dr. C. E. Benjamins (Groningen) brought forward some interesting work on ablation of parts of the internal ear in pigeons; they found that destruction of the lower part, including the saccule, produces no demonstrable effect on the movements of the birds; while ablation of the superior part containing the utricle and three ampullæ has the same result as complete destruction of the labyrinth. Mr. V. E. Negus (London) put forward in his paper the ingenious suggestion that the function of the cricopharyngeus sphincter was to prevent air passing into the œsophagus during inspiration. In addition to the scientific work there was much entertainment offered by the President, the Committee, and the civic authorities, and Dr. N. Rh. Blegvad deserves a special word of mention for his all-embracing labour as general secretary.

PINEAPPLE JUICE.

CHILDREN have always preferred the raw pineapple, when obtainable and however crude, to the uniform and refined product in sealed tins; and their choice is wise, for, as the *Journal* of the American Association has reminded us again, fresh pineapple juice contains an active proteolytic enzyme known as bromelin, which is destroyed when the juice is heated or the fruit is canned. No doubt both clauses are true when canning implies heat; but our own chemist pointed out a quarter of a century ago that, while the peculiar digestive agent of pineapple is destroyed by cooking, there is no reason why tinned fruit should not retain its digestive power, provided that the pineapple is not preserved by heat. Bromelin, as we then showed, would digest as much as 1000 times its weight of protein, whether of meat or eggs, within a few hours, and there is an abundant supply of the enzyme in the pineapple for the average sized pine will yield nearly two pints of juice. Unlike pepsin, the digestive principle of the pine appears to operate equally well in an acid, neutral or alkaline medium. There would therefore be more justification for eating pineapple and beefsteak together than there is in eating red currant jelly with roast mutton, although we may reasonably assume in the latter case that it was because an enzyme accompanied the pleasant taste that this culinary constellation arose and retained its sway. Bromelin must not, of course, be confused with bromalin, a combination of hexamine and ethyl bromide which has had some vogue in neurasthenia and epilepsy. It is curious that Remington's Practice of Pharmacy, which is such a complete collection of drug lore in America, contains no mention of this pineapple enzyme, although it is mentioned in Tibbles's Foods and is well recognised so far afield as in Mayerhofer and Pirquet's Lexikon, and in Nadkarni's Indian Materia Medica.

THE LATE INFECTIVITY OF SCARLET FEVER.

It used to be thought that after about six weeks, and the completion of desquamation, the scarlet fever patient was free from infection. Later it came to be noted that after the discharge of scarlet fever patients from hospital a fresh infection occasionally arose in the home. For example, in 1894 Dr. A. K. Chalmers reported that among 2593 patients discharged from the infectious hospitals in Glasgow fresh cases appeared in 70 of the houses to which they were sent. An investigation set up by the Metropolitan Asylums Board culminated in a lengthy and valuable report[1] by the late Dr. A. G. R. Cameron in 1904. In this report he emphasised—what was already known to many—that it was the convalescent with unhealthy mucous membranes who was more likely to be infectious and that there was no evidence of infection arising from late desquamation. Of late years there has arisen a tendency to curtail the detention period of this disease. In his report[2] to the Ministry of Health Dr. Allan C. Parsons gives information concerning the minimum period of detention of uncomplicated cases in 46 hospitals. The authorities of 15 of these required 42 days detention as the minimum, one 40 days, three 35 to 42 days, six 35 days, one 30 days, eighteen 28 days, and two 21 days. Thus it will be seen that 25 observers do not differ much from the old dictum. There is little doubt that a number of sufferers from scarlet fever are free from infection at the end of four weeks and probably earlier, and if diphtheria can be taken as an analogy it is certainly so, but the difficulty is in picking out those who are free from infection from those who are not. It is admittedly unsafe to consider free from infection those who suffer from a pathological condition of the throat or of the nose, or those who may have an unhealthy condition of an ear. But it is not always easy to decide that the tonsils are quite normal, and it may be quite impossible to discover a tiny nidus of infection in the small nasal passages of a young child. It may be said that this is also so at a later stage of the disease, but it is to be remembered that the natural tendency of the human being is to rid himself of infection and therefore the risk in early discharge is greater. In detecting infection in similar cases of diphtheria careful bacteriological examination is of some help, but this can hardly be said of scarlet fever, for it is difficult to differentiate the streptococcus of this disease from other hæmolytic streptococci. On the whole, therefore, and admitting our want of precise knowledge, it may be considered wise to regard scarlet fever patients who show no pathological condition of the throat, nose, or ear as possibly infectious for a period of about five or six weeks after the onset of the disease. There is ample evidence that the late desquamation is not in itself infectious, and there is no definite evidence that the earlier desquamation is capable of causing infection to others. On the other hand, patients suffering from pathological conditions of the nose or throat should not be considered free from infection until recovery from them has taken place. A discharge from the ear does not appear to be so fruitful of infection, and consequently some observers consider it comparatively safe to discharge such cases at the end of three months. It is easy, even for the experienced, to fail to observe some small unhealthy area of the mucous membrane, and it should always be borne in mind before declaring a patient to be free from infection that a most careful examination should be made.

ALUM IN BAKING POWDERS.

Food prepared by modern methods frequently contains small quantities of constituents, the presence of which is not suspected either by the consumer or his physician, and which by their long-continued action may set up symptoms which are distressing to the one and puzzling to the other. Five workers at the Institute of Physiology of the University of Strasbourg[1] have investigated the effects of "mineral leavens" or baking powders containing alum; a matter which is not new, but which, having regard to the very different views held in Europe and America, fully justified reinvestigation more especially as the Strasbourg workers, as they point out, have considered the physiology rather than the gross toxicology of the question. They say "we would like to show by a precise example to what social dangers we are exposed through the daily use of products which have no justification from the physiological point of view, but only mean a slight economy of time to cooks and housekeepers." This way of looking at things may well be commended to those who would suffer the addition of boric acid to food.

The American tolerance of alum in baking powders, which the health authorities of most European countries virtually forbid—even in blockaded Germany when potassium bitartrate could not be procured, "hygienists" we are told, "severely opposed themselves to the production or sale of mineral leavens containing alum, even as an *ersatz*"—is due to the belief that if the powder is a scientifically calculated mixture of acid calcium phosphate, alum, and bicarbonate of soda, all that remains in the bread when the reaction is finished will be sodium sulphate, acid sodium phosphate, calcium carbonate, and aluminium phosphate. The insolubility of the last substance is apparently assumed. As a matter of fact, although the Strasbourg workers do not refer to it, W. D. Bigelow and C. C. Hamilton in 1894[2] concluded that the influence of alum in flour on digestion was overestimated, but that, notwithstanding statements as to its insolubility, aluminium phosphate had a retarding effect on gastric and pancreatic digestion in vitro, while two years earlier O. Hehner had shown by experiments on himself and two assistants that baking powder containing alum when taken alone caused diarrhœa and painful indigestion. Comparative experiments on mice have shown Schaeffer that bread containing aluminium phosphate gives rise to a paracellular necrosis of the superficial epithelium of the stomach and of the tops of certain intestinal villi, these lesions greatly resembling erosions found in human pathology. When dogs are fed with similar aluminous bread lesions are not formed in either stomach or small intestine, but in the large intestine, and especially in the descending colon and the sigmoid flexure. Further, there seems to be a specific action of the aluminium ion on the ovary, as the productivity of female mice is much diminished if they are fed on the aluminious diet, and the offspring succumb more easily to infantile disease. Anatomo-pathological examination confirms these experimental results in a striking manner. While in the case of male mice having absorbed aluminium the testicles remain normal and the spermatogenesis active, the female mice show characteristic lesions of the ovaries.

[2] Jour. Amer. Chem. Soc., xvi., 587–597.

The Strasbourg chemists' concluding paragraph is well worth reproducing: "We hope," they write, "that this summary of our researches will be sufficient to make clear the nature of the danger spoken of at the beginning of this article. We see that certain bodies, not poisons in themselves in the usual sense of the word, can provoke physiological disorders and organic lesions, the ætiology of which remains generally unnoticed, when they are absorbed daily for months and years. Such products are most certainly responsible for many illnesses, the frequence of which augments with the alimentary conditions imposed on us by modern civilisation in a manner inexplicable beforehand. Our object will have been attained if we succeed in attracting the attention of physicians and hygienists to certain problems, the study of which is perhaps not very attractive, but the solution of which is of considerable practical interest."

THE MEDICAL RELATIONS OF LAFONTAINE.

THE author of the celebrated "Fables" was by no means an admirer of the medical practice of his time, yet he associated on friendly terms with quite a number of physicians, some of whom were distinguished in their day. On the mother's side he was descended from two royal physicians, and he had two maternal uncles who practised medicine. Yet, as Dr. George Morin writes,[1] he does not seem to have inherited any therapeutic instincts from his medical forbears. His mother was Françoise Pidoux, whose family was well-to-do and important in Poitou for many years. The great-grandfather of the poet was François Pidoux, who received his diploma of Doctor at Montpellier, and settled in Poitiers instead of his native town of Châtellerault, became the doyen of the medical faculty of Poitiers, and waged war against charlatans of all sorts, of which Poitou was always a happy hunting-ground. He also insisted on the application of the edict of Blois which prohibited the sale of medicines by druggists, except on medical prescription. This was in 1541—so long has been the struggle against counter prescribing! François Pidoux was called in to treat important personages and at length was appointed first physician to King Henry II. He died in 1600, leaving the family of Pidoux among the most influential in all Aquitaine. His second son, John, following in his footsteps, studied under his father in Poitiers and became personal physician to the Duke of Anjou, afterwards Henry III. of France, whom he accompanied on an expedition to Poland, on which occasion he proved useful to the father of Cardinal Richelieu and secured his favour. On the accession of Henry IV. he became also his physician. Jean Pidoux was the author of the first book in French on hydrotherapy and balneology. He published, in 1587, a treatise on "La vertu et usage des fontaines de Pougues en Nivernais et discours qui peut servir aux fontaines de Spa et autres de pareil goût." Not content with his doctorate of Poitiers he obtained 20 years later the similar degree at Paris. His inaugural thesis was entitled De Febrium Curatione. He lived in influential and literary society in Paris and was employed in various important political and social affairs connected with the Court. His ambition to shine as an author of verse was not gratified, for his efforts, says Dr. Morin, are not worthy of the grandfather of the author of the fables. If Lafontaine inherited from the Pidoux no aptitude for the practice of physic, he seems at least to have received through his mother their love of good cheer and of good company and their capacity for enjoyment. He describes in a letter to his wife a visit to one of the Pidoux of Châtelleráult, a kindred spirit who at the age of 80 was full of the joy of life. Dr. Morin concludes by deciding that Lafontaine was a regular Pidoux, a Pidoux full of life and spirit, imaginative, light-hearted, and frivolous.

A NEW ANTHELMINTIC.

THE search for a vermicide harmless to man continues. Dr. J. Chevalier[1] brings forward the claims of two pyrethrines obtained from *Chrysanthemum cinerariaefolium*, the insecticidal pyrethrum, and isolated by fractional distillation in vacuo. They are non-crystalline, insoluble in water, but easily dissolved in organic solvents, and can readily be rendered almost inert by saponification. It has been found impossible to kill warm-blooded animals by oral ingestion or by subcutaneous injection of these substances, though intravenous injection at the rate of 2 mg. per kg. of body-weight produces clonic convulsions, and 6 mg. is fatal. On the other hand, cold-blooded animals such as fish, leeches, earthworms, and frogs die in dilutions of from 1 in 1,000,000 to 1 in 3,000,000. Classing intestinal worms as akin to cold-blooded animals, Chevalier found experimentally that *Ascaris lumbricoides* of the pig and tænias of the dog became detached and convulsive, and presently died when placed in a "dilute" solution of the drug. Experiments in the treatment of animals are reported as successful, and excellent results are said to have followed its use in human beings infected by various worms and by giardia; the drug is also being tested on the hookworm in Egypt. Detailed reports of the dosage used and of the grounds on which these conclusions have been reached will be awaited with interest, seeing that the preliminary note is silent on these essential matters.

THE LATE SEQUELÆ OF EPIDEMIC ENCEPHALITIS.

THE serious prognosis of the later manifestations of epidemic encephalitis, to which we drew attention in a leading article on June 30th, is confirmed by the studies of Dr. Lloyd H. Ziegler, published in the *Journal of the American Medical Association* of July 21st. Working from the Mayo Clinic he has followed up 752 patients who had attended the clinic for epidemic encephalitis during the period 1918 to 1927. The mortality-rate for this group was low at 13·2 per cent., but on the other hand the complete recovery-rate was only 1·3 per cent.; of the total number of patients 15·7 per cent. were able to work regularly, and 25·7 per cent. were able to do light or part-time work. Unfortunately there is little doubt that the work figures for the same group of patients will diminish in time, owing to the fact that the condition usually progresses slowly, and many of the patients in the series only had their attack within the past four years. Half of them developed chronic sequelæ immediately after the acute attack; nearly 10 per cent. recovered entirely from their acute attack, only to develop chronic sequelæ 15 (average) months later, and in one case the latent period was actually seven years. Fully a quarter of the patients exhibited a residual stage practically indistinguishable from post-influenzal debility for 14 (average) months before sequelæ emerged, and no fewer than 15 per cent. of these patients are now Parkinsonians. The mental aspect does not appear to have received the same careful attention as the neurological in this investigation, only very obvious symptoms being recorded. There seems little doubt that when the encephalitic temperament is more generally recognised it will be appreciated that the chronic invalidism of the encephalitic is due as much to mental as to physical disabilities. The lowering of emotional values, the craving for sympathy and attention with exaggeration of physical deficiencies, and the childish outlook and lack of concentration of the average encephalitic are often more important factors in the economic question of ability for self-support than are the tremors, mild rigidity, ocular symptoms, and other neurological manifestations. The futility of our present methods of treatment of this disease is brought out by Dr. Ziegler's study. All the recognised methods were tried in this series of cases, and apart from the undoubted value of scopolamine as a palliative measure in Parkinsonism no therapy can be regarded as of any appreciable value. At the Mayo Clinic sodium cacodylate is regarded as a useful tonic, and supplemented by good general care and attention to obviously active foci of infection forms the usual method of treatment. Streptococcal vaccines, autogenous or prepared from patients with similar disorders, have been extensively used at this clinic, but the results obtained were no better than with other therapeutic measures. It appears that the most hopeful sign in the realm of this disabling disease is the steady diminution in the number of fresh cases which has occurred in each succeeding year since the severe epidemic of 1924.

LOCAL MALARIA CONTROL IN BENGAL.

Birnagar or Ula, credited with being the place whence spread the disastrous malaria epidemic of 1856, is one of those half derelict towns so frequent in the upper Gangetic delta, with a population of 2300 in place of the 40,000 of 70 years ago before malaria, speaking without metaphor, laid it waste. Five years ago some inhabitants, stung by the position, formed a local public health society, whose keen honorary secretary has just issued one of his periodical reports.[1] Funds are supplied by considerable private subscriptions, by a substantial grant from the Bengal Government, and by a large gift of quinine from its director of public health. The antimalarial measures used have been the oiling of anopheline breeding-places and a wide administration of quinine. The difficulties encountered in this private enterprise have been those familiar when such campaigns have been attempted in India by Government officers. There has been some stubborn opposition to oiling, two and a half out of eight and a half miles of water edge in the small area actually covered having had to be left unprotected. These untreated tanks have bred larvæ profusely, and it is significant that while the municipal authority has contributed generously to the funds of the society, the municipal tank is not one of those which the society has been permitted to oil. Some of the observations made have a wide applicability. The washing of muddy water into tanks was followed by destruction of all larvæ, breeding recommencing immediately as it settled and cleared. While, apart from this, mosquitoes bred continuously they did not torment human beings during dry weather, but as soon as rain fell entered houses and bit, while the malaria-rate rose after the usual interval. It is believed that in dry weather the insects remained inactive in the all-embracing jungle, and that this is also the explanation of the immediate but temporary influx of mosquitoes into houses when neighbouring jungle is felled. Such clearance has been begun with sale of wood and cultivation of land, but permission for further clearance is being withheld by owners. The future is not looked forward to with hope. It is felt that the determination of the mosquito species most implicated locally in transmitting malaria requires more expert knowledge than is available on the spot, but it is, after all, improbable that the ungrudging coöperation of the Bengal Malaria Research Laboratory, already afforded in identifying larvæ, will not be extended to the dissection of mosquitoes locally collected, a subject particularly appropriate. It is believed, too, that the local campaign should be merged in a wider one to be undertaken, the writer suggests, by the District Board. If certain indications in the report are read aright it is questionable whether anything will replace adequately an enthusiastic local patriotism.

CHEMISTS AND BENZOL.

We owe to research in America, originated in industry,[1] the disclosure that benzol possesses definite toxic properties. When its fumes are regularly inhaled in a strength of 100 parts per 1,000,000 of air the hæmopoietic organs are attacked, and anæmia follows with decrease of polymorphonuclear leucocytes. Industrially benzol is used as a valuable solvent, particularly of rubber. Fortunately less toxic solvents, such as toluol, xylol, or high flash naphtha, can be substituted, and it has never come into widespread use in English factories. Now a useful note[2] of warning is given to chemists working in laboratories, who are notoriously careless about exposing themselves to unnecessary risks. They are urged to confine the use of benzol to testing, and to abolish it as a cleansing agent for which it is far too often used in profusion. If for any reason continued exposure is unavoidable, the chemist should place himself under medical examination once every month or two. Chemists tend to disregard the fact that the human body is a delicate reagent always ready to react when exposed to unsatisfied compounds, of which benzol is one.

THE PHYSIOLOGY OF FASTING.

Many religions exhort believers to fast for the good of their souls, and most unqualified and some qualified schools of medical thought advocate occasional fasting for the good of the body. There is no doubt that some degree of reduction in the diet produces excellent results in a great many persons, but there is much uncertainty about the mechanism by which these results are produced. Prof. P. F. Richter holds the view that for lack of knowledge of the physiology of hunger a valuable therapeutic weapon is being neglected. In a recent address[3] to the Berlin Society for the Study of Internal Medicine he dealt exhaustively with hunger from the clinical point of view. Its syndrome is, he says, primarily a defence mechanism. Deprived of a part of its supplies, the organism promptly adapts itself for work on a restricted intake. It reduces its combustion rate and institutes economy in all its departments. By lessening the pangs of hunger it enables itself to endure the new conditions as long as possible. Fasting is, therefore, an effective means of lowering the metabolic rate at need. One of the most important fields for its use is diabetes, and research into the biochemistry of hunger would almost certainly elucidate many diabetic phenomena which are as yet unexplained. What evidence there is suggests that the effect of hunger on the nerves and musculature is rather to improve their condition than to do them any harm. It causes a slight fall in blood pressure, but a constant level is soon reached. A change from a meat to a vegetarian diet. according to O. Müller and M. Gänsslen, quoted by Richter, improved the state of the peripheral circulation; this is because meat proteins cause spasm of the arterioles and dilatation of the capillaries, a condition which is rectified when they are removed from the diet. For the victims of Graves's disease fasting is indicated. War-time researches showed that compulsory semi-starvation was beneficial to over-active thyroids, and it is probably this action on the thyroid which determines the drop in basal metabolism. Fasting seems to have no deleterious after-effects. Oxidation is apt to be somewhat unduly rapid when the fast is first broken, and the cells show such a large capacity for absorbing protein as seems to contradict all the known laws of nitrogen metabolism. According to Richter, fasting should benefit disorders of carbohydrate metabolism (although the pancreas may suffer in diabetic patients) and spastic disorders of the blood-vessels such as glomerulonephritis. In allergic conditions such as migraine, eclampsia, epilepsy, and asthma it acts by reducing the intake of foreign proteins. The leakage of protein into the blood stream through the intestinal mucosa is responsible for a multitude of ailments, and the alteration in the membranes is thought by some workers to be due to an interference by unwise dieting with the balance of flora in the bowel. A fast will often restore this balance. Fasting for high blood pressure is, in Prof. Richter's opinion, not indicated, since the pressure is not appreciably altered. Summing up, he likens its action to the stimulation of a foreign protein, but gives a warning that the estimation of the patient's tolerance is a difficult matter.

AMYLOID DISEASE.

THE cure of three out of 15 patients in whom the existence of amyloid disease was definitely proved is recorded by Prof. J. H. Waldenström in a beautifully illustrated monograph [1] on the formation and disappearance of this condition.

The author is unable to tell us anything new about the chemical structure of amyloid. He notes that it is a protein substance rich in tyrosin, and suggests that the toxic effects of prolonged suppuration prevent the formation of certain unknown proteolytic enzymes; in the absence of these the body becomes saturated with this protein substance which is deposited along the visceral blood-vessels. As a result of considerable clinical and pathological investigation he holds that if amyloid occurs at all it is invariably found in the liver, where it is evenly distributed. A further observation made is that a liver may be rich in perivascular amyloid deposit and yet show no enlargement, because of the tendency for the amyloid strands to crush the liver parenchyma. Prof. Waldenström believes that a mixed infection is necessary for the production of amyloid, but in spite of careful search he could not incriminate any particular combination of organisms. By protein saturation he produced amyloid in mice. He found that one mouse in four is amyloid-immune, and believes that there is a similar constant proportion of human subjects amyloid-immune. The production of amyloid seems to take about two years from the time of the establishment of the septic focus; and about the same period is required for its eradication. Prof. Waldenström's treatment for the causative surgical lesion is conservative; at his hospital the patients live in big sunny verandas, and are given abundance of butter and cream. The diagnostic methods adopted in suspected amyloid disease are drastic, but leave no doubt as to the nature of the condition. A trocar and cannula similar to a lumbar puncture needle, except that its calibre is 1¼ mm., is thrust into the liver and the trocar is withdrawn. The cannula is thrust forwards about 2 cm. and twisted slightly in its long axis. A rod of liver tissue is thus cut, withdrawn from the cannula by a powerful little suction syringe, and examined microscopically. In each of the three cured cases at least three liver punctures were made, and by sections of material so obtained Prof. Waldenström demonstrated successively over a period of about three years normal liver tissue, liver tissue stuffed with amyloid deposit and finally restored normal liver tissue. In THE LANCET of July 21st Dr. G. F. Walker recorded a case of amyloid disease of considerable duration which yielded to treatment, and we welcome this further evidence that a disease which was long held to be both common and fatal is now not only rare but also in certain conditions curable.

STRONTIUM FOR MIGRAINE.

GOOD results from a new method of treatment of migraine are reported by Dr. Max Serog, of Breslau, in a paper [1] which has just been published. Having found, in occasional instances, an improvement after intravenous injection of a preparation of strontium, he made a systematic trial of treatment with this metal and now reports the results in 20 cases. All the patients experienced great relief; many of them suffered previously from very frequent attacks, and, after a course of strontium, were free from headaches for many weeks; some are described as being "quite free" from attacks but, unfortunately, it is not stated how long such patients were kept under observation. The preparation used by Dr. Serog was "neostrontan," made by the firm of Tosse, Hamburg. Five cubic centimetres of a 10 per cent. solution of this strontium derivative were given intravenously, followed at intervals of two days by two injections of 5 c.cm. each of a 20 per cent. solution. The injections were well tolerated; the only unpleasant symptom was a feeling of heat or flushing of the face, and this could be greatly reduced if the injection was given very slowly and, when the flushing began, temporarily stopped until it had passed off. The best results were obtained with the younger patients. It is noteworthy that in several cases it was possible to cut short an attack of migraine by giving an injection of neostrontan—even when the attack was at its height. It seems that this treatment is capable of attaining successful results, especially in cases in which the attacks are very frequent, and it may be used either in combination with other methods or where other methods have failed. But the path of the physician is strewn with discarded remedies for migraine.

CURRENT VITAL STATISTICS.

ON another page we deal with some of the lessons which may be drawn from the text of the Registrar-General's Review of the year 1926. In the meantime the early appearance of Part I. (Medical Tables [2]) of the Review for 1927 has almost bridged the gap between the two years. The salient features of this review were embodied in a provisional statement,[3] which has, of course, not been substantially modified. The birth-rate of 16·6 for the year 1927 is the lowest rate recorded since the establishment of civil registration in this country, the lowest rates previously being those for 1918 (the last year of the war)—viz., 17·7 and for 1926—viz., 17·8 per 1000 population. The death-rate was 12·3 per 1000 population, slightly higher than for any year since 1922. The rise affects the two sexes almost equally, and was due to a severe epidemic of influenza in the March quarter. The death-rate in the June quarter was the lowest on record for the second quarter of the year, while the rates in the third and fourth quarters were below the average rate in the corresponding quarters of the last five years. The deaths of infants under 1 year of age were equal to 70 per 1000 births, being the same as for the previous year; thus the two years 1926 and 1927 have the lowest infant mortality-rate on record except only that for 1923—viz., 69. The mortality from the infectious diseases differed little from that for the previous year, except that the deaths from influenza numbered 22,263 and were equal to a rate sequelæ emerged, and no fewer than 15 per cent. of these patients are now Parkinsonians. The mental aspect does not appear to have received the same careful attention as the neurological in this investigation, only very obvious symptoms being recorded. There seems little doubt that when the encephalitic temperament is more generally recognised it will be appreciated that the chronic invalidism of the encephalitic is due as much to mental as to physical disabilities. The lowering of emotional values, the craving for sympathy and attention with exaggeration of physical deficiencies, and the childish outlook and lack of concentration of the average encephalitic are often more important factors in the economic question of ability for self-support than are the tremors, mild rigidity, ocular symptoms, and other neurological manifestations. The futility of our present methods of treatment of this disease is brought out by Dr. Ziegler's study. All the recognised methods were tried in this series of cases, and apart from the undoubted value of scopolamine as a palliative measure in Parkinsonism no therapy can be regarded as of any appreciable value. At the Mayo Clinic sodium cacodylate is regarded as a useful tonic, and supplemented by good general care and attention to obviously active foci of infection forms the usual method of treatment. Streptococcal vaccines, autogenous or prepared from patients with similar disorders, have been extensively used at this clinic, but the results obtained were no better than with other therapeutic measures. It appears that the most hopeful sign in the realm of this disabling disease is the steady diminution in the number of fresh cases which has occurred in each succeeding year since the severe epidemic of 1924.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

I.

THE WIDAL OR AGGLUTINATION REACTION IN THE DIAGNOSIS OF INFECTIONS DUE TO ENTERIC GROUP OF MICRO-ORGANISMS.

By A. B. Rosher, M.R.C.S., D.P.H.,
DIRECTOR OF THE CHARING CROSS HOSPITAL INSTITUTE OF PATHOLOGY.

In order to estimate the value and limitations of the agglutination reaction in the diagnosis of these infections it is necessary to have some knowledge of the modern technique employed for the test and to appreciate the behaviour of agglutinins under certain conditions.

Macroscopic Method.

The macroscopic technique is nowadays almost invariably used in preference to the microscopic method. By this means the end-point of agglutination can be obtained more accurately, and there is no chance of the laboratory worker being infected, since dead bacilli are used instead of living ones. The test is very sensitive when this method is employed, and it is by no means uncommon to demonstrate agglutinins in a serum after it has been diluted 1/40,000 times. The highest dilution of patient's serum still having the power of agglutinating the bacilli is commonly called the "agglutinin titre." The criterion of diagnosis by the old-fashioned microscopic method was an agglutinin titre in the neighbourhood of 1/100, whereas agglutination to this titre could not by itself be regarded as diagnostic when the macroscopic technique is employed.

It is customary to put the patient's serum up against *B. typhosus*, *B. paratyphosus* A, B, and C, *B. enteritidis* Gaertner, and *B. aertrycke*. The vast majority of infections in this country are due to *B. typhosus* and *B. paratyphosus* B.

B. enteritidis Gaertner and *B. aertrycke* are the organisms usually associated with food poisoning when the symptoms of acute gastro-enteritis predominate, but on rare occasions are stated to give rise to febrile conditions resembling enteric in some respects.[1] [2] [3]

Collection of Blood.

More blood is required when the macroscopic test is employed, and this represents the only disadvantage of the method. Not less than 2 or 3 c.cm. of blood are desirable, and whatever method of collection is employed it is advisable that the tube or syringe into which it is collected should be perfectly dry and free from any chemical substance. otherwise the blood is likely to become hæmolysed and useless for the test.

If a syringe be used and sterilised by boiling or with alcohol and ether, it is essential to wash it out with sterile saline before withdrawing the blood. The blood is usually obtained either (1) by pricking the finger or thumb with a No. 2 triangular-pointed needle, a small indiarubber tourniquet having been previously applied to the base of the digit; or (2) by inserting a hollow needle into the median basilic vein and collecting the blood direct into a syringe or into a test-tube.

However, by using a Behring venule ample quantity of blood can be obtained quite easily, and the procedure is practically painless. Special venules are supplied for the diagnosis of enteric whereby blood is drawn from the patient for the agglutination test and blood culture simultaneously. thereby saving the patient the inconvenience of being punctured twice. Since the blood goes straight into the culture medium the risk of contamination is eliminated.

Technique.

Briefly, the technique is as follows:—

The blood is allowed to clot and, after centrifuging, the serum is drawn off. Various dilutions—e.g., 1/10, 1/20, 1/40, &c., to 1/1280—of the serum in normal saline are made in a series of test-tubes. The dilutions are made with graduated pipettes or by using Dreyer's dropping pipettes.[4]

Seven Dreyer's agglutination tubes[4] are then placed in a rack and 0·5 c.cm. of an emulsion of dead typhoid bacilli is put in each tube. (These emulsions are made by growing the organisms in bouillon for 24 hours, after which a small quantity of formalin is added to kill them. The emulsion is then standardised to contain so many organisms per c.cm., and if kept cool and in the dark can be used for some months.) Half a cubic centimetre of the 1/10 dilution of the patient's serum is now transferred to the first agglutination tube, and the same amount of the 1/20 to the second tube, and so on with all the dilutions. We now have a series of seven tubes containing a range of dilutions from 1/20 to 1/1280 of the patient's serum mixed with typhoid emulsion; each tube contains 1 c.cm. of fluid. The patient's serum is then put up against emulsions of paratyphoid bacilli in exactly the same manner, seven tubes being devoted to each organism. The rack is then placed in a water-bath at 55° C. for two hours or so. Agglutination usually commences in 10 to 15 minutes, and can easily be observed with the naked eye against a dark background. The contents of tubes showing no agglutination appear slightly cloudy, owing to the millions of bacilli in suspension, but when agglutination has occurred they become aggregated into large clumps which fall to the bottom of the tubes, resembling a precipitate, and the supernatant fluid is quite clear. The tubes are inspected occasionally, and if any organism is agglutinated in all dilutions up to 1/1280 further dilutions are put up—e.g., 1/2560, 1/5120, 1/10,240, &c.—so that the end-point of agglutination can be established.

Occurrence of Agglutinins in the Serum of Apparently Normal People.

If we test blood from these members of the population who have not been inoculated with T.A.B. vaccine and give no history of having had enteric against this group of organisms, we find that about 4 per cent. of them agglutinate *B. typhosus*, *B. paratyphosus* B and C, and *B. enteritidis* Gaertner, whereas about 10 per cent. react with *B. aertrycke* (Mutton).[5] The reason for this agglutination is unexplained, but it is possible that the people have passed through unrecognised infections with these organisms or closely allied ones. (A point in favour of this theory is the absence of people who can agglutinate *B. paratyphosus* A, for infections with this organism are extremely rare in the British Isles.) Some of these people may be carriers, for it is well recognised that the serum of the majority of carriers contains agglutinins; not enough cases have been investigated for any definite conclusions to be formed. The majority of sera give low agglutination titres, such as 1/20, 1/40, 1/80, but occasionally one finds a serum that will agglutinate when diluted as much as 1/640 times. As far as one can ascertain, these titres remain constant and do not fluctuate over a period of weeks.

Behaviour of Agglutinins as a Result of Infection.

Agglutinins do not appear in the blood until the end of the first week of disease, and therefore it is useless to expect any immediate diagnostic information from the reaction before this. Nevertheless, it is very important to perform the test during the first few days, since a negative result is invaluable in assessing the significance of results obtained later in the disease, especially in cases which only give low agglutinin titres throughout. However, it is during the early days that the chances of isolating the causative organism from the blood, fæces, &c., are best, and therefore cultures should also be made.

The agglutinins increase rapidly in intensity, reaching a maximum towards the end of the third week and then start to fall gradually (see Chart 1). They fade away over a period of months, but may last for years. There is a considerable variation in the amount of agglutinin production in different cases. Thus sometimes the highest agglutinin titre reached may be more than 1/40,000, whereas in other cases the maximum titre may be on the 1/100 mark. The of 567 per million living. The mortality-rates recorded in earlier epidemics were as follows :—

1848 .. 459	1892 .. 533	1918 .. 3078	1922 .. 563
1891 .. 574	1900 .. 504	1919 .. 1181	

From these figures it will be seen that the mortality in 1927 was the highest recorded since the great epidemic of 1918–19, and was but 7 per million below that of 1891. The increased mortality from pulmonary tuberculosis and heart and respiratory diseases may also be in part due to the prevalence of influenza. The death-rate from cancer was 1376 per million population, or 14 per million higher than in 1926, being the highest crude death-rate yet recorded. The 4907 deaths from suicide were equal to a rate of 125 per million, which is the highest recorded rate from this cause ; the rates in the three preceding years were 96, 105, and 114. The Review indicates the increasing use of lysol and coal-gas as means of self-destruction.

Prof. Robert Muir, Sir John Parsons, and Sir Charles Trevelyan have been appointed members of the Medical Research Council, succeeding Prof. G. Dreyer, Sir Archibald Garrod, and Mr. William Graham.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

(Dental Branch.)

In the Educational Number of The Lancet last week, when placing before our readers the advantages offered by joining this Service, we were unable to give the following current rates with regard to Dental Officers, the information not arriving in time for press.

On the completion of two years' service in the rank of Surgeon Lieutenant Commander (D), dental officers on the Active List are eligible for a three months' post-graduate course at a dental hospital and school at the public expense, and will draw full pay while attending the course.

Pay.—The current rates of full pay for Dental Officers are as follows :—

	£ £
Surgeon Lieutenant (D)	377–462
Surgeon Lieutenant Commander (D) (promoted after six years' service)	556–687
Surgeon Commander (D) (promoted by selection to fill vacancies in Establishment)	730–933
Surgeon Captain (D) (promoted by selection to fill vacancy in Establishment).. ..	1073–1329

The Regulations regarding Pension and Withdrawal Gratuities are the same as for Medical Officers in the corresponding Ranks.

HONORARY APPOINTMENTS TO THE KING.

The King has approved of the appointment of Lieut.-Colonel R. McCarrison, C.I.E., and Lieut.-Colonel W. H. Leonard to be honorary physicians to His Majesty, with the brevet rank of Colonel, in succession to Colonel C. R. Bakhle and Major-General A. A. Gibbs, retired ; and the appointment of Lieut.-Colonel G. D. Franklin, C.I.E., O.B.E., to be honorary surgeon to His Majesty, with the brevet rank of Colonel, in succession to Colonel R. W. Knox, D.S.O., retired.

RESTRICTED LEAVE OWING TO SMALL-POX.

Owing to the presence of small-pox in the area, restrictions have been placed on the granting of leave at Brechin (Forfarshire) and Kingston-upon-Hull. There are now two districts scheduled in London (St. Marylebone and Wandsworth) and 53 outside.

ROYAL NAVAL MEDICAL SERVICE.

To be Surg. Lts. : J. G. Ollerenshaw, T. W. Froggatt A. N. Forsyth, C. H. Birt, A. J. Burden, D. R. F. Bertram and D. L. Pow.

Sub-Lts. to be Lts. : B. E. W. Logan, J. B. G. Temple, K. H. Fraser, and H. C. Browne.

The following appts. are notified : Surg. Comdrs. C. F. O. Sankey to *Barham*, and to *Warspite* (on transfer of flag) ; and G. H. Hayes to *Ramillies*. Surg. Lts. J. Johnston to *Resolution* ; L. P. Spero to *Dahlia* ; H. J. McCann to *Pembroke* for R.N. Barracks, Chatham, temp. supy. ; V. G. Horan to *Heliotrope* ; C. B. Fox to *Rodney* ; D. R. Campbell to *Iroquois* ; I. J. Corbett to *Victory* for R.N. Barracks, Portsmouth, temp. ; and S. J. Savage to *Pembroke* for R. N. Hospital, Chatham, temp.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lt.-Comdr. W. J. Payne and Surg. Lt. R. L. Stubbs to *Victory*, for R.N. Hospl., Haslar, for training.

ROYAL ARMY MEDICAL CORPS.

Maj. G. S. Parkinson retires on retd. pay and is granted the rank of Lt.-Col.

Maj. J. St. A. Maughan to be Lt.-Col., vice Lt.-Col. W. C. Croly to retd. pay.

Capt. J. Vallance, Reg. Army Res. of Off., relinquishes his appt. and resumes the rank of Maj.

Capts. R. H. C. Pryn and T. L. Henderson to be Majs.

Capt. B. C. W. Pasco, late R.A.M.C., to be temp. Capt., and temporarily relinquishes the rank of Capt.

Lts. (on prob.) W. R. C. Spicer, J. H. Anderson, T. F. M. Woods, S. M. Burrows, G. T. L. Archer, M. R. Burke, P. J. L. Capon, D. R. W. Burbury, K. McNeill, P. Dwyer, P. W. A. Agnew, and J. W. Kendall are confirmed in their rank.

The undermentioned Lts. from the secd. list are restd. to the estab. : L. R. S. MacFarlane and W. F. Lane.

To be Lts. on prob. : Lt. A. T. H. Marsden, from R.A.M.C. (T.A.) ; 2nd Lt. L. R. H. Keatinge, from T.A. Res. of Off., Gen. List ; Temp. Lt. G. L. Grieve, and relinquishes the temp. rank of Lt.

The undermentioned Lts. on prob. are secd. : F. Welsh, N. J. Nicholson, H. W. Daukes, and D. C. MacE. Macpherson.

ARMY DENTAL CORPS.

Capt. A. Gibson to be Maj.

Temp. Lt. H. Quinlan, Dental Surg., Gen. List, to be Lt.

ARMY RESERVE OF OFFICERS.

Cols. J. W. Leake and F. Ashe, having attained the age limit of liability to recall, cease to belong to the Res. of Off.

Maj. J. H. Barbour, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY.

Maj. E. T. Burke resigns his commn. and is granted the rank of Lt.-Col.

Capt. J. V. Bates to be Lt.-Col. and to comd. the 131st (Home Counties) Fd. Amb., vice Lt.-Col. P. J. Gaffikin, vacated.

Capt. E. B. Hinde resigns his commn. and is granted the rank of Maj.

2nd Lt. W. E. Hayes (late R.E.) to be Lt.

Supernumerary for service with O.T.C. : Capt. H. P. Malcolm to be Maj.

ROYAL AIR FORCE.

Flight Lt. A. F. Cook is seconded for duty with the Transjordan Frontier Force.

Flying Officer E. A. Rice is promoted to the rank of Flight Lt.

Flight Lt. C. Sempill de Segundo relinquishes his temporary commission on completion of service.

RESERVE OF AIR FORCE OFFICERS.

Squadron Leader E. P. Punch relinquishes his commission on completion of service.

INDIAN MEDICAL SERVICE.

Lt.-Col. T. Hunter retires.

Guy's Hospital.—The annual report upon the work of Thomas Guy's foundation shows that in 1927 11,313 in-patients were admitted, an increase of 1000 over the previous year. There were 122,446 new out-patients who made 537,676 attendances : they cost 7*s.* each. The in-patients cost £11 19*s.* 2*d.* each. The total income was £164,000 and the expenditure £172,000 ; the accumulated adverse balance of expenditure over income now exceeds £100,000, and an appeal is being made for £500,000 for the re-endowment of the hospital.

be capable of demonstration, whereas the causative organisms can only be isolated from the blood in from 70 to 80 per cent. of cases. and from the fæces in about 50 per cent. A blood culture when positive is the most satisfactory means of diagnosis, because it gives conclusive proof of infection, while the agglutination reaction only gives indirect proof. The presence of typhoid or paratyphoid bacilli in the fæces or urine means that the patient is either a carrier or is suffering from an active infection with these organisms, and it is permissible to assume an active infection if the symptoms are sufficiently suggestive.

Each method of diagnosis, therefore, has its limitations, and in order to obtain the best results it is essential on encountering a suspected case: (1) to make cultures from the blood, fæces, urine, and sputum (if present); (2) to perform an agglutination reaction; (3) to perform a leucocyte count. These three investigations should be carried out whatever the stage of disease. The leucocyte count is invaluable because it takes very little time to perform, and if a leucopenia is present one can usually rule out most of the infections likely to resemble enteric clinically, with the exception of influenza. The result of the agglutination reaction should be obtainable in two or three hours, but isolation and identification of the causative organism may take some days.

The Diagnosis of Bacterial Food Poisoning.

The agglutination test also has some value in the diagnosis of bacterial food poisoning. These infections are usually due to various types of *B. aertrycke* and to *B. enteritidis* Gaertner. Blood cultures are of very little value, and the diagnosis is usually made by isolating the causative organism from the fæces. The agglutination reaction affords valuable support, but needs to be interpreted with care, owing to the "normal" people who agglutinate these organisms; furthermore, people who have been inoculated with T.A.B. frequently agglutinate *B. aertrycke* and *B. enteritidis* Gaertner, owing to the close serological relationship of members of this group of bacilli.

However, this non-specific or group agglutination as regards *B. aertrycke* can be avoided by using type emulsions, as shown by Andrewes.[9]

Conclusion.

In conclusion, attention must be drawn to the importance of supplying the bacteriologist with brief details of the case under investigation, especially regarding the duration of the disease, inoculation, and so forth. Neglect to do this is, no doubt, responsible for the complaints sometimes made by practitioners of incomprehensible laboratory reports. The successful diagnosis of enteric can only be accomplished by close coöperation between the clinician and the laboratory worker.

MARIE CÉLESTE SAMARITAN SOCIETY.—During the first six months of the present year this society, which was established to help patients of the London Hospital, assisted 6739 persons, an increase of 402 as compared with the corresponding period of last year. Surgical appliances have been supplied to 2625 patients, and 1323 have been sent to the sea or the country.

TREASURER OF RADCLIFFE INFIRMARY.—The Rev. G. B. Cronshaw, upon his appointment as Principal of St. Edmund Hall, has resigned the treasurership of the Radcliffe Infirmary, which he has held for the last 18 years. During that period the hospital, by reason of his energy and activity, has been greatly improved and its usefulness widely extended. In recognition of his services Mr. Cronshaw has been made a vice-president.

ANNUAL MEETING AT CARDIFF.

(Continued from p. 351.)

SECTION OF MEDICAL SOCIOLOGY.

THE FALLING BIRTH-RATE.

Prof. W. J. ROBERTS (University College, South Wales), in opening the subject from

The Economic Aspect,

referred to the writings of Malthus, and stated that nowadays no simple and definite theory as to the law of population held the field. Official statistical data threw no light on the means by which the reduction of births was secured. Apprehensions had found expression with respect to the decline of the French population, and in the U.S.A. as to the higher birth-rate among unassimilated immigrants when compared with the pure Americans. It was also believed that in Britain birth control prevailed more widely among the relatively better situated. Sir Arthur Newsholme had dealt with the thesis that it was not a matter of indifference as to which races peopled the unfilled portions of the world and took the preponderant share in shaping the destinies of mankind. He had also referred to the fact that in the earlier years of certain industries each child was his parents' savings bank, and that now the child was a less profitable asset than in the past. Economic inquiry tended to destroy utterly the impression that the people of this island were divided by social circumstances into breeds, some of which were fitted by origin and nature to bear rule over the others. The economist wished to have many questions answered, both by the biologist and the social investigator. For example: Are the "comfortable classes" the result of biological excellence? Are the classes which exhibit aptitude for leadership and command in danger of perishing if their stock is not continued? The obstacles to the growth of population and the causes of misery and restricted livelihood in the mass of the people are not due to any law of population or to the niggardliness of nature. Neither our own little planet nor our own little island was overcrowded. The causes were rather to be sought in habits and institutions whose origin and purpose was mastery, privilege, and monopoly. The continuous unfolding of productive capacity depended on the prevalence of justice throughout the whole economic community. He did not pretend to any social or medical knowledge, but as an economist would like answers to many questions. How did gambling or the desire to get rich quickly operate? What was the effect of outdoor games and a life of pleasure on fertility? What was the effect of the conventions of each social class on its individuals? Did people follow medical advice on these subjects? And did people really know why they acted in a certain way? The term "overcrowding" was used very loosely, the standards adopted were rough, and halving of the population did not necessarily diminish overcrowding, even if the number of houses remained the same. Ordinary economic explanations were of no avail for this problem, and far more detailed inquiry and intelligent questioning of all classes by people who could put themselves in other peoples' places was needed.

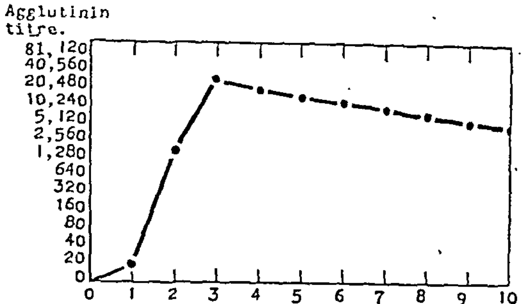
The Biological Aspect.

Prof. F. A. E. CREW (Animal Breeding Research Department, University of Edinburgh) said the birth-rate of this country had fallen and was still falling, and that this was a matter of grave concern to those who chose to envisage the overwhelming of our prized culture by hordes of barbarians of this or that particular hue, but all equally and amazingly fertile. To the biologist, however, there was nothing remarkable and nothing necessarily ominous in this decline. If the conclusions which had emerged from the work of Pearl, Elton and others had been known when the birth-rate was soaring, the present fall would have latter event is unusual, and this is fortunate, since in these cases a diagnosis cannot be established on a single test, and repeated tests have to be performed (see below)..

Behaviour of Agglutinins Resulting from Protective Inoculation.

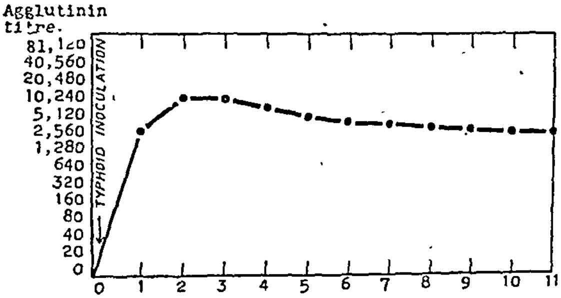
As a result of inoculating a person with a vaccine prepared from typhoid and paratyphoid bacilli (T.A.B.), agglutinins to these various organisms appear in the serum (see Chart 2). They reach their maximum after two or three weeks, and then usually fall to a level round about the 1/500 mark; here they remain for many years, and in some cases no doubt for a lifetime. The tendency is for them to get less as time goes on, but the process is so gradual that when tests are made once a week for several weeks and no change in agglutinin titre can be demonstrated. There is considerable evidence[6] to show that nothing will cause any fluctuation of the agglutinin titre at this stage unless a person becomes infected with one of the enteric group of bacilli. In the event of this happening the agglutinins for the infecting organism rapidly rise and reach a maximum towards the end of the third week. Then they gradually fall, and in all probability become stationary once again on a level somewhat higher than they were before the infection took place. Thus the behaviour of the agglutinins in a person suffering from enteric infection is the same whether the person has been inoculated or not, except that in the inoculated they start from a definite level (see Chart 3), whereas in the uninoculated they start from zero.

CHART 1.



Showing the behaviour of agglutinins during an infection. Note the rapid rise in the second and third weeks.

CHART 2.



Showing the behaviour of agglutinins resulting from inoculation.

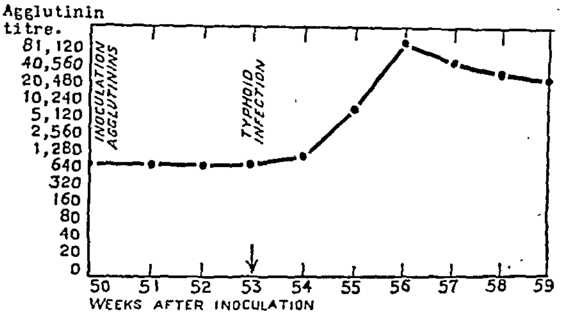
Diagnosis of Infection Agglutinins.

If we are confronted with a serum which agglutinates one or more of these organisms it should be clear from the above remarks that the agglutination may be due to: (1) "normal" agglutinins; (2) infection agglutinins; (3) inoculation agglutinins; (4) a combination of the above. It then becomes necessary to distinguish infection agglutinins from the remainder. One can usually rule out inoculation agglutinins by questioning the patient; but, apart from this, the fact that a serum agglutinates the three organisms, *B. typhosus*, *B. paratyphosus* A and B, is usually sufficient indication that inoculation has taken place.

The essentials for diagnosis *in the uninoculated* must then be considered. A titre of 1/1000 must always be regarded as strongly suspicious, and if it is considerably higher than this a presumptive diagnosis of infection can be made. It must be remembered, however, that occasionally titres as high as this are not registered even when the agglutination is at its maximum at the end of the third week. In these cases it is necessary to perform two or even three tests with an interval of three or four days between them; if there is any appreciable increase or decrease in titre (according to the stage of the disease) a diagnosis of infection is justified. The occurrence of these cases makes it of the utmost importance to test the blood in the first few days of disease, for if it is then negative and a few days later agglutinins appear, a diagnosis of infection is justified, even if the titre of the second test is only on the 1/20 or 1/40 mark.

The diagnosis by means of repeated tests is fairly easy during the first three weeks of disease, since the rise in agglutinins is rapid; but after this period it is less satisfactory, and may be a lengthy procedure, for the fall in agglutinins may be very gradual.

CHART 3.



Showing the behaviour of the agglutinins in the case of an inoculated person becoming infected. This chart gives an idea of what would happen to the agglutinins if a person became infected with *B. typhosus* 53 weeks after being inoculated.

In the inoculated a single test by itself is of very little value, and it is essential to perform, at any rate, two tests with an interval of three or four days between them in order to demonstrate the fluctuation in titre characteristic of infection. As has been noted above, after inoculation agglutinins have settled down to a steady level no change can be detected in them over a short period unless the patient becomes infected with organisms of the enteric group.

Value of the Test.

The agglutination reaction thus has a definite value in the diagnosis of these infections, and may be even more useful in the future. The work of E. Weil and A. Felix[7] and others has shown that typhoid and paratyphoid bacilli contain two kinds of antigen, which differ in their resistance to heat and to certain chemical agents. These, for reasons which do not concern us here, have come to be called the H and O antigens. It has been claimed by Felix that agglutinins acting on the O antigens appear only as a result of infection, and that, by using an emulsion containing O antigens, it is possible to arrive at a diagnosis on the result of a single agglutination test even in an inoculated individual. Burnet[8] has recorded similar results. If these observations are widely confirmed by future investigations they will clearly make an important advance in the diagnostic application of the test.

The great value of the agglutination test, compared with other methods of diagnosis of these infections, is the fact that agglutinins after the first week or so are almost always present, and therefore should be capable of demonstration, whereas the causative organisms can only be isolated from the blood in from 70 to 80 per cent. of cases, and from the fæces in about 50 per cent. A blood culture when positive is the most satisfactory means of diagnosis, because it gives conclusive proof of infection, while the agglutination reaction only gives indirect proof. The presence of typhoid or paratyphoid bacilli in the fæces or urine means that the patient is either a carrier or is suffering from an active infection with these organisms, and it is permissible to assume an active infection if the symptoms are sufficiently suggestive.

Each method of diagnosis, therefore, has its limitations, and in order to obtain the best results it is essential on encountering a suspected case: (1) to make cultures from the blood, fæces, urine, and sputum (if present); (2) to perform an agglutination reaction; (3) to perform a leucocyte count. These three investigations should be carried out whatever the stage of disease. The leucocyte count is invaluable because it takes very little time to perform, and if a leucopenia is present one can usually rule out most of the infections likely to resemble enteric clinically, with the exception of influenza. The result of the agglutination reaction should be obtainable in two or three hours, but isolation and identification of the causative organism may take some days.

The Diagnosis of Bacterial Food Poisoning.

The agglutination test also has some value in the diagnosis of bacterial food poisoning. These infections are usually due to various types of *B. aertrycke* and to *B. enteritidis* Gaertner. Blood cultures are of very little value, and the diagnosis is usually made by isolating the causative organism from the fæces. The agglutination reaction affords valuable support, but needs to be interpreted with care, owing to the "normal" people who agglutinate these organisms; furthermore, people who have been inoculated with T.A.B. frequently agglutinate *B. aertrycke* and *B. enteritidis* Gaertner, owing to the close serological relationship of members of this group of bacilli.

However, this non-specific or group agglutination as regards *B. aertrycke* can be avoided by using type emulsions, as shown by Andrewes.[9]

Conclusion.

In conclusion, attention must be drawn to the importance of supplying the bacteriologist with brief details of the case under investigation, especially regarding the duration of the disease, inoculation, and so forth. Neglect to do this is, no doubt, responsible for the complaints sometimes made by practitioners of incomprehensible laboratory reports. The successful diagnosis of enteric can only be accomplished by close coöperation between the clinician and the laboratory worker.

SECTION OF MEDICAL SOCIOLOGY.

THE FALLING BIRTH-RATE.

Prof. W. J. ROBERTS (University College, South Wales), in opening the subject from

The Economic Aspect,

referred to the writings of Malthus, and stated that nowadays no simple and definite theory as to the law of population held the field. Official statistical data threw no light on the means by which the reduction of births was secured. Apprehensions had found expression with respect to the decline of the French population, and in the U.S.A. as to the higher birth-rate among unassimilated immigrants when compared with the pure Americans. It was also believed that in Britain birth control prevailed more widely among the relatively better situated. Sir Arthur Newsholme had dealt with the thesis that it was not a matter of indifference as to which races peopled the unfilled portions of the world and took the preponderant share in shaping the destinies of mankind. He had also referred to the fact that in the earlier years of certain industries each child was his parents' savings bank, and that now the child was a less profitable asset than in the past. Economic inquiry tended to destroy utterly the impression that the people of this island were divided by social circumstances into breeds, some of which were fitted by origin and nature to bear rule over the others. The economist wished to have many questions answered, both by the biologist and the social investigator. For example: Are the "comfortable classes" the result of biological excellence? Are the classes which exhibit aptitude for leadership and command in danger of perishing if their stock is not continued? The obstacles to the growth of population and the causes of misery and restricted livelihood in the mass of the people are not due to any law of population or to the niggardliness of nature. Neither our own little planet nor our own little island was overcrowded. The causes were rather to be sought in habits and institutions whose origin and purpose was mastery, privilege, and monopoly. The continuous unfolding of productive capacity depended on the prevalence of justice throughout the whole economic community. He did not pretend to any social or medical knowledge, but as an economist would like answers to many questions. How did gambling or the desire to get rich quickly operate? What was the effect of outdoor games and a life of pleasure on fertility? What was the effect of the conventions of each social class on its individuals? Did people follow medical advice on these subjects? And did people really know why they acted in a certain way? The term "overcrowding" was used very loosely, the standards adopted were rough, and halving of the population did not necessarily diminish overcrowding, even if the number of houses remained the same. Ordinary economic explanations were of no avail for this problem, and far more detailed inquiry and intelligent questioning of all classes by people who could put themselves in other peoples' places was needed.

The Biological Aspect.

Prof. F. A. E. CREW (Animal Breeding Research Department, University of Edinburgh) said the birth-rate of this country had fallen and was still falling, and that this was a matter of grave concern to those who chose to envisage the overwhelming of our prized culture by hordes of barbarians of this or that particular hue, but all equally and amazingly fertile. To the biologist, however, there was nothing remarkable and nothing necessarily ominous in this decline. If the conclusions which had emerged from the work of Pearl, Elton and others had been known when the birth-rate was soaring, the present fall would have been foreseen and accurately predicted. The growth of all living things, whether pumpkins or peoples, followed the law enunciated by Pearl—namely, that the population at first grows slowly, gradually gains impetus, and then grows rapidly. Rapid growth is succeeded by a slowing off which ends in no growth at all. Increasing density led ultimately to complete saturation, and reduction in population was achieved by removing the surplus or by reducing the rate of growth. The first method of reduction was the catastrophic and was exemplified in rabbits, mice, and human populations, the catastrophic instruments being war, pestilence, and famine. The second or gradual method of reduction was revealed in the work of Pearl on Drosophila, the primary factor being a fall of fecundity and fertility with increasing density. Among pigs under similar conditions there was noticed a reduction in the size of the litters. Group biology was a new study. Experiments with animals did not necessarily apply to human beings. Man could adapt himself to a changed environment, and every advance in knowledge which enabled him to derive from his environment things conducive to his material welfare increased the potentialities for population growth in a given area. A rising birth-rate heralded an extension of the conquest of man of his environment, while a falling birth-rate was an indication that mankind was temporarily imprisoned. The birth-rate was now falling because this was the end of a population growth-cycle. A new growth-cycle would be initiated and the birth-rate would rise when those factors which were at present overriding the inherent tendency to increase were recognised or removed.

Fecundity was affected by inborn and environmental factors and different races, stocks, and individuals were distinguished, one from the other, by true-breeding differences in fecundity. In the human subject the tendency to multiple births was faithfully transmitted through both male and females. The time of onset of puberty and of the climacteric and also longevity were true-breeding characters. It was possible that in the past the inherently longer-lived had contributed disproportionately to the population, and that under modern conditions the shorter-lived lived longer and transmitted to their progeny a lowered fecundity. This would be a reasonable explanation of a lowered birth-rate if it could be shown that there was a high correlation between longevity and high reproductive rate. This country was now relatively overcrowded. Lack of houses was an indication of a relative regional over-population. If the builders failed to keep pace with the babies the birth-rate would fall. It was not known how density provoked its results, but the work of Pitt-Rivers suggested that sheer discouragement was enough to destroy a people.

What effect had the conflict of cultures? The birth-rate of the vanishing peoples of the South Seas was steadily falling, apparently because these peoples were discontented and discouraged, and consequently dying out. Did the arrival of an immigrant Irishman in Glasgow prevent a Scottish baby from being born? There must be joyousness, eagerness, roominess for potential parents or else the babies would not come. The birds, when they mated, built nests, but for human lovers the tenements were built by those who were ignorant of the relation which existed between population density and the reproductive rate. The sex ratio could not as yet be controlled. The fact that many women could not become mothers could not explain the falling birth-rate. A high marriage-rate associated with a low per-reproductive-woman birth-rate could yield the same reproductive rate as a low marriage-rate associated with a high per-reproductive-woman birth-rate. Few marriages and larger families might yield a high reproductive rate with less variety among the offspring and surely variety was to be desired. The present low birth-rate was in part due to sterile marriages. Two individuals mutually sterile might be fruitful in other matings. Possibly recent social and economic developments had encouraged the survival of stocks, which were relatively infecund or which reacted more readily to the disharmonies of industrialism. The peak of sexual activity was at about 29 in the male and the woman's reproductive power dropped shortly after 30.

Prosperity implied plentiful food and comforts, and therefore a lower death-rate and a rising birth-rate, and an unequally distributed prosperity might create differential fertility among the social grades. If a large section of the community were relatively unsuccessful and left with no other modes of nervous release than excessive drinking and sexual over-indulgence, there would be a higher reproductive rate, in this section than among the community as a whole. Social advancement implied a lower reproductive rate, as those who experienced it were presented with more varied modes of self-expression and self-indulgence. Unless it could be shown that the methods adopted for birth control were effectual, it could not be accepted that birth control was largely responsible for a fall in the birth-rate. The fall in the birth-rate had been too gentle; it had proceeded with evolutionary steadiness and had been universal. This suggested the expression of some biological factor. He doubted if birth control had affected the crude birth-rate, but suggested that it might have slammed the doors of suburban houses to open those of a slum. The problem, thus, was to determine the biological worthiness of the social grades. What was fitness? There was no reason to suppose that it was linked with high-grade fecundity. The elephant and the earwig were fit and had quite different reproductive rates. Was the human standard of fitness to be good physique, good brain, and low-grade fecundity? If so, this ideal could be found abundantly among all social grades. The suggestion that the relatively unfit were more abundant among the socially submerged was not necessarily true. It was easier for a good man to climb out of the gutter than for a biologically unworthy scion of an established family to descend because the latter was buoyed up by his associates. If birth control had played a part, it would have been well for humanity if it had been the only responsible agent, used intelligently by a people, who knew what they did and why they did it. At present it seemed that the methods adopted were too uncertain to allow of any policy being based upon them. In his concluding remarks Prof. Crew said he had tried to be provocative and had incautiously stepped from the solid ground of fact to the uncertain terrain of opinion, but that he set no great store on his opinions and would not mind exchanging them for better ones.

The Medical Aspect.

Sir THOMAS HORDER thought the falling birth-rate was a matter outside the province of medical men. They must have more facts from the biologist and the economist. Sex incompatibility was a mystery and the laws of reproduction were inscrutable. The prolongation of life was a small matter, but the saving of life and the improvement of health were great matters. Old age was on the increase. We had a lower birth-rate and would ultimately have a higher death-rate. A visitor from another planet would be amused to find us worrying over a falling birth-rate when so recently we were complaining of the rapid increase of the population. He did not think the differentiation of the birth-rate resulting in poorer quality came within the doctor's sphere. The husband and wife usually consulted the doctor when they had made up their own minds on this matter. If the doctor was to enter this field he must be taught very differently. If they were to breed from superior parents Government would have to fix a minimum of, say, three children with a double minimum for very superior parents, and subsidies would have to be provided from those who did not comply with the minimum. Sociologists must arouse interest in eugenics before the doctors could take a hand. The profession had stood aloof owing to want of data.

Lady BARRETT (London) dissented from Sir Thomas Horder's view that this was not a matter for the medical profession. She gave many statistics with regard to the fall in the birth-rate, and also gave statistics with regard to the fertility of women according to their age at marriage, derived from the experience of Scotland in 1855. She concluded that 25 was the best age for marriage. If the true facts were known with regard to the chances of immediate conception many more young couples would begin their married life in a natural manner. If there was danger to the mother from childbearing the family doctor was the best person to advise. Medical students should be taught all that was known on this subject in order that they might give suitable advice to their patients. Unless the medical profession took an interest in this problem and spoke out there was a great danger of race deterioration as the result of the differential birth-rate.

Discussion.

Dr. **William Collier** (Oxford) said that for 40 years birth control had been practised in the professional classes, and they had no right to deny information to the working classes. If medical science set itself to improve methods they would be improved. They must not sit on a hedge because the subject was distasteful. Panel practitioners had no time to advise, and should refer their patients to good clinics. A first-class birth control clinic had been inaugurated at Cambridge under medical direction, but in spite of the support of the Oxford Medical Society they had met with much opposition and had been unable to establish one at Oxford.

Dr. **Letitia Fairfield** said that the doctor's training gave him no locus standi. More biological data were wanted. Causes of the falling birth-rate were voluntary and involuntary, but the involuntary causes were not really natural laws. Joy in life produced the desire for children, and regard for the health of the mother produced a reasonable form of birth control. She did not think they need worry about the falling birth-rate.

Dr. **Binnie Dunlop** (London) said there was a real demand for information on this subject, and caused some amusement by his suggestion that there should be no more children till all the adults had been satisfactorily provided for.

Mrs. **Neville Rolfe** dealt with the effect of motivation. The birth-rate in Italy had declined, but it remained high in China and among the Jews, from religious motives. The necessary fillip to the birth-rate referred to by Prof. Crew could readily be supplied by emigration. We had areas crying out for white population, and we ought to emigrate good stock. Under the 1922 Act local authorities could train, equip, and emigrate, but they only emigrated boys. They should go in for group emigration with unbroken British family traditions. Local authorities should send out girls and boys in equal numbers. Emigration was the best means of stemming the decline in the birth-rate.

Dr. **N. E. Waterfield** (Banbury), from his experience as a general practitioner, thought parents asked for and acted on the doctor's advice.

Reply.

Prof. **Roberts** asked if social conditions were just, and suggested that many of these problems would be solved if the ideals of the community were raised.

Prof. **Crew** agreed with the importance of the motivating force, and said a new religion was needed. Emigrants should be successful people at the reproductive age.

SECTION OF PREVENTIVE MEDICINE.

CONTROL OF INFECTIOUS DISEASE.

The value of present methods of controlling infectious diseases was discussed under the presidency of Dr. **E. Colston Williams** (Cardiff).

Small-pox.

Dr. **L. J. Rajchmann** (Director of the Health Organisation, League of Nations) surveyed the behaviour of small-pox in the various countries of the world. Events at Rio de Janeiro in 1926, and in Algeria in 1926 and 1927, showed, he said, that severe outbreaks of small-pox had not ceased to occur. During 1927 a large area of Europe was free from small-pox; since 1919 there had been a huge drop in its prevalence in Rumania and Soviet Russia; in each case notification had improved. In the Far East there had also been a drop. During the late war England and France remained clear; in Germany in 1917 the barriers against small-pox broke down, and this was much more the case in Austria, Hungary, and Italy. The crest was reached in 1920; after that came the decline. In 1927 there were no cases in 15 European countries, and very few in 15 others. In France, in spite of efficient vaccination, the prevalence was said to be kept up by imported cases. In France, Germany, and Italy the disease was of the classical type. In Switzerland a mild type of small-pox, similar to that in England at present, was prevalent from 1921 to 1926, but has now entirely disappeared. The case mortality of small-pox varied greatly not only between one country and another, but also from year to year. Italian statistics were particularly interesting, and showed that the severity of the disease and its case fatality underwent cyclical variation, roughly in seven-year periods. There was no evidence that the classical type was being replaced anywhere by the mild type. The case fatality in England from the mild type was now between 0·2 and 0·3 per cent. In Germany during 1919 to 1922 the case fatality varied from 12 to 16 per cent. In France the case fatality was between 28 and 29 per cent. from 1919 to 1921. In Rumania the figure of 28 per cent. for 1919 became 12 per cent. in 1923. In extra-European countries the figure varied from 10 to 30 per cent. In India and Korea during 1926 and 1927 it was about 25 per cent. In Java the figure 26 per cent. in 1918 fell to 12 per cent. in 1923, and was only 2·7 per cent. in 1927—a very low figure for a tropical country. Figures for Africa show that a low case fatality of 2 to 10 is not uncommon, but that severe epidemics with a 30 per cent. mortality do occur. In European countries there are no statistics for trustworthy death-rates according to age-periods, but the Italian statistics show a marked excess of the female rate at ages from 20 to 44. Owing to the influence of the vaccinal condition it is difficult to determine whether fluctuations due to any other cause occur. The seasonal distribution of the mild and severe types did not differ materially.

Dr. **J. Middleton Martin** (Gloucestershire) pointed out that mild small-pox was no new thing, and that in the past inoculation had come into fashion when the type of the disease was mild. The tendency to regard infection as being spread by persons rather than by infected articles was growing, and belief in aerial spread of infection was practically given up. Their main business was to prevent case to case infection. Their principal difficulty was the detection of mild small-pox. Small-pox was not a dual disease but one disease of varying severity. The percentage of vaccinated school-children in Gloucestershire had dropped from 70 to 25, and their present means of control depended upon quickness in detection.

Dr. **T. Eustace Hill** (Durham County) had no doubt that the mild disease was true small-pox. They had had 12,634 cases from 1922 to May 31st, 1928, with 34 deaths. Of the 34 deaths, 6 occurred under 1 month of age, 4 under 3 months, 2 at 1–2 years, 3 at 2–5 years, 3 at 5–15 years, 5 at 15–25 years, 1 at 25–45 years, 5 at 45–65 years, and 5 at 65 and upwards. The cost to the county had been £120,000, but nevertheless he thought they ought to continue isolating the cases as they could not trust to the mild disease breeding true. Discussing methods of control, he argued that it was impossible to make vaccination compulsory at present. He paid tribute to the valuable work done by the port sanitary authorities. Wilful concealment and failure to diagnose impeded prompt notification. All medical officers of health should make themselves expert in diagnosis. and county medical officers of health should act as consultants. The supervision of contacts was not always efficient. They had successfully pooled the hospital accommodation in Durham County, and they had not found that overcrowding the hospitals had caused septic cases. "Return" cases had occurred owing to the demand for hospital accommodation. Disinfection was still advisable. He had had no experience of the supposed relation between encephalitis and vaccination. (Dr. Rajchmann in his opening remarks mentioned that a Special Commission of the League of Nations was at present investigating this matter.)

Dr. R. P. GARROW (Chesterfield) explained the continuous prevalence of small-pox in this country by the extraordinary mildness of the cases. Even confluent cases were not ill. The refusers of vaccination were of the lowest class. He suggested the omission of hospital isolation and the treatment of cases at home with vaccination of the contacts. At the present time in his district it was considered preferable to have a pleasant three weeks in hospital with small-pox than to suffer from vaccination at home. He believed that the mild type was a separate disease, and that even if it did change its type the occurrence of a few deaths would stimulate the demand for vaccination.

Dr. R. BRUCE LOW (Ministry of Health) thought the mild type was not so trivial, and was apt to be fatal to the newly born; he urged the need for stamping out the disease, and showed that the present failure was caused by the well-tried preventive methods not being properly enforced. He suggested that owing to the mildness of the disease the general practitioner regarded it with scorn; the cases were not promptly removed, the contacts were not followed up carefully, and there was no propagandism with regard to vaccination. He suggested that the mild type was more easily stamped out because it was less infectious, and that supervision of contacts should be extended from 16 to 20 days because the appearance of the rash was frequently delayed. To show that the mild type was no new thing he quoted from the letter of a doctor in 1722: "one type of small-pox the nurse cannot kill and one type the doctor cannot cure."

Sir MALCOLM WATSON (Malaya) showed how small-pox had been stamped out in the Malay States by efficient vaccination, and suggested the advisability of postponing vaccination till after the first year of life.

Dr. A. E. BRINDLEY (Derby) emphasised the large amount of concealment of the disease which went on.

Prof. HAROLD KERR (Newcastle-on-Tyne) said that contacts dreaded vaccination more than the disease, and hoped that it would be possible to reduce the virulence of the lymph even if it shortened the period of immunity. His town gave compensation to those who were laid off work owing to vaccination. He mentioned the case of seven painters who were exposed to infection and vaccinated. Three were off work, one of them for 11 weeks, and received their wages all the time. He did not agree with Dr. Garrow's proposal to leave the cases at home. The medical officer of health of a neighbouring district had refused to believe that the disease was small-pox. As a result infection spread to Newcastle and the consuls arranged for ships to be taken to other ports. In any ordinary big town the mild type of the disease could be controlled without difficulty.

Dr. R. M. F. PICKEN (Cardiff) said that better-class persons were also refusing vaccination. It was impossible to get efficient vaccination and revaccination against this mild type of the disease. Stunts for the vaccination of the whole population would only make us a laughing stock.

Diphtheria and Scarlet Fever.

Dr. R. A. O'BRIEN gave many instances to show how outbreaks of diphtheria could be prevented and controlled in resident schools and among hospital staffs, and went on to discuss some of the failures to apply our present knowledge. If antitoxin were given in the first 24 hours of the disease there would be no deaths from diphtheria. Statistics from the U.S.A. and from the reports of British medical officers of health showed that there was much delay of parents in calling in the doctor, much delay of doctors in making a diagnosis, further delay in waiting for the examination of the swab, and that frequently in the end an ineffective dose was given. Recent work showed that out of a thousand Schick-negative cases 97 per cent. remained negative after periods varying from one to seven years. Immunised persons who became Schick-positive rapidly regained their negativity with a Schick test. Three doses at intervals of one week was still the best method administratively, but it was possible to give the Schick test and the first immunisation dose simultaneously. Some persons became immune after the first dose and some after the second. Dr. O'Brien described the work which was going on for the purpose of improving our methods.

Dr. J. GRAHAM FORBES (London) described the progress which is being made in London and throughout the provinces in immunising the children at welfare centres and in the schools against diphtheria. Thirteen of the London boroughs have now provided such facilities, and some outside districts, such as Willesden and Tottenham. In addition to this, very satisfactory results had been obtained in many residential institutions and among the staffs of the M.A.B. hospitals. There was a considerable increase in this work during 1927 throughout the whole country.

Dr. B. A. I. PETERS (Bristol) described the very satisfactory results obtained in the immunisation of the hospital staffs of Bristol. They had found that the Schick test was not always reliable in the case of very virulent strains of diphtheria. They had now adopted for the hospital staffs immunisation without previous Schick testing. Their experience of immunisation against scarlet fever had also been satisfactory; he thought that all local authorities should adopt immunisation methods for their hospital staffs.

Dr. E. H. R. HARRIES (Birmingham) referred to the great value of surgical treatment of the nasopharynx in reducing the number of "return" cases of scarlet fever and diphtheria. The examination of throat swabs as a method of testing the fitness of diphtheria patients for discharge was now being given up. Although scarlet fever was usually mild in the case of children it was *not* always so in the case of probationer nurses, and it was well worth while to protect them by immunisation. He said it was high time that more facilities were provided for the education of medical students in the fever hospitals. They should act as clinical clerks for, say, a month, instead of the present spasmodic visits. "Return" cases of scarlet fever could best be prevented by immunisation of the contacts in the home. In order to secure the success of these new methods it was very necessary to have the full coöperation of the general practitioners.

SECTION OF PUBLIC HEALTH.

THE TEACHING OF HYGIENE.

In opening this discussion, over which Dr. R. M. F. PICKEN (Cardiff) presided, Prof. W. W. JAMESON (London School of Hygiene) limited his remarks to the teaching of preventive medicine to medical students, and to the training of other members of the health services. General practitioners being in the first rank of health workers every effort must be made to arouse the preventive outlook among medical students. In this teaching mere sanitary engineering need not fill a large place; lectures for medical students should not be regarded as lectures by experts for the use of experts. Although the syllabus was much too wide at present it failed to deal with the sociological aspect. In the training of sanitary inspectors he attached great importance to experience as craftsmen in one of the building trades. There was a danger that such craftsmen might be kept out by the demand for too high a standard of general education. He thought there should be more than one port of entry for health visitors, although he valued highly the training of a nurse. These should be probationary, and the salaries of health visitors proper should equal those of teachers in elementary schools. In the training of midwives a distinction should be made between those who intend to practise and those who are going to take up other health work. The principal midwifery schools should be reserved for the former, who should also have district training. For the latter a minor qualification, which might be termed "obstetric nurse," would suffice. Nurses who underwent training in a fever hospital were in an unsatisfactory position. If general hospitals accepted them subsequently they were treated as if their fever training had been of no account. Every trained nurse should have some fever training, and one year of her training might be devoted to this purpose. Health education in the schools should be carried out by teachers of the right type, and not by doctors or school medical officers. The teachers needed to be taught hygiene on more attractive and practical lines than at present. Many local authorities had not taken any interest in health education. He referred with approval to a syllabus drawn up by Dr. Brackenbury in 1904, when chairman of the Hornsey Education Committee, which, with minor alterations, had been in use ever since. Finally, they must get the general practitioner to take an interest in the education of the public. As regards broadcasting, he would prefer four-minute broadcasts on matters of special health interest at the particular moment, to the present 15 minutes health talks.

Dr. H. B. BRACKENBURY (chairman of B.M.A. Council) expressed himself in agreement with Dr. Jameson. The General Medical Council, he pointed out, has no direct power over the teaching bodies, but it can prescribe curricula and inspect examinations. It was impossible to coördinate the work of existing voluntary health education bodies, 100 in number. He thought that schools and general practitioners should be the most effective instruments of education. By educating the children they re-educated the parents. Education in sexual matters should only be given to older girls by head teachers or specially qualified teachers; it had been successfully done on these lines in Hornsey. There had hitherto been no attempt to deal with these questions in secondary schools. The question of mental hygiene had been neglected, and teachers needed instruction how to deal with mentally unstable and irritable children. He had not much faith in the benefits likely to accrue from public lectures or from the lectures of insurance practitioners to their patients. He would put first in importance the schools, second the day by day advice given by practitioners, and third the work of the health visitors in the homes.

Dr. D. LLEWELYN WILLIAMS (Welsh Board of Health) believed that the panel doctors had done much good since 1913, and were in a position to do good research into the beginnings of disease. They must secure a preventive outlook all through the medical curriculum. Birmingham had instituted lectures by panel doctors to their own patients, for which the insurance committee paid full fees. The results were claimed to be good.

Dr. BRACKENBURY intervened to say that the Representative Body was doing its best to encourage education by practitioners. A new household magazine was about to appear, and the Council of the Association had accepted the responsibility of supplying one page on health matters. The articles would be unsigned.

Dr. OLIVE WHEELER (Professor of Education, Cardiff) emphasised the importance of close coöperation between medical and educational bodies. For the teaching of hygiene in the secondary schools qualified biologists were needed; at present there were more females than males taking up biology among those trained. Some of the biological teaching must be practical—e.g., gardening. For the primary schools the teaching of hygiene is not living and imaginative enough; nature study should be correlated with hygiene and health practice. In their four years' course for teachers the fourth year was given up to the application of biology and other sciences. They also studied psychology and such questions as fatigue and development from a biological point of view. Practical teaching in physical exercises and the playing of healthy games was important. They had in Cardiff a "College adviser of games," who worked in close touch with the medical officer of health. It was too late to begin at the age of 5, and therefore nursery schools were needed for the teaching of habits.

Prof. HAROLD KERR (Newcastle-on-Tyne) thought much could be done to make the course of lectures in hygiene for medical students more interesting. He showed what a large amount of field work was included in the course given at Newcastle, and claimed that as a result the students who subsequently practised in the neighbourhood were his best supporters.

Mr. JAMES MACKENZIE (Secretary, Industrial Health Education Society) described how his society was getting in touch with workers in all occupations, and arranging medical lectures to such workers. The workers chose the subject, the medical officer of health helped to find the right lecturer, and "heckling" was encouraged. The workers were anxious for information about the many occupations inimical to health and life. In spite of huge expenditure on sick and medical benefits not a penny was spent on education under the Insurance Act.

Dr. ERNEST JONES (M.O.H., Cardiganshire) agreed that the teaching of hygiene had failed because the teachers had no knowledge of the sciences on which it was founded. Health knowledge would be a better name for the subject. He described the methods of teaching biology and physiology and their application to the students at Aberystwyth College. His suggestion that the clergy would benefit by a course of biology aroused applause. There was too much psychology and too little biology; they needed more science and less classics.

Mr. CREW (Sec., Central Health Education Council) favoured education by panel doctors. Ordinary public lectures did not reach the right people, and his society's experience of lectures by panel doctors was not very good. His society arranged successful medical lectures in the schools, and for the explanation of health films.

Mr. H. S. BOMPAS (Sec., Dental Board Health Campaigns) described what the Board did in the matter of organising dental lectures and supplying first-class apparatus free of charge. He found that local authorities sometimes had good schemes only on paper, and that teachers and health visitors knew the requirements of the district best. Some education committees had little enthusiasm. The Dental Board's films had been shown all over Northern Ireland, but they were not allowed in Scotland.

Prof. F. E. WYNNE pointed out that the public health lecturer could not choose the subjects which he thought best because he had to fit his students for an examination conducted by other examiners.

Dr. A. G. ROBB (Belfast Fever Hospitals) thought every nurse should spend some portion of her training in a fever hospital.

Dr. CARSTAIRS DOUGLAS (Anderson College, Glasgow) agreed that sanitary engineering figured too largely in the public health course.

Dr. C. F. L. LEIPOLDT (Cape Town) pointed out that there was no teaching with regard to the normal child in the medical curriculum, and that the qualified medical man had to learn by experience in the schools.

Dr. LETITIA FAIRFIELD urged that teaching should be practical, and Mrs. NEVILLE ROLFE drew attention to the failure to supply health education for the three million adolescents of the country.

SECTION OF THERAPEUTICS.

TREATMENT OF GASTRIC DISEASES.

Dr. A. F. HURST (New Lodge Clinic) opened a discussion on recent advances in treatment, remarking that he was himself unwilling to diagnose gastric or duodenal ulcer without direct X ray evidence, or to diagnose cancer of the stomach without evidence of occult blood in the stools. The fractional test-meal had also led to far more precise diagnosis. Dealing with the treatment of gastric ulcer, he said that the first factor to be dealt with was the acid factor, and this must be combated by diet and by such drugs as belladonna and alkalis. The second factor was that of focal sepsis; he doubted whether any ulcer could occur without such a factor. He stressed the importance of sinus infection and residual infection in the jaws of edentulous patients, to be found only by careful radiography. The other factors of importance were tobacco, worry, and fatigue. The latter factors necessitated treatment in bed. He showed by charts the effect of small feeds at frequent intervals in preventing the appearance of free HCl even when no alkali was given. Repeated X ray examination and search of the stools for occult blood were of value in demonstrating the progress of treatment. As regards after-treatment, he stressed the importance of an ulcer diathesis. Recurrences were usually due to a return to faulty habits, which must be prevented. Recent work had shown that bismuth salts were ineffective as alkalis whereas sodium citrate had high anti-acid powers; it was valuable in that its use involved no risk of alkalosis. Tribasic magnesium or calcium phosphate was also of great value and preferable to sodium bicarbonate and magnesium hydroxide. In conclusion Dr. Hurst spoke of the value of gastric lavage in pyloric obstruction; cicatricial obstruction was rare and would not result if the cases with spasmodic obstruction were rapidly treated. In chronic gastritis, associated with achlorhydria and excess of mucus, great improvement followed gastric lavage with hydrogen peroxide solutions.

Dr. T. IZOD BENNETT (London) said that it was perhaps difficult to speak of recent advances in the treatment of peptic ulcer at a time when the treatment adopted by many of the physicians chiefly interested in this subject had not yet been accepted by the professional in general, although such treatment had been successfully in vogue for ten years or more and had not been greatly modified during that period. He found that surgeons were inclined to condemn physicians merely because they were not magicians; the physician did not expect to cure except by the logical application of certain scientific principles over a period of time which must in some cases be somewhat lengthy. The essentials for successful treatment were, said Dr. Bennett, as follows:—

1. The removal of all sources of focal sepsis.
2. Prolonged and efficient arrest and neutralisation of gastric hyperacidity.
3. The reduction of peristaltic movements in the stomach and duodenum by an appropriate diet given at suitable intervals and so prescribed that the diet itself would exert a neutralising or adsorbing effect on acid.
4. The maintenance of active treatment during a period sufficient to secure permanent healing.
5. Prophylactic treatment aiming at the prevention of relapses.

All of these essentials were important and many of them were missing or insufficiently emphasised in treatments devised prior to that of the late Dr. Bertram Sippy. From a different point of view few of the treatments recommended were exactly on the lines of Sippy's because diets had to be devised to meet the requirements of patients of different nationalities. Prof. W. C. Alvarez, of Rochester, recently stated he had never seen a patient seeking relief for peptic ulcer who had, in his opinion, been efficiently treated prior to his first consultation with him, and it was a fact to-day, said Dr. Bennett, that the vast majority of patients coming under observation had never had treatment in which it could be claimed that the essentials outlined above had been carried out. Alkali is frequently given and almost invariably in insufficient dosage. Patients are treated for weeks and often undergo severe operations without important sources of oral sepsis ever being removed. It is an easy matter to relieve the pain for a patient with gastric or duodenal ulcer, in most cases by restricted diet and the administration of alkali, but unless such treatment is carefully planned and carried out for months after all symptoms have finished, relapse is almost sure to follow. In his opinion patients should be seen in consultation at regular intervals of three months or six months for a long time after they are apparently restored to full health, and at such consultations care should be taken to see that oral sepsis has been removed, that food likely to promote excessive peristalsis or hypersecretion is being avoided, and that large meals are never taken, reliance being placed on intermediate feeds to secure adequate nutrition. Proper attention to these points led to successful results.

Dr. J. H. ANDERSON (Ruthin) stressed the importance of coöperation with the patient. Three months was the minimum time for strict treatment; the first month should be in an institution; the second month as convalescence, and during the third a gradual return to work could be begun. After-treatment should go on for at least two years under supervision and consultation with his own doctor. The appendix was an additional source of infection and should be removed if necessary, but after-treatment should again be in the hands of a physician. Regarding diet he advocated a graduated diet beginning with olive oil and egg and milk at two-hourly intervals, boiled rice and pounded chicken being gradually added. By the twentieth day dry toast, steamed fish, custards, and milk puddings are given. At the end of the month a light bland diet with olive oil between meals is given. The rate at which the diet can be increased varies in individual cases and must be determined according to progress. Of alkalis he supported the use of magnesia salts, although the subject of the most suitable alkali was still being examined. He agreed with Dr. Izod Bennett as to the necessity of time to secure firm healing.

Dr. P. HAMILL (London) stressed the necessity of impressing on the patient the fact that his cure lay in his own hands. He felt that elaborate systems were bad because of the difficulty of applying them at home. He agreed with Dr. Hurst as to the value of sodium citrate. Ten grains of magnesium oxide would neutralise 10 oz. of gastric juice as secreted, 10 g. of magnesium carbonate or chalk, on the other hand, would only neutralise 4 oz., and bismuth was almost without effect. Citrates were valuable for avoiding the clotting of milk. The value of atropine in preventing spasm was to be remembered. It was remarkable how readily patients with gastric ulcer tolerated olive oil. A most important adjuvant to treatment was the use of blood transfusion in cases which had had severe hæmorrhage. Duodenal feeding was sometimes of great value in cases where obstinate pain and vomiting prevented adequate nutrition under oral administration.

Dr. A. P. CAWADIAS (London) emphasised the fact that focal infection was but one of many factors, amongst which constitutional factors in the endocrine system were equally important. He thought protein shock therapy was very valuable in alleviating pain and hastening healing.

The President, Dr. W. LANGDON BROWN (London), summing up the discussion, said that he felt the stomach was often more sinned against than sinning, being an organ essentially resistant to disease. He felt, however, that gastric ulcer was a disease which had become commoner without obvious cause. Rectal feeding had rightly fallen into disrepute. He felt that the Lenhartz diet had been a great advance in its day, but modern treatment recognised the importance of the individual patient's requirements. The importance of hydrochloric acid as a germicide was being more fully recognised, and the administration of this acid in cases of achlorhydria was of great importance. He praised the work of Gibson and others in putting on a firmer basis our knowledge of the alkalis of real value. The pendulum was swinging against the tendency to operate hastily. Hæmorrhage was no longer an indication for operation before adequate medical treatment had been tried. He concluded by refuting the doctrine enunciated at the Cancer Conference that all ulcers should be excised on account of the risk of malignant change. The evidence was that gastric cancer almost invariably arose in cases where there was no sign of any previous disease of the stomach, and the public were already sufficiently alarmed about cancer without the introduction of such a bogy.

Dr. HURST, in reply, emphasised the importance of chronic gastritis as revealed by fractional gastric analysis. He briefly reviewed the results of surgical treatment of gastric ulcer; the mortality of gastrectomy in a famous hospital was 15 per cent.; the mortality of medical treatment was nil and there were practically no cases which could not be cured medically if proper care was given to them.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED AUGUST 11TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 114 (last week 111); scarlet fever, 1322; diphtheria, 813; enteric fever, 174; pneumonia, 592; puerperal fever, 45; puerperal pyrexia, 99; cerebro-spinal fever, 5; acute poliomyelitis, 14; acute polio-encephalitis, 1; encephalitis lethargica, 20; continued fever, 1; dysentery, 22; ophthalmia neonatorum, 132. No case of cholera, plague, or typhus fever was notified during the week.

The following counties each notified three or more cases of enteric fever:—London, 40; Devon, 6; Essex, 28 (of these 22 from Colchester); Kent, 9; Lancaster, 13; Middlesex, 7; Norfolk, 4; Southampton, 7; Surrey, 11; Warwick, 3; Yorks, West Riding, 5; City of York, 5. The total of 174 includes 85 cases of paratyphoid fever, of which 37 were notified in London and 6 in Surrey.

The number of patients in the Infectious Hospitals of the Metropolitan Asylums Board on August 21st–22nd was as follows:—Small-pox under treatment, 12; scarlet fever, 1542; diphtheria, 1553; enteric fever, 120; measles, 169; whooping-cough, 216; puerperal fever, 15 (plus 7 babies); encephalitis lethargica, 71; poliomyelitis, 2; "other diseases," 16. At St. Margaret's Hospital there were 19 babies (plus 11 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 7 (5) from enteric fever, 12 (1) from measles, 2 (0) from scarlet fever, 23 (4) from whooping-cough, 23 (6) from diphtheria, 72 (18) from diarrhœa and enteritis under two years, and 27 (5) from influenza. The figures in parentheses are those for London itself. The monthly statement of deaths from small-pox contains the information that no such death was returned for the month of July.

The fatal cases of enteric fever outside London were reported from Leyton and Rochdale. Of the 19 fatal cases of whooping-cough outside London 6 were reported from Birmingham while Glasgow reported the same number that week. Of deaths from diarrhœa Liverpool reported 11; no other town in England and Wales outside London more than 4, but Glasgow 7 and Dublin 8.

The number of stillbirths registered during the week was 299 in the great towns (corresponding to a rate of 40 per 1000 births), including 48 in London.

A REVOLVING OPEN-AIR HOUSE.—The West London Hospital at Hammersmith has been presented with a revolving open-air house which has been placed on the flat roof of one of the wings. It has been the practice to place convalescent children on the roof in settled weather, but the revolving house now enables them to take shelter in the event of rain. The house will hold from seven to ten children.

VITAL STATISTICS OF ENGLAND AND WALES.

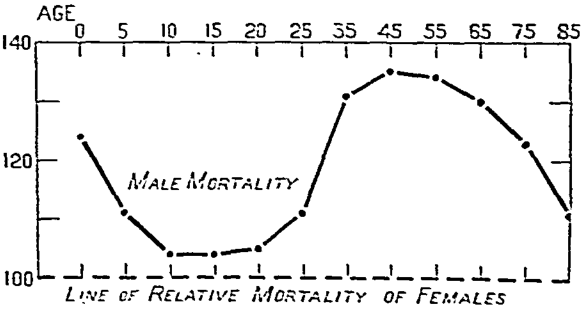
THE REGISTRAR-GENERAL'S REVIEW OF 1926.

THIS third of the volumes[1] in which the General Register Office now presents its annual statistical review is one which is, or at least ought to be, eagerly looked for by all medical officers of health and others interested in the incidence of disease. In fact, we fear it is read by few, and there can be no question that the public health service is the poorer by this default. The health officer who has studied this annual volume has increased his competence for his routine work year by year; he has had suggested to him problems for research which he can pursue; and his faith is fortified in the belief that for the pursuit of such researches there is not needed that knowledge of higher mathematical methods, fear concerning which has restrained timorous persons from inquiries of real public value. The present volume is perhaps the most interesting of a series of valuable medical reports which appear year by year; we can only hope to touch on a few points illustrative of the further riches waiting for extraction from a rich storehouse.

Progressive Ageing.

The progressive ageing of the English population is a phenomenon which it is difficult always to remember, although it has momentous bearing on our present and prospective vital history. The fact that the female death-rate in England and Wales last year was only 10 per 1000 illustrates the importance of remembering that the steadily falling birth-rate is now meaning a relatively small proportion of children under 5, and will before long mean a larger proportion of persons over 55, whose death-rate is higher than that at intermediate ages. It is very easy to fall into the error that such a death-rate means an average duration of life for each person of 100 years. In truth, it only means a duration of about 59·6 years, owing to the facts just mentioned. Hence the necessity for the standardised death-rates used throughout this report, in which adjustments are made for these excesses of persons at certain ages, as compared with an arbitrary standard population.

FIG. 1.



LINE OF RELATIVE MORTALITY OF FEMALES
at each age in 1926.

Much interest attaches to the death-rates in the two sexes at different ages. In Fig. 1 these are shown graphically in relation to each other. Let the straight be the death-rate at such successive age-period for females. Then the upper curve gives the corresponding male death-rate. The curve of the male death-rate is profoundly interesting. At ages 0–5 the male is 24 per cent. in excess of the female death-rate, an early female superiority of which no full explanation has been made. Between 10 and 25 the male inferiority is only some 4 or 5 per cent.; but at ages 45–55 the male death-rate is some 35 per cent. in excess of that of women. As old age approaches so do the death-rates for the two sexes come nearer together.

---

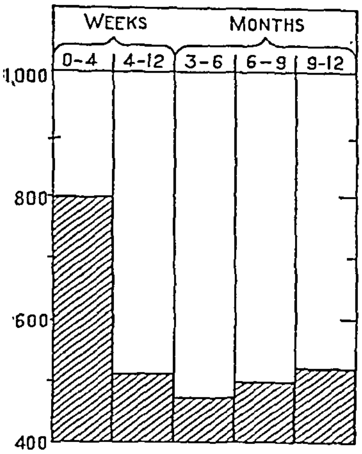
Infant Mortality.

The whole question of infant mortality is dealt with exhaustively, and the student will find here data bearing on every phase of this multiform problem. We can only draw attention to one point. This relates to the constantly reiterated statement that practically no progress has been made in securing a reduced death-rate during the first four weeks after live birth. The real facts are shown in Fig. 2. Comparing the average experience of 1906–10 with that of 1926, it will be seen that at this earlier period of "irreducible" mortality a reduction of over 20 per cent. has been experienced; while at the four subsequent divisions of the first year of life shown in the diagram a reduction of from 47 to 52 per cent. has occurred. It cannot be said that a 20 per cent. improvement is negligible; and with increased care of pregnancy, of childbirth, and of the lying-in period there is ample room for further improvement in this mortality of early infancy—in many parts of the country at all events.

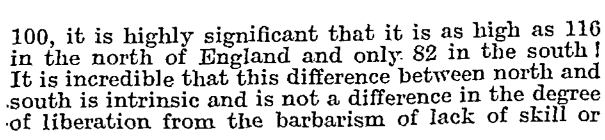
FIG. 2.



Relative infant mortality in 1926 as compared with that in 1906–10 taken as 1000 for five consecutive age-periods in infancy.

That this is so is further illustrated by Table X. on p. 12 of the Review. If the death-rate in the first month of life for England and Wales be stated as 100, it is highly significant that it is as high as 116 in the north of England and only 82 in the south! It is incredible that this difference between north and south is intrinsic and is not a difference in the degree of liberation from the barbarism of lack of skill or care.

FIG. 3.



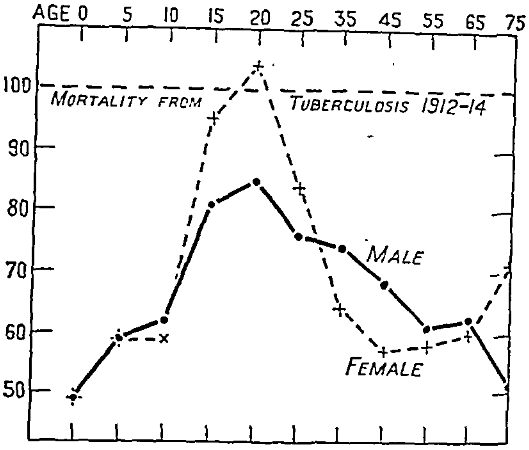
Total Death-rates North and South.

That this latter explanation holds is confirmed by the experience of north and south as regards total death-rate from all causes at successive periods of life. Fig. 3 shows the percentage excess of the northern areas of England over the average for England as a whole in the year 1926. This excess, which as shown in previous reviews, is not limited to industrial towns, calls for painstaking health inquiries in each northern community. The diagram contrasts the north with the whole of England. Evidently if north were contrasted with south the contrast would be even greater.

Tuberculosis.

The whole of this section of the Review should be studied by tuberculosis officers and others. The amount of improvement in the registered death-rate from total tuberculosis, when so recent a period as 1912–14 is compared with 1926, is shown in Fig. 4. Even after allowance has been made for the fact that the decrease of tuberculosis at ages 0–5 may be exaggerated owing to changes in nomenclature, the reduction shown at most ages is most striking. It will be noted that actual death-rates for each age-period are not shown in this diagram, but the percentage difference of the death-rate (male or female) in each age-period from that of 1912–14. For males it is seen that reduction has been experienced at all ages, and that even at the age-period 15–20 this decrease is 19 per cent., while at the age-period 20–25 it is 15 per cent. The smaller decrease at these ages than at other ages indicates a continuance of inimical influences which remain to be studied and removed. The course of the female relative death-rate brings out this point even more strikingly. At ages 15–20 the reduction in the tuberculosis death-rate is only 5 per cent. and at ages 20–25 it has actually increased by 4 per cent. It is impossible to avoid connecting this increase of the female death-rate in early adult life with the increasing migration into towns and the assumption of industrial and commercial in lieu of domestic life.

FIG. 4.

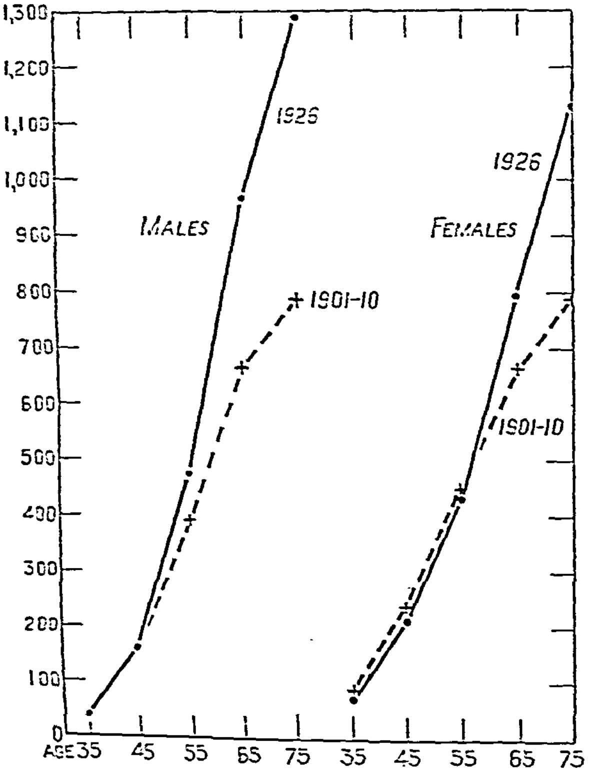


Relative death-rate from total tuberculosis in 1926 for each sex and all age-periods compared with the corresponding rate for 1912–14 taken as 100.

Cancer.

The section of the Review dealing with malignant disease is so important as almost to call for a special article. Doubtless this section of the report will be more eagerly scanned than any other, and it may be hoped that it will serve to temper and curtail the rash statements on the statistics of cancer which recur with monotonous inaccuracy. In view of the exaggerated statements as to increase of cancer Fig. 5 is very instructive. It is drawn from Table XLIII. on p. 64 of the Review. The age-distributed cancer death-rate at successive decades of life from 35 onwards for 1901–10 is compared with that of 1926, for males and females separately. Earlier ages are ignored, as the cancer death-rate is almost negligible prior to age 35. In both males and females an increased death-rate is shown, but this is practically limited to ages over 55 and does not become serious until the age of 65 is reached. This shows in the first instance the folly of writing about crude death-rates from cancer and the need for so-called standardisation. When this is done the registered increase at all ages in male cancer between 1901–10 and 1926 is 30 per cent.; according to the crude death-rate it is 71 per cent. One must remain in some doubt as to the extent to which the increase in cancer at the higher ages is real, and the extent to which it is due to increased accuracy in diagnosis and especially to the greater frequency with which skilled autopsies are now made. In this connexion it may be noted that registered cancer mortality is highest in the denser centres of population, and as pointed out in the Review, the excess in urban centres is much greater for males than for females. It is well-known that the proportion of inaccessible growths, liable to escape recognition as cancer, is much higher for the male sex.

FIG. 5.



Death-rates per million at each age-period 35–45 to 75 and upwards from cancer in the two sexes, 1901–10 being compared with 1926.

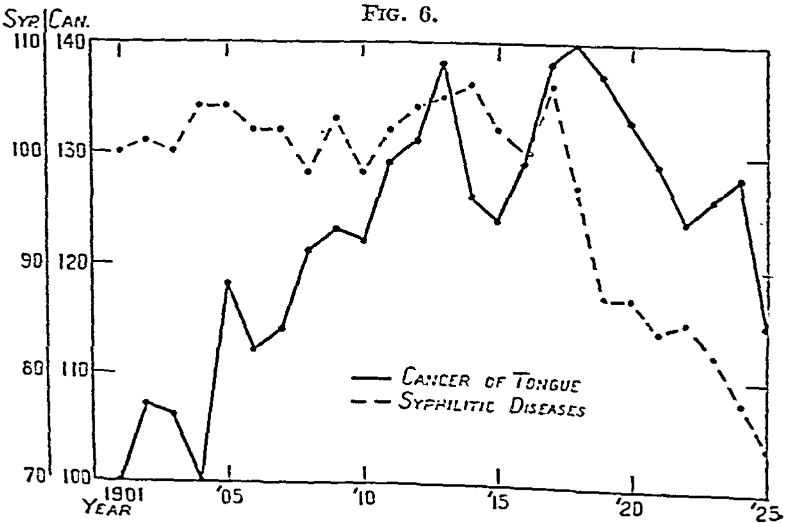
A noteworthy fact is that since 1913 there has been a practical absence of recorded increase of cancer for females, there being no increase of mortality from accessible growths and a comparatively slight rise for cancers in females of inaccessible sites. An important statement on p. 68 of the Registrar-General's Review is based on a revision of a former comparison made between cancer in accessible (easily diagnosable) and inaccessible parts of the body. In a preceding review such a comparison showed definite increase in accessible cancers, a result supporting the view of continuing increase in the death-rate from cancer. More recent returns, however, show that "for both sexes alike, there is no longer any evidence afforded by the comparison of accessible and inaccessible sites in favour of the reality of the recorded increase."

The interpretation of this result, which fits with observations made many years ago on the statistics of Frankfort-on-Main by King and Newsholme, is of course doubtful. It may mean that any apparent increase in inaccessible cancer is due to improved diagnosis; or, as pointed out in the Review, the facts are capable of an explanation of a totally different character. It may be that surgery has secured for the community a stationary position in the death-rate from "accessible" cancers which otherwise would have displayed a death-rate increasing like that of "inaccessible" cancers. Who shall decide? This opens up the great question as to the extent to which death certificates can be trusted to state the localisation of the primary growth when death occurs from cancer. For instance, if several years after a successful operation for cancer of the tongue or mamma (i.e., successful in the sense of no recurrence in the same site) a patient dies of cancer of the liver or some other internal organ, in what proportion of such cases is the primary site of cancer stated in the death certificate? It is hoped that this is usually done, as it ought to be always; but is this view consistent with probabilities; and if not, what is the unknown margin of error? On the individual answer to this question must depend the weight attaching to consideration of death statistics for cancer of various sites. We regard as extremely important the statistics of localised cancer published in the Registrar-General's Review, and trust they will be continued, for every year they will tend to approximate more closely to the natural history of each certified death from cancer. Notwithstanding the inevitable doubt expressed above, Table XLV. on p. 69 of the Review is intensely interesting. In the table of death-rates from cancer we give an incomplete summary of its larger items.

Death-rates from Cancer per Million Living.

Site of disease.	Males.	Females.
Lip, tongue, jaw	105	15
Pharynx and œsophagus	79	18
Stomach and liver	283	223
Intestinal (not rectum)	132	135
Rectum and anus	107	60
Uterus, ovary, vulva	—	206
Breast	2	184
All sites	1010	994

FIG. 6.



Relative (not actual) death-rates from cancer of the tongue and syphilitic diseases, the death-rate for each of these in the year 1900 being taken as 100.

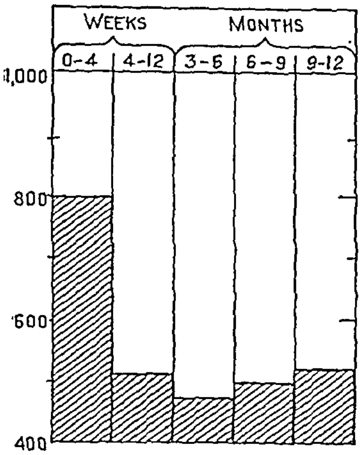
The table, and still more the fuller table from which it has been extracted, is pregnant with suggestions.

early female superiority of which no full explanation has been made. Between 10 and 25 the male inferiority is only some 4 or 5 per cent.; but at ages 45–55 the male death-rate is some 35 per cent. in excess of that of women. As old age approaches so do the death-rates for the two sexes come nearer together.

Infant Mortality.

The whole question of infant mortality is dealt with exhaustively, and the student will find here data bearing on every phase of this multiform problem. We can only draw attention to one point. This relates to the constantly reiterated statement that practically no progress has been made in securing a reduced death-rate during the first four weeks after live birth. The real facts are shown in Fig. 2. Comparing the average experience of 1906–10 with that of 1926, it will be seen that at this earlier period of "irreducible" mortality a reduction of over 20 per cent. has been experienced; while at the four subsequent divisions of the first year of life shown in the diagram a reduction of from 47 to 52 per cent. has occurred. It cannot be said that a 20 per cent. improvement is negligible; and with increased care of pregnancy, of childbirth, and of the lying-in period there is ample room for further improvement in this mortality of early infancy—in many parts of the country at all events.

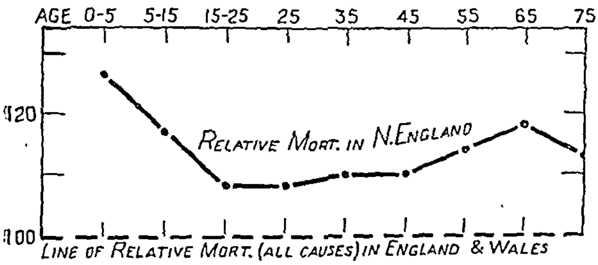
FIG. 2.



Relative infant mortality in 1926 as compared with that in 1906–10 taken as 1000 for five consecutive age-periods in infancy.

That this is so is further illustrated by Table X. on p. 12 of the Review. If the death-rate in the first month of life for England and Wales be stated as 100, it is highly significant that it is as high as 116 in the north of England and only 82 in the south! It is incredible that this difference between north and south is intrinsic and is not a difference in the degree of liberation from the barbarism of lack of skill or care.

FIG. 3.



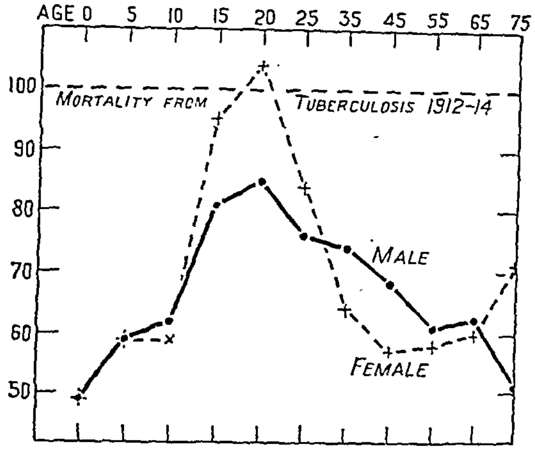
Total Death-rates North and South.

That this latter explanation holds is confirmed by the experience of north and south as regards total death-rate from all causes at successive periods of life. Fig. 3 shows the percentage excess of the northern areas of England over the average for England as a whole in the year 1926. This excess, which as shown in previous reviews, is not limited to industrial towns, calls for painstaking health inquiries in each northern community. The diagram contrasts the north with the whole of England. Evidently if north were contrasted with south the contrast would be even greater.

Tuberculosis.

The whole of this section of the Review should be studied by tuberculosis officers and others. The amount of improvement in the registered death-rate from total tuberculosis, when so recent a period as 1912–14 is compared with 1926, is shown in Fig. 4. Even after allowance has been made for the fact that the decrease of tuberculosis at ages 0–5 may be exaggerated owing to changes in nomenclature, the reduction shown at most ages is most striking. It will be noted that actual death-rates for each age-period are not shown in this diagram, but the percentage difference of the death-rate (male or female) in each age-period from that of 1912–14. For males it is seen that reduction has been experienced at all ages, and that even at the age-period 15–20 this decrease is 19 per cent., while at the age-period 20–25 it is 15 per cent. The smaller decrease at these ages than at other ages indicates a continuance of inimical influences which remain to be studied and removed. The course of the female relative death-rate brings out this point even more strikingly. At ages 15–20 the reduction in the tuberculosis death-rate is only 5 per cent. and at ages 20–25 it has actually increased by 4 per cent. It is impossible to avoid connecting this increase of the female death-rate in early adult life with the increasing migration into towns and the assumption of industrial and commercial in lieu of domestic life.

FIG. 4.



Relative death-rate from total tuberculosis in 1926 for each sex and all age-periods compared with the corresponding rate for 1912–14 taken as 100.

Cancer.

The section of the Review dealing with malignant disease is so important as almost to call for a special article. Doubtless this section of the report will be more eagerly scanned than any other, and it may be hoped that it will serve to temper and curtail the rash statements on the statistics of cancer which recur with monotonous inaccuracy. In view of the exaggerated statements as to increase of cancer Fig. 5 is very instructive. It is drawn from Table XLIII. on p. 64 of the Review. The age-distributed cancer death-rate at successive decades of life from 35 onwards for 1901–10 is compared with that of 1926, for males and females separately. Earlier ages are ignored, as the cancer death-rate is almost negligible prior to age 35. In both males and females an increased death-rate is shown, but this is practically limited to ages over 55 and does not become serious until the age of 65 is reached. This shows in the first instance the folly of writing about crude death-rates from cancer and the need for so-called standardisation. When this is done the which subsoil water percolates. Preventive measures have hitherto failed owing to lack of a unified control in antimalarial operations.

Pasteur Institute at Kasauli.

The Government of India has recognised the value of the work done by the Pasteur Institute of India at Kasauli in offering a grant of Rs.1,14,500 towards non-recurring expenditure besides increasing the annual grant by Rs.10,000. To this offer, however, was attached a provision that this financial help would be given only in case the Institute raised an equivalent amount from other sources, which may be a difficult task. In the meantime rebuilding is urgent. The Maharajah of Dholpur has offered Rs.12,000 towards the provision of electric lighting.

Daylight Saving in Burma.

Among the items for discussion at the forthcoming session of the Burma Legislative Council is the Daylight Saving Bill, which is unique in India. The proposal is similar to the Summer Time Act in England —namely, that from Sept. 1st until April 1st all clocks should be advanced an hour and all business carried on according to the new time.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

The Medical Civil Service.

THE standards of the public health service in American municipalities still leave much to be desired. In a recent survey made by a committee of the American Public Health Association it was found that among 1281 State, county, and city health officers, listed by the U.S. Public Health Service up to the beginning of this year, only 29 had a degree in public health. In 1926 only 104 degrees in public health were granted in our Universities, whereas it has been estimated that the needs of the country as a whole require that 570 health officers should be trained each year. It is obvious that men are not attracted by the profession. Probably the outstanding reason for this is the insecurity of tenure of public health office. It will be remembered how the president of the association recently lost his office in Chicago on purely political grounds. In 156 cities investigated it was found that in less than 20 per cent. was the office regulated by civil service. About one-quarter of these cities appoint their health officers for a term of not more than two years, less than half of them make the appointment "indefinite, or at the pleasure of the appointing body." As a result of these conditions applicants must either be excessively devoted to public service or very badly in need of employment before they are willing to accept office.

Criticism of the B.C.G. Vaccine.

S. A. Petroff and Arnold Branch, of the Trudeau Sanatorium, as a result of a very thorough search of the literature and of their own laboratory experiments with B.C.G. vaccine, come to the conclusion that "watchful waiting is the best position at present in reference to the vaccination of infants." Contrary to the findings of many European workers, these American workers do not find the vaccine constantly innocuous to small laboratory animals. In two instances they were able to demonstrate generalised tuberculosis by direct inoculation into guinea-pigs and in one other instance tuberculosis was established after the second animal passage. Noticing that when B.C.G. was grown on fluid media there appeared two types of colonies, the Trudeau workers became suspicious of the existence of variants similar to those observed in the reproduction of other acid-fast organisms. A small amount of culture received directly from Calmette was triturated in salt solution, filtered through two layers of Whatman paper No. 5, and plated on a gentian-violet medium. After six weeks there appeared two morphologically distinct types of colonies. A comprehensive study of the biology of these two types is to be published shortly. Suffice it to report here that while the type christened "R" always produces some tubercles which in time heal, the type they have named "S" invariably produces progressive disease terminating in the death of the guinea-pig. As regards the reports of successful infant inoculation in Europe they criticise especially the lack of adequate control. They would like to see a series of thoroughly controlled experiments in cattle and on a large scale.

International Congress of Mental Hygiene.

The first International Congress of Mental Hygiene, it is announced, will be held in Washington in the spring of 1930. The meeting was to have been held in 1929, but has been postponed in order to secure greater coöperation with psychiatric associations in this country. It is believed at present that a large and representative attendance of American psychiatrists is now assured. Information on the progress of the plans for the conference may be had by writing to the general secretary, Mr. Clifford W. Beers, 370, Seventh Avenue, New York City.

Small-pox in 1927.

For the fifth year in succession the United States reported more small-pox cases than any other country except India, a total of 38,498 cases for 1927 as against 33,343 cases in 1926. There were, however, only 135 deaths. The New York State Department of Health has been commendably thorough in obtaining vaccination histories for every one of the 368 cases reported in their jurisdiction. Analysis shows that not a single case occurred among those vaccinated successfully during the last seven years; 31 cases occurred among those vaccinated more than seven years previously, and the remaining 337 among individuals who have never been successfully vaccinated.

The Ethics of Pay Clinics.

The Medical Society of the County of New York recently appointed a special committee to inquire into the relation between the pay clinic (for people able to contribute towards the cost of the service rendered) of Cornell University and the practising members of the profession. The committee reports in part as follows:—

> 1. The welfare of the public must be the first consideration of a medical problem, the economic difficulties of the physician being of secondary importance. 2. The Cornell Pay Clinic was a decided departure from the prevailing type of dispensary: (*a*) in that an attempt was made to charge fees that would make the clinic self-supporting; (*b*) in that a diagnostic group clinic was formed for persons of moderate means. 3. There is at present in New York no other dispensary which excludes the indigent poor and to which the person of moderate means may go and have a thorough diagnostic study within his capacity to pay. *Less than* 20 per cent. of the work of the Cornell Pay Clinic is diagnostic. Over 80 per cent. is devoted to the routine treatment of patients. The clinic is thus in active competition with physicians who earn their living.

The committee concludes that the Cornell Clinic does not actually violate any State law; it does not object to Cornell holding a diagnostic clinic for teaching purposes, provided such a clinic is subsidised by the University, but it is opposed on principle to pay clinics for treatment under all circumstances. Counsel for the Society is instructed to investigate the legal aspects of the situation more thoroughly.

Rocky Mountain Spotted Fever.

Recent investigations into the ætiology and prevention of this disease were reported by Dr. R. R. Parker, of the U.S. Public Health Service, to the Fourth International Congress of Entomology now being held at Ithica, New York. There is a remarkable variation in the case-mortality of this tick-borne disease. In some parts of Montana the fatalities amount to 90 per cent. of the case-incidence, for further research, and invites immediate speculation—which may lead to research—as to the causation of the extraordinary sex differences in the incidence of fatal cancer. Why this excess of cancer of the mouth in men? Is it due to their lower standard of oral hygiene? Is it due to smoking or to the drinking of strong alcoholic spirits, or to syphilis? To this point we return later. Does a similar explanation apply to the excessive male cancer mortality of the pharynx and stomach. Or do other indulgences of the table explain the difference? The possible relation of uterine cancer to avoidable traumatism in child-bearing necessarily arises, and the fact that mammary cancer is increasing unlike uterine cancer calls for separate investigation.

Preceding remarks have a bearing on a diagram on p. 72 of the Review displaying a most suggestive comparison between the course in recent years of mortality from cancer of the tongue and from syphilis. In Fig. 6 the course of the death-rate from cancer of the tongue and that for the death-rate from the diseases which collectively give a fair index of fatal syphilis in the community are compared. In each case we have reduced the death-rates to a relative amount, each death-rate being given in proportion to the initial item stated as 100. The earlier part of the cancer curve shows a rapid increase in the death-rate from cancer of the tongue without any evidence of relation to the syphilitic death-rate. This may or may not indicate increasing accuracy in certification of the original site of cancer, or it may or may not mean an actual increase of cancer of this site, or both. The second half of the two curves from 1914 onwards displays a suggestive parallelism, though the Review is most cautious in deprecating premature pronouncement on this point. The general course of the curves shows that with decreased syphilis has gone decreased cancer of the tongue (as certified in death-returns) and confirms the wide pathological impression that there is a causal relation between the injury produced by earlier syphilitic lesions and later cancerous changes. As pointed out in the Review, "decrease of syphilis is not the only influence making for decrease of lingual cancer known to have been operative during the last few years." Among other influences may be mentioned improved dental care.

The continuing increase in the death-rate recorded from cancer of the breast is intriguing. In 1901–10 it averaged 158, in 1911–20 it was 171, and in 1926 it had increased to 184 per million of population (standardised). But in the period under comparison operations on mammary cancer have become more drastic and complete, and the real increase in mammary cancer may be greater than the figures display, for two reasons: more patients completely recover than in the past, and if the interval between operation and recurrence in another part of the body has increased, there is a greater likelihood that the medical certifier omits the mamma in his death certificate. But, on the other hand, such omission of primary breast cancer when death is directly due to an internal cancer was even more likely in the earlier years of registration, as is clearly shown in the parallel case of the decline in mortality from cancer of the liver. Who shall decide? We are left with an increased sense of the necessary limitations of massed statistics of cause of death when one attempts refinements of localisation of disease.

THE RETIREMENT OF DR. E. C. THOMPSON.—The committee of management of Tyrone County Hospital has accepted, with regret, the resignation of Dr. Edward Charles Thompson, who was appointed surgeon to the hospital in March, 1875. He succeeded his father, who had held the appointment for 40 years, making a total, for father and son, of 93 years' service. Dr. Thompson, who early in life received the Albert Medal and the St. John's Medal for bravery in saving life on land, sat in Parliament as a Constitutional Nationalist for North Monaghan from 1900 to 1906. He was formerly President of the North of Ireland Branch of the British Medical Association.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

The Incidence of Leprosy.

KNOWLEDGE of the incidence of leprosy in India is dependent on the 1921 census figures which were collected by untrained enumerators and are avowedly inaccurate. These figures, while they give very little idea of the total number of lepers in India, are useful as indicating the relative incidence in different provinces and districts. With a view to the collection of more accurate information an experimental survey of selected areas was instituted which has brought to light such facts and figures as to carry conviction of the necessity of continuing it at least to the end of 1928. The survey was begun experimentally in the Manbhum district of Bihar and Orissa, the Manbazar and Raghunathpur *thanas* being surveyed. Then the Onda and Gangajalghati *thanas* of the Bankura district of Bengal were surveyed; thereafter three areas in the Sonthal Parganas, and the end of the year found the survey party in the Chin Hills of Burma. In the first three districts the incidence of leprosy was found to be between four and five times that given by the census figures, but it cannot be claimed that even this survey has revealed the total incidence. The important advance made in the treatment of leprosy is the adoption of potassium iodide, the effect of which has been known for a long time, although the reactions caused by ordinary doses in the best known types of leprosy had led to its being considered dangerous. Clinical and pathological study at the Calcutta School has led to a classification of certain types and phases of leprosy which benefit from iodide. The full significance of the survey may be seen in the report of the Indian Council of the British Empire Leprosy Relief Association, which has just appeared.

Street Watering and Disease.

A prominent public health authority has again drawn attention to the dangers associated with the indiscriminate use of unfiltered water for spraying the streets of Calcutta. The water that is used for spraying is drawn from the most polluted portion of the river; it is practically raw sewage. When the silt that is thrown on the streets along with the water is nearly dry, and before it is sterilised by the sun, it is scattered all over the city by the wind. The dust teems with microbes and is undoubtedly a potent cause of eye, throat, ear, and nose ailments in the city. It is also responsible for many cases of septic pneumonia. Until the unfiltered water-supply is stopped and only filtered water used Calcutta will remain a city in which respiratory complaints flourish.

Malaria Problem in Bombay City.

That malaria has become much more widely diffused in Bombay within the last 15 years is the keynote of a report presented recently by the Government malariologist to the Bombay Corporation. The disease is still prevalent to a serious extent in the southern part of the city, due chiefly to the presence of unprotected wells; but the most intense malaria at the present time is in the vicinity of the mills, more especially in the Worli section. In certain areas from 30 to 70 per cent. of the children examined have shown evidence of malarial infection. It is possible that there is more endemic malaria in Bombay at the present time than there was in 1911. Apart from its effect on the health of the population and on the infant mortality of the city, the disease is the cause of very heavy financial loss to the city. There is no natural malaria in Bombay, the chief reason being the absence of natural streams. The cause of its prevalence in the city is the presence of thousands of permanent breeding-places artificially produced by man, the most important of which are wells, cisterns, fountains, tanks, water used in building construction, leakages from reservoirs, water-pipes, and cellars into which subsoil water percolates. Preventive measures have hitherto failed owing to lack of a unified control in antimalarial operations.

Pasteur Institute at Kasauli.

The Government of India has recognised the value of the work done by the Pasteur Institute of India at Kasauli in offering a grant of Rs.1,14,500 towards non-recurring expenditure besides increasing the annual grant by Rs.10,000. To this offer, however, was attached a provision that this financial help would be given only in case the Institute raised an equivalent amount from other sources, which may be a difficult task. In the meantime rebuilding is urgent. The Maharajah of Dholpur has offered Rs.12,000 towards the provision of electric lighting.

Daylight Saving in Burma.

Among the items for discussion at the forthcoming session of the Burma Legislative Council is the Daylight Saving Bill, which is unique in India. The proposal is similar to the Summer Time Act in England—namely, that from Sept. 1st until April 1st all clocks should be advanced an hour and all business carried on according to the new time.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

The Medical Civil Service.

THE standards of the public health service in American municipalities still leave much to be desired. In a recent survey made by a committee of the American Public Health Association it was found that among 1281 State, county, and city health officers, listed by the U.S. Public Health Service up to the beginning of this year, only 29 had a degree in public health. In 1926 only 104 degrees in public health were granted in our Universities, whereas it has been estimated that the needs of the country as a whole require that 570 health officers should be trained each year. It is obvious that men are not attracted by the profession. Probably the outstanding reason for this is the insecurity of tenure of public health office. It will be remembered how the president of the association recently lost his office in Chicago on purely political grounds. In 156 cities investigated it was found that in less than 20 per cent. was the office regulated by civil service. About one-quarter of these cities appoint their health officers for a term of not more than two years, less than half of them make the appointment "indefinite, or at the pleasure of the appointing body." As a result of these conditions applicants must either be excessively devoted to public service or very badly in need of employment before they are willing to accept office.

Criticism of the B.C.G. Vaccine.

S. A. Petroff and Arnold Branch, of the Trudeau Sanatorium, as a result of a very thorough search of the literature and of their own laboratory experiments with B.C.G. vaccine, come to the conclusion that "watchful waiting is the best position at present in reference to the vaccination of infants." Contrary to the findings of many European workers, these American workers do not find the vaccine constantly innocuous to small laboratory animals. In two instances they were able to demonstrate generalised tuberculosis by direct inoculation into guinea-pigs and in one other instance tuberculosis was established after the second animal passage. Noticing that when B.C.G. was grown on fluid media there appeared two types of colonies, the Trudeau workers became suspicious of the existence of variants similar to those observed in the reproduction of other acid-fast organisms. A small amount of culture received directly from Calmette was triturated in salt solution, filtered through two layers of Whatman paper No. 5, and plated on a gentian-violet medium. After six weeks there appeared two morphologically distinct types of colonies. A comprehensive study of the biology of these two types is to be published shortly. Suffice it to report here that while the type christened "R" always produces some tubercles which in time heal, the type they have named "S" invariably produces progressive disease terminating in the death of the guinea-pig. As regards the reports of successful infant inoculation in Europe they criticise especially the lack of adequate control. They would like to see a series of thoroughly controlled experiments in cattle and on a large scale.

International Congress of Mental Hygiene.

The first International Congress of Mental Hygiene, it is announced, will be held in Washington in the spring of 1930. The meeting was to have been held in 1929, but has been postponed in order to secure greater coöperation with psychiatric associations in this country. It is believed at present that a large and representative attendance of American psychiatrists is now assured. Information on the progress of the plans for the conference may be had by writing to the general secretary, Mr. Clifford W. Beers, 370, Seventh Avenue, New York City.

Small-pox in 1927.

For the fifth year in succession the United States reported more small-pox cases than any other country except India, a total of 38,498 cases for 1927 as against 33,343 cases in 1926. There were, however, only 135 deaths. The New York State Department of Health has been commendably thorough in obtaining vaccination histories for every one of the 368 cases reported in their jurisdiction. Analysis shows that not a single case occurred among those vaccinated successfully during the last seven years; 31 cases occurred among those vaccinated more than seven years previously, and the remaining 337 among individuals who have never been successfully vaccinated.

The Ethics of Pay Clinics.

The Medical Society of the County of New York recently appointed a special committee to inquire into the relation between the pay clinic (for people able to contribute towards the cost of the service rendered) of Cornell University and the practising members of the profession. The committee reports in part as follows:—

> 1. The welfare of the public must be the first consideration of a medical problem, the economic difficulties of the physician being of secondary importance. 2. The Cornell Pay Clinic was a decided departure from the prevailing type of dispensary: (*a*) in that an attempt was made to charge fees that would make the clinic self-supporting; (*b*) in that a diagnostic group clinic was formed for persons of moderate means. 3. There is at present in New York no other dispensary which excludes the indigent poor and to which the person of moderate means may go and have a thorough diagnostic study within his capacity to pay. Less than 20 per cent. of the work of the Cornell Pay Clinic is diagnostic. Over 80 per cent. is devoted to the routine treatment of patients. The clinic is thus in active *competition* with physicians who earn their living.

The committee concludes that the Cornell Clinic does not actually violate any State law; it does not object to Cornell holding a diagnostic clinic for teaching purposes, provided such a clinic is subsidised by the University, but it is opposed on principle to pay clinics for treatment under all circumstances. Counsel for the Society is instructed to investigate the legal aspects of the situation more thoroughly.

Rocky Mountain Spotted Fever.

Recent investigations into the ætiology and prevention of this disease were reported by Dr. R. R. Parker, of the U.S. Public Health Service, to the Fourth International Congress of Entomology now being held at Ithica, New York. There is a remarkable variation in the case-mortality of this tick-borne disease. In some parts of Montana the fatalities amount to 90 per cent. of the case-incidence, whereas in the neighbouring State of Idaho the case-mortality has been no higher than 5 per cent. During the last few months, however, the use of a serum has been definitely effective in cutting down the death-rate.

THE GERMAN SICKNESS INSURANCE SYSTEM.*

THIS volume, the latest addition to the valuable series of publications issued by the International Labour Office on the subject of national health insurance, fully maintains the high standard set by its predecessors. It is evidently the fruit of much study and reflection and should be found useful by those who in other countries are grappling with the various problems of sickness insurance. Hitherto the recent experience of compulsory insurance against sickness in the land of its origin has been almost inaccessible to English readers who do not read German, for the two leading books in English on the subject, Mr. Dawson's "*Social Insurance in Germany*" and Mr. Gibbon's "Medical Benefit in Germany and Denmark," were published in 1912, and much has happened to the German insurance system within the past 16 years. To English readers, therefore, this book makes an especially welcome appearance.

Compulsory insurance against sickness on a national scale in Germany dates from June, 1883, although the principle of compulsion had already been introduced in various parts of the Empire; in Prussia miners had been compulsorily insured since 1854. At first the national scheme applied only to persons employed in certain named occupations, but others were added from time to time, especially by the important Act of 1911, which brought agricultural labourers and domestic servants within the scheme. At the present time the number of insured persons is rather more than 20,000,000, or nearly one-third of the total population. In Germany, insurance is compulsory not only against sickness, but also against invalidity and old age, and against industrial accidents (workmen's compensation). Each of these three forms of insurance is administered by a separate body of organisations; sickness insurance by the sickness funds (*Krankenkassen*), which are self-governing associations of insured persons and contributing employers; invalidity and old age insurance by the local insurance authorities, which are bureaucratic institutions with some representation of insured persons and employers; and accident insurance, to which the employees do not contribute, by mutual associations of employers. Moreover, sickness insurance is not regulated by a single code as in this country; there is a separate body of law for wage-earners, and another for salaried employees, while miners are insured under special Acts which provide a single system of sickness, invalidity, and old age insurance. The whole subject is exceedingly complex and difficult to understand, and Dr. Goldmann and Dr. Grotjahn are to be congratulated on the very considerable measure of success they have achieved in explaining it to the general reader.

Tendencies of Sickness Insurance.

Compulsory sickness insurance appears everywhere to develop on certain broad lines, which may most profitably be studied in Germany, where insurance on a compulsory basis has existed longer than in other countries. First, the proportion of the total population coming under insurance tends continually to increase, partly by the inclusion of additional occupations, but chiefly by the extension of insurance benefits to the dependents of the insured persons. This extension has made great progress in Germany since the war, and it is now estimated that in addition to the 20 million insured persons there are nearly 19 million dependents for whom benefits are available under the sickness insurance system, the total number forming more than three-fifths of the whole population. Secondly, cash benefits have become relatively less important than benefits in kind—medical treatment, &c. Experience has shown that it is more economical to provide the treatment necessary to restore working capacity than to provide the disabled worker with money to use at his own discretion. Consequently, the range of treatment provided by the sickness funds has greatly increased. Thirdly, a rapidly increasing activity is being displayed in the field of prevention.

Range of Treatment.

Treatment is given on a scale that is surprising to the English reader. The insured person in Germany is not only entitled to the services of a general practitioner, as in this country, but he has also provided for him the whole range of modern therapeutic measures—specialist services, including electro-physical, balneological, and orthopædic treatment, and treatment and maintenance in sanatoriums and other residential institutions. Treatment may be given by arrangement between the sickness fund and outside institutions, but in many cases the funds make direct provision in their own institutions. The General Local Sickness Fund of Hamburg has four institutes for artificial sunlight therapy and a large orthopædic institute for making appliances, where in 1925 there were made 5424 trusses, 16,305 flat-foot supports, 3352 abdominal belts, and nearly 18,000 other articles. In 1924 no less than 19,906 X ray examinations were made in the institute of the Association of Berlin Sickness Funds, and 13,715 in the Institute of the Dresden Local Sickness Fund. Diagnostic facilities are provided on a large scale. The Institute of the Association of the Berlin Sickness Funds contains chemical, pathological, bacteriological, and serological departments, and makes between 5000 and 6000 examinations monthly. In 1924 it was consulted by about 3000 insurance doctors in Berlin. In-patient hospital treatment is usually provided by arrangement with institutions established by the communes or voluntary organisations, but some funds have established hospitals of their own; the miners' funds have 21 hospitals with 3970 beds.

Dental treatment is given on a rapidly increasing scale. There are some 8000 dentists in Germany, and about 6000 are employed by the sickness funds. The average expenditure on dental treatment per member by the funds rose from M.0·50 in 1914 to M.2·35 in 1925. In the Hamburg funds the average expenditure in the latter year was M.3·72 per member.

Preventive Work of the Sickness Funds.

In recent years there has been a remarkable development of the preventive side of sickness insurance. For instance, special attention is given to maternity and child welfare. The statutory maternity benefits, which are provided for both insured and their dependents, include (1) attendance by a midwife, and, if necessary, medical attendance; (2) a lump sum payment of M.10; (3) a weekly payment during the four weeks preceding and the six weeks following confinement; and (4) an additional weekly cash payment during 12 weeks after confinement to those mothers who nurse their babies. The funds contribute to the communal maternity and child welfare centres, and some have established centres of their own, which are widely consulted; the centre of the Erfurt Sickness Fund is consulted by nearly 80 per cent. of the mothers of the area. Dr. Goldmann and Dr. Grotjahn think that the effort put forth in this direction is still inadequate, but there seems no doubt that an enormous amount of good work is being done. The funds participate in welfare work among school-children, they contribute towards the provision of country homes, forest schools, open-air baths, games, &c. Some funds maintain their own country institutions; the Sonneberg Fund has its own forest school, where the children have facilities for sun baths, swimming, gymnastics, &c. Contributions are made towards school meals; in 1925 the Cologne Funds contributed 45 per cent. of the cost of the meals provided by the municipality for school-children. Many funds provide orthopædic gymnastics for the children of the members.

* Benefits of the German Sickness Insurance System. By Franz Goldmann, M.D., and Alfred Grotjahn, M.D. International Labour Office. Studies and Reports, Series M (Social Insurance), No. 8. Published in the United Kingdom for the International Labour Office by P. S. King and Son. 1928. Pp. 188. 4s.

In the antituberculosis campaign the lead, so far as the insurance organisations are concerned, has been taken by the invalidity insurance institutions, but the sickness funds are now taking an active part in the work. The facilities they afford for free medical examination, with various kinds of specialist assistance, tend to the early detection of the disease, and the sick visitors of the funds encourage the members to seek medical advice when disease is suspected. The funds contribute largely to the maintenance of sanatoriums and dispensaries and some have established institutions of their own. What is regarded as an important health measure, especially in this connexion, is the provision of convalescent treatment and recuperation in country convalescent and holiday homes, forest camps, &c., particularly for young workers newly exposed to the stress of economic employment. The funds participate in the anti-alcohol and antivenereal movements, and a system of compulsory notification of venereal disease, with supervision of the patients, has been instituted by a number of the funds. Much health propaganda is carried out by such means as the distribution of pamphlets and periodicals, the organisation of lectures, health exhibitions, films, plays, &c. The Central Union of German Sickness Funds publishes a monthly health journal which has a circulation of nearly half a million. The first German "Health Week" was organised jointly in 1925 by the municipality of Berlin and the sickness funds, and this was followed in 1926 by a "National Health Week" largely owing to the efforts of the funds.

The Sickness Funds and the Medical Profession.

The extensive range of the medical services provided by the sickness funds brings them into close relation with the great body of the medical profession in Germany. It is estimated that about 30,000 doctors, or 80 per cent. of the whole profession, work for the funds, and that for the great majority this work forms the chief source of their income. Dr. Goldmann and Dr. Grotjahn estimate that more than half of all incomes from medical practices in Germany is derived from sickness insurance. The system of employment of doctors and the methods and amount of remuneration differ widely amongst the various funds, but the system of free choice of doctor, which is one of the basic demands of the profession, appears to be making headway. Before 1923 the funds were practically autonomous in making arrangements with the doctors, but in that year provisions were introduced into the Federal Insurance Code to regulate the doctors' contracts, so that certain conditions of service are common to the whole country. The funds, however, still possess a considerable measure of autonomy.

Some Criticisms of the German System.

The German sickness insurance system is a wonderful achievement in the field of social reform, but as the authors of this volume do not hesitate to point out, it is by no means free from defects. The work of the funds appears to be imperfectly coördinated with the health work of other agencies and there is much overlapping and duplication of effort, which could be avoided by improvements in organisation. Again, the system has not succeeded in attaining the vitally important object of securing harmonious relations between the administrative bodies and the medical profession, and our authors think that no real improvement may be expected until something like the British system is adopted under which the local arrangements with the doctors are made by an insurance committee on which the local medical profession is represented.

The utility of this volume to the foreign reader would have been enhanced if the authors had included a preliminary account of the general framework of the German social insurance system, explaining the organisation of the different agencies concerned in the various forms of insurance, their relation to each other and to the local authorities and the State. Certain technical terms—e.g., "basic wage"—might usefully have been defined and explained and the statistics brought to a later date than 1925, when for the most part they end. And the medical reader would have welcomed fuller information on the subject of the relation of the funds to the doctors, the nature of the problems that have arisen in that connexion, and the progress that is being made towards their solution. These, however, are but minor criticisms of an important work of sterling value and utility.

MEDICINE AND THE LAW.

Dangerous Drugs Legislation.

THE *London Gazette* of August 17th gave notice that the Dangerous Drugs Act of 1925 will come into force on Sept. 25th, 1928, that being the date when the International Opium Covention signed at Geneva in February, 1925, begins to operate. The notification will recall to our readers the abrupt termination of the proceedings against Colonel Kynaston, when counsel for the Crown admitted in the Court of Criminal Appeal that the Act of 1925 (cited, possibly unnecessarily, in the framing of the charges in that case) was not yet operative. The proceedings consequently resembled, as the Lord Chief Justice remarked, the pulling of a bell-rope when there was no bell at the other end. The Geneva Convention of 1925 provided (by Article 8) that, if the Health Committee of the League of Nations, after having submitted the question for advice and report to the Permanent Committee of the Office International d'Hygiène Publique in Paris, found that any preparation containing any of the narcotics referred to in Chapter III. of the Convention—i.e., drugs to which Part III. of our Dangerous Drugs Act, 1920, as amended, applies—could not give rise to the drug habit on account of the medicaments with which those narcotics are compounded and which in practice preclude the recovery of the said drugs, then the Health Committee should communicate the finding to the parties to the Convention and thereupon the provisions of the Convention should not apply to the preparation concerned. Our 1925 Act was passed to give effect to the Geneva Convention. The resultant changes in our dangerous drugs legislation are these: Part I. of our Dangerous Drugs Act of 1920 (regulating dealings in raw opium and restricting its import and export) is extended to coca leaves, Indian hemp, and resins obtained from Indian hemp, and all preparations of which such resins form the base. "Coca leaves" and "Indian hemp" are specially defined. Section 2 of the 1920 Act enacted that nobody should export raw opium from the United Kingdom except under licence and from approved ports, *and except in packages marked in the prescribed manner with an indication of the contents thereof*. The italicised words now cease to have effect. The 1925 Act also substitutes a new definition of the drugs to which Part III. of the 1920 Act applies, and a new definition of "medicinal opium." Finally, it authorises the making of Orders in Council excluding preparations from Part III. of the 1920 Act where there has been a finding under Article 8 of the Geneva Convention as already described.

whereas in the neighbouring State of Idaho the case-mortality has been no higher than 5 per cent. During the last few months, however, the use of a serum has been definitely effective in cutting down the death-rate.

THE GERMAN SICKNESS INSURANCE SYSTEM.*

THIS volume, the latest addition to the valuable series of publications issued by the International Labour Office on the subject of national health insurance, fully maintains the high standard set by its predecessors. It is evidently the fruit of much study and reflection and should be found useful by those who in other countries are grappling with the various problems of sickness insurance. Hitherto the recent experience of compulsory insurance against sickness in the land of its origin has been almost inaccessible to English readers who do not read German, for the two leading books in English on the subject, Mr. Dawson's "Social Insurance in Germany" and Mr. Gibbon's "Medical Benefit in Germany and Denmark," were published in 1912, and much has happened to the German insurance system within the past 16 years. To English readers, therefore, this book makes an especially welcome appearance.

Compulsory insurance against sickness on a national scale in Germany dates from June, 1883, although the principle of compulsion had already been introduced in various parts of the Empire; in Prussia miners had been compulsorily insured since 1854. At first the national scheme applied only to persons employed in certain named occupations, but others were added from time to time, especially by the important Act of 1911, which brought agricultural labourers and domestic servants within the scheme. At the present time the number of insured persons is rather more than 20,000,000, or nearly one-third of the total population. In Germany, insurance is compulsory not only against sickness, but also against invalidity and old age, and against industrial accidents (workmen's compensation). Each of these three forms of insurance is administered by a separate body of organisations; sickness insurance by the sickness funds (*Krankenkassen*), which are self-governing associations of insured persons and contributing employers; invalidity and old age insurance by the local insurance authorities, which are bureaucratic institutions with some representation of insured persons and employers; and accident insurance, to which the employees do not contribute, by mutual associations of employers. Moreover, sickness insurance is not regulated by a single code as in this country; there is a separate body of law for wage-earners, and another for salaried employees, while miners are insured under special Acts which provide a single system of sickness, invalidity, and old age insurance. The whole subject is exceedingly complex and difficult to understand, and Dr. Goldmann and Dr. Grotjahn are to be congratulated on the very considerable measure of success they have achieved in explaining it to the general reader.

Tendencies of Sickness Insurance.

Compulsory sickness insurance appears everywhere to develop on certain broad lines, which may most profitably be studied in Germany, where insurance on a compulsory basis has existed longer than in other countries. First, the proportion of the total population coming under insurance tends continually to increase, partly by the inclusion of additional occupations, but chiefly by the extension of insurance benefits to the dependents of the insured persons. This extension has made great progress in Germany since the war, and it is now estimated that in addition to the 20 million insured persons there are nearly 19 million dependents for whom benefits are available under the sickness insurance system, the total number forming more than three-fifths of the whole population. Secondly, cash benefits have become relatively less important than benefits in kind—medical treatment, &c. Experience has shown that it is more economical to provide the treatment necessary to restore working capacity than to provide the disabled worker with money to use at his own discretion. Consequently, the range of treatment provided by the sickness funds has greatly increased. Thirdly, a rapidly increasing activity is being displayed in the field of prevention.

Range of Treatment.

Treatment is given on a scale that is surprising to the English reader. The insured person in Germany is not only entitled to the services of a general practitioner, as in this country, but he has also provided for him the whole range of modern therapeutic measures—specialist services, including electro-physical, balneological, and orthopædic treatment, and treatment and maintenance in sanatoriums and other residential institutions. Treatment may be given by arrangement between the sickness fund and outside institutions, but in many cases the funds make direct provision in their own institutions. The General Local Sickness Fund of Hamburg has four institutes for artificial sunlight therapy and a large orthopædic institute for making appliances, where in 1925 there were made 5424 trusses, 16,305 flat-foot supports, 3352 abdominal belts, and nearly 18,000 other articles. In 1924 no less than 19,906 X ray examinations were made in the institute of the Association of Berlin Sickness Funds, and 13,715 in the Institute of the Dresden Local Sickness Fund. Diagnostic facilities are provided on a large scale. The Institute of the Association of the Berlin Sickness Funds contains chemical, pathological, bacteriological, and serological departments, and makes between 5000 and 6000 examinations monthly. In 1924 it was consulted by about 3000 insurance doctors in Berlin. In-patient hospital treatment is usually provided by arrangement with institutions established by the communes or voluntary organisations, but some funds have established hospitals of their own; the miners' funds have 21 hospitals with 3970 beds.

Dental treatment is given on a rapidly increasing scale. There are some 8000 dentists in Germany, and about 6000 are employed by the sickness funds. The average expenditure on dental treatment per member by the funds rose from M.0·50 in 1914 to M.2·35 in 1925. In the Hamburg funds the average expenditure in the latter year was M.3·72 per member.

Preventive Work of the Sickness Funds.

In recent years there has been a remarkable development of the preventive side of sickness insurance. For instance, special attention is given to maternity and child welfare. The statutory maternity benefits, which are provided for both insured and their dependents, include (1) attendance by a midwife, and, if necessary, medical attendance; (2) a lump sum payment of M.10; (3) a weekly payment during the four weeks preceding and the six weeks following confinement; and (4) an additional weekly cash payment during 12 weeks after confinement to those mothers who nurse their babies. The funds contribute to the communal maternity and child welfare centres, and some have established centres of their own, which are widely consulted; the centre of the Erfurt Sickness Fund is consulted by nearly 80 per cent. of the mothers of the area. Dr. Goldmann and Dr. Grotjahn think that the effort put forth in this direction is still inadequate, but there seems no doubt that an enormous amount of good work is being descendants never will produce diphtheria toxin, there is no means, so far as I know, of distinguishing them from other races similar in all respects except that their recent ancestors were known to have been toxigenic—i.e., to have possessed a different antigenic make up. As the word indicates, antigenic characters in a parasite imply reactions in the host and hence are of paramount importance in medicine. In spite of this fact, it is debatable if antigenic qualities are in general sufficiently stable for differentiation of "species," however useful they may be in describing subspecies, types, races, varieties, and special strains within the species.

* Benefits of the German Sickness Insurance System. By Franz Goldmann, M.D., and Alfred Grotjahn, M.D. International Labour Office. Studies and Reports, Series M (Social Insurance); No. 8. Published in the United Kingdom for the International Labour Office by P. S. King and Son. 1928. Pp. 188. 4s.

For these reasons I personally dislike including any reference to toxigenicity in the description of *C. diphtheriæ* as a "species"; but the subject is full of difficulties of which this correspondence is only able to give a hint. However, Dr. Arkwright's letter illustrates clearly one point of practical importance—that, until there is a universally used standard bacterial nomenclature, where an author refers to a subdivision of the bacteria, he must take care that it is possible for others to understand exactly what he means. I plead guilty to not having done so in my previous letter.

I am, Sir, yours faithfully,
SHELDON F. DUDLEY.

PAPWORTH COLONY AND SANATORIUM TREATMENT.

To the Editor of THE LANCET.

SIR,—Several daily papers represented at the recent Dublin Congress have been devoting leading articles to the above; and, so far as they help Dr. Varrier-Jones's cause, they will do nothing but good. Unfortunately, however, they give the impression that sanatorium treatment has been a failure, a statement which is at most a half-truth, and much to be deplored.

The immediate results of sanatorium treatment are surprisingly good; favourable cases are restored to health, and many unfavourable ones are much improved. In the most favourable, the good results are permanent; but, unfortunately, four-fifths of those applying for treatment have already passed the most favourable stage, or for other reasons are not likely to make a complete recovery, whatever the treatment. In such cases the results of sanatorium treatment are conditional, and relapses happen if the quarters are unsatisfactory, the conditions of life are unhealthy, or the rules learnt in the sanatorium forgotten or ignored. To blame the methods of treatment because the after-conditions are not satisfied is not logical. One of these after-conditions is the possibility of earning an adequate wage under healthy conditions. Another is to permit of rest in the open-air if symptoms arise which call for it. It is a great merit of Dr. Varrier-Jones's arrangements at Papworth that these three essentials are provided. His methods are not a substitute for sanatorium methods (for there is no substitute), but they are a valuable extension. Many of his inmates have had some treatment in a sanatorium; and any of them receives a similar treatment in the colony whenever he needs it.

From the earliest days of sanatorium propaganda it was clearly stated that the sanatorium is only one link—though an essential one—in the chain of treatment. So long as the fear of infection prevents the sanatorium patient from obtaining remunerative employment under suitable conditions, the need for colonies like Papworth, or for special workshops as advocated by the late Dr. F. S. Tinker, will be urgent; but they are not, and cannot be, a substitute for the sanatorium, which combines advantages in the same way as a hospital for other ailments.

I am, Sir, yours faithfully,
F. R. WALTERS.

Farnham, Surrey, August 25th, 1928.

THE LATER RESULTS OF PARTIAL GASTRECTOMY FOR GASTRIC AND DUODENAL ULCER.

To the Editor of THE LANCET.

SIR,—A study of the figures relating to chronic gastric and duodenal ulcer given by Mr. Norman Lake in his paper on the "Later Results of Partial Gastrectomy" in THE LANCET of August 11th shows that (1) gastro-enterostomy was *unsatisfactory in 36 per cent.* of 61 cases, but there was no mortality; (2) partial gastrectomy was unsatisfactory in only 2·5 per cent. of 51 cases, but there was a *mortality of 9 per cent.* (5 out of 56), which is greater than the risk of malignant degeneration.

These are the "later" results, but experience shows that the "last" results—i.e., after an interval of ten years or more instead of five years or less, would give a much greater number of unsatisfactory results, especially in view of the fact that Mr. Lake allows his patients to eat whatever they like. In the German and American clinics, in which partial gastrectomy has been the routine surgical treatment of ulcer for ten years, so many anastomotic ulcers have followed the operations recommended by Mr. Lake that nothing less than excision of four-fifths of the stomach is now performed. This would presumably have a still higher mortality, and we shall have to wait another ten years before we know how often it is followed by jejunal ulcer. Then I expect complete gastrectomy will become the operation of choice, for nothing short of this will produce achylia, as Klein has shown that when the secretion of appetite juice is stimulated by tasting or seeing food, but nothing is swallowed, free acid appears in the small portion of the stomach still remaining after subtotal gastrectomy.

It is clear that, *if* Mr. Lake's results can be taken as typical: (1) gastro-enterostomy is unjustifiable except for pyloric obstruction because of the 36 per cent. unsatisfactory results; and (2) partial gastrectomy is unjustifiable because of the high mortality.

An interesting commentary on Mr. Lake's paper is the fact that since 1921 we have had at New Lodge Clinic 37 patients suffering from gastric ulcer, 165 from duodenal ulcer, and no less than 67 from the ill-results of gastro-enterostomy or partial gastrectomy, performed in most instances for ulcer. Our experience shows that gastro-enterostomy is the commonest gastric disorder to-day, and undoing gastro-enterostomies is the gastric operation we now most frequently recommend. I am, Sir, yours faithfully,
ARTHUR F. HURST.

New Lodge Clinic, Windsor Forest, August 15th, 1928.

To the Editor of THE LANCET.

SIR,—I have read with interest Mr. Lake's paper published in your issue of August 11th; there is a good deal in it, however, which does not coincide with my own experience. An extensive inquiry into the after-results of a short-circuiting operation for duodenal ulcer show that these are at least as good as those following any surgical procedure in the abdomen. I am not concerned here with the respective merits of gastro-duodenostomy and gastro-jejunostomy; and for the sake of convenience will hereafter refer to both as gastro-enterostomy.

I am sure that surgeons who are constantly and fully carrying out the technique involved in the operation of gastro-enterostomy will regard Mr. Lake's figure of 36 per cent. unsatisfactory results as much too high. Indeed, such a figure is undoubtedly a very strong reason for seeking some other operative procedure. In my experience the unsatisfactory results are not more than 10 per cent., and in many of these the symptoms are so slight and evanescent that the cases should be included under Mr. Lake's heading of "satisfactory." Again, it is not clear on reading this paper how many gastrectomies were done for duodenal ulcer and how

Another notification in the same *Gazette* announces that Part III. of the Act of 1920 is henceforth to apply to benzoyl-morphine, dihydro-oxycodeinone, dihydrocodeinone, and their respective salts, and to any preparation, admixture, and extract containing benzoyl-morphine, dihydro-oxycodeinone, and dihydrocodeinone. This Order in Council is made under Section 8 Subsection (2) of the 1920 Act, whereby His Majesty may apply Part III. to any drug whatever, if it appears that such drug is or is likely to be productive, if improperly used, of ill-effects substantially like those produced by morphine or cocaine.

TUBERCULOSIS IN IRELAND.

(FROM OUR OWN CORRESPONDENT.)

SOME of the communications made to the Congress of the Royal Institute of Public Health held recently in Dublin give interesting information on the subject of tuberculosis in the Irish Free State. Sir William Thompson, formerly Registrar-General of Ireland, showed slides exhibiting the death-rates from tuberculosis in England and Wales, Scotland, and Ireland from 1904 to 1926. The rate for England and Wales had decreased from 1·75 per 1000 living in 1904 to 0·95 in 1926; for Scotland from 2·25 to 1·00; and in Ireland from 2·85 to 1·45. In 1912 tuberculosis came first on the list of causes of death in Ireland with 9400 deaths; in 1926 it came fourth with a little under 7200 deaths. It was generally agreed, Sir William added, that there were eight people suffering from tuberculosis for each death, and one might conclude, therefore, that there were some 16,000 fewer people suffering from tuberculosis than in 1912. Somewhat different figures were given by Mr. E. P. McCarron, Secretary of the Department of Local Government and Public Health. Contrasting the years 1912 and 1927, he found that in the area now comprised in the Irish Free State the number of deaths from tuberculosis in 1912 exceeded those in 1927 by 2600. If both writers are correct then there would appear to be a slight increase in the number of deaths in the area of Northern Ireland. Mr. McCarron added that in respect of the operation during last year of 19 of the approved tuberculosis schemes in the Irish Free State, 1536 tuberculous patients were made fit to resume their ordinary life. He gave these figures as an illustration of the value of wise expenditure in the preservation of the public health. "The blunderer with an axe at public expenditure was a menace to all that was best in our civilisation."

Mr. J. H. Norris, Director of Veterinary Research, Department of Lands and Agriculture, Irish Free State, gave valuable information as to the extent of tuberculosis among cattle in the Irish Free State. There were, he said, no complete or even extensive statistics bearing on the incidence of tuberculosis in dairy cattle in the Irish Free State, but from results of tuberculin tests carried out in various herds it might be assumed that at least 20 per cent. were tuberculous. This evidence was supported by separate statistics kept at the Dublin abattoir. During 1926 23·69 per cent. of cows slaughtered were found to be tuberculous, but of these only 3·17 per cent. showed lesions extensive enough to call for total destruction of the carcass. Only 6·52 of bullocks and 5·59 of heifers were found affected. For some time past mixed samples of milk from herds in various parts of the country had been examined at the Department of Agriculture's veterinary laboratory. Up to June 30th last 391 samples from different herds, containing 3884 cows, or an average of 10 cows in each herd, had been dealt with. All samples, in addition to microscopic examination, were submitted to the biological test, with the result that 18, or 4·60 per cent., were found to contain tubercle bacilli. Positive cases were followed up and dealt with under the Tuberculosis Order.

Correspondence.

"Audi alteram partem."

SMOOTH AND ROUGH VARIANTS OF BACTERIA.

To the Editor of THE LANCET.

SIR,—On the whole I concur in Dr. Arkwright's criticisms, in THE LANCET of August 11th, of my letter in the previous number. Especially would I support him in the quest for biological generalisations, without which clear thinking becomes impossible. I therefore deeply regret my letter conveyed any impression to the contrary. Moreover, the exceptions to such "laws" are of prime importance since they often furnish a clue to the relationships between bacterial races. Doubtless, also, it would lead to less confusion had the terms "rough" and "smooth" been reserved for the contrasted antigenic and other characters as originally described by Dr. Arkwright. Unfortunately, smooth and rough are everyday words, which so aptly point the antithesis between two widely distributed types of colony appearance and consistence that it is difficult to resist using them for this purpose. The strains of parasites termed *C. diphtheriæ* in my letter, were, in the vast majority of cases, isolated from separate hosts, or the same host at different times; only a few strains were derived from a common parent strain during their laboratory existence. Surgeon-Commander Parker only describes the laboratory side of the investigations referred to. The work was an attempt to find out what variations took place in certain "non-specific" characters of a group of bacteria all of which had enough "specific" characters to satisfy my concept of *C. diphtheriæ*. The results indicated that during their existence in their natural habitat, the human throat, this group varied widely in composition at different times and places. As Dr. Arkwright truly points out, any value this work may have depends on the meaning given to *C. diphtheriæ*. Perhaps a brief attempt to explain what I do mean may to a slight extent indicate the relationship between the species-concept and variation as applied to bacteria. I believe it to be unwise at the present time to define too rigidly any bacterial species. As a working hypothesis an organism must have certain stable and definite criteria before it is assigned to a "conventional type species." As facts accumulate it may be found advisable to add or subtract criteria from these which determine the "type species," in order to exclude or include certain strains of bacteria. For example, in the Greenwich investigations a bacterium had to possess the following attributes before it was diagnosed as *C. diphtheriæ*. The organism must ferment glucose but not saccharose, grow aerobically on congulated serum without liquefying it, and form non-chromogenic colonies. Smears from cultures of suitable age on solid serum had to show Gram-positive, Neisser-positive, pleomorphic *bacilli*. It is evident, from Dr. Arkwright's letter, that although I *feel* that the above definition is the most practicable to work round, yet he *feels* some reference to toxin production is essential in order to identify an organism with *C. diphtheriæ*—i.e., should a culture of an organism, otherwise qualified for inclusion in the species, produce no diphtheria toxin, it must be known that its ancestors were toxigenic before it can be named *C. diphtheriæ*. It may be taken as now definitely established that many toxigenic races of *C. diphtheriæ* are able to throw off avirulent variants. Before this was generally accepted, many bacteriologists considered that *all* avirulent bacilli were species distinct from virulent diphtheria bacilli. Such an opinion is no longer tenable, and even if there should be "pure lines" of bacilli, possessing the criteria given above, whose ancestors never have and whose descendants never will produce diphtheria toxin, there is no means, so far as I know, of distinguishing them from other races similar in all respects except that their recent ancestors were known to have been toxigenic—i.e., to have possessed a different antigenic make up. As the word indicates, antigenic characters in a parasite imply reactions in the host and hence are of paramount importance in medicine. In spite of this fact, it is debatable if antigenic qualities are in general sufficiently stable for differentiation of "species," however useful they may be in describing subspecies, types, races, varieties, and special strains within the species.

For these reasons I personally dislike including any reference to toxigenicity in the description of *C. diphtheriæ* as a "species"; but the subject is full of difficulties of which this correspondence is only able to give a hint. However, Dr. Arkwright's letter illustrates clearly one point of practical importance—that, until there is a universally used standard bacterial nomenclature, where an author refers to a subdivision of the bacteria, he must take care that it is possible for others to understand exactly what he means. I plead guilty to not having done so in my previous letter.

I am, Sir, yours faithfully,
SHELDON F. DUDLEY.

Royal Naval College, Greenwich, S.E., August 11th, 1928.

PAPWORTH COLONY AND SANATORIUM TREATMENT.

To the Editor of THE LANCET.

SIR,—Several daily papers represented at the recent Dublin Congress have been devoting leading articles to the above; and, so far as they help Dr. Varrier-Jones's cause, they will do nothing but good. Unfortunately, however, they give the impression that sanatorium treatment has been a failure, a statement which is at most a half-truth, and much to be deplored.

The immediate results of sanatorium treatment are surprisingly good; favourable cases are restored to health, and many unfavourable ones are much improved. In the most favourable, the good results are permanent; but, unfortunately, four-fifths of those applying for treatment have already passed the most favourable stage, or for other reasons are not likely to make a complete recovery, whatever the treatment. In such cases the results of sanatorium treatment are conditional, and relapses happen if the quarters are unsatisfactory, the conditions of life are unhealthy, or the rules learnt in the sanatorium forgotten or ignored. To blame the methods of treatment because the after-conditions are not satisfied is not logical. One of these after-conditions is the possibility of earning an adequate wage under healthy conditions. Another is to permit of rest in the open-air if symptoms arise which call for it. It is a great merit of Dr. Varrier-Jones's arrangements at Papworth that these three essentials are provided. His methods are not a substitute for sanatorium methods (for there is no substitute), but they are a valuable extension. Many of his inmates have had some treatment in a sanatorium; and any of them receives a similar treatment in the colony whenever he needs it.

From the earliest days of sanatorium propaganda it was clearly stated that the sanatorium is only one link—though an essential one—in the chain of treatment. So long as the fear of infection prevents the sanatorium patient from obtaining remunerative employment under suitable conditions, the need for colonies like Papworth, or for special workshops as advocated by the late Dr. F. S. Tinker, will be urgent; but they are not, and cannot be, a substitute for the sanatorium, which combines advantages in the same way as a hospital for other ailments.

I am, Sir, yours faithfully,
F. R. WALTERS.

Farnham, Surrey, August 25th, 1928.

THE LATER RESULTS OF PARTIAL GASTRECTOMY FOR GASTRIC AND DUODENAL ULCER.

To the Editor of THE LANCET.

SIR,—A study of the figures relating to chronic gastric and duodenal ulcer given by Mr. Norman Lake in his paper on the "Later Results of Partial Gastrectomy" in THE LANCET of August 11th shows that (1) gastro-enterostomy was *unsatisfactory in 36 per cent.* of 61 cases, but there was no mortality; (2) partial gastrectomy was unsatisfactory in only 2·5 per cent. of 51 cases, but there was a *mortality of 9 per cent.* (5 out of 56), which is greater than the risk of malignant degeneration.

These are the "later" results, but experience shows that the "last" results—i.e., after an interval of ten years or more instead of five years or less, would give a much greater number of unsatisfactory results, especially in view of the fact that Mr. Lake allows his patients to eat whatever they like. In the German and American clinics, in which partial gastrectomy has been the routine surgical treatment of ulcer for ten years, so many anastomotic ulcers have followed the operations recommended by Mr. Lake that nothing less than excision of four-fifths of the stomach is now performed. This would presumably have a still higher mortality, and we shall have to wait another ten years before we know how often it is followed by jejunal ulcer. Then I expect complete gastrectomy will become the operation of choice, for nothing short of this will produce achylia, as Klein has shown that when the secretion of appetite juice is stimulated by tasting or seeing food, but nothing is swallowed, free acid appears in the small portion of the stomach still remaining after subtotal gastrectomy.

It is clear that, *if* Mr. Lake's results can be taken as typical: (1) gastro-enterostomy is unjustifiable except for pyloric obstruction because of the 36 per cent. unsatisfactory results; and (2) partial gastrectomy is unjustifiable because of the high mortality.

An interesting commentary on Mr. Lake's paper is the fact that since 1921 we have had at New Lodge Clinic 37 patients suffering from gastric ulcer, 165 from duodenal ulcer, and no less than 67 from the ill-results of gastro-enterostomy or partial gastrectomy, performed in most instances for ulcer. Our experience shows that gastro-enterostomy is the commonest gastric disorder to-day, and undoing gastro-enterostomies is the gastric operation we now most frequently recommend.

I am, Sir, yours faithfully,
ARTHUR F. HURST.

New Lodge Clinic, Windsor Forest, August 15th, 1928.

To the Editor of THE LANCET.

SIR,—I have read with interest Mr. Lake's paper published in your issue of August 11th; there is a good deal in it, however, which does not coincide with my own experience. An extensive inquiry into the after-results of a short-circuiting operation for duodenal ulcer show that these are at least as good as those following any surgical procedure in the abdomen. I am not concerned here with the respective merits of gastro-duodenostomy and gastro-jejunostomy; and for the sake of convenience will hereafter refer to both as gastro-enterostomy.

I am sure that surgeons who are constantly and fully carrying out the technique involved in the operation of gastro-enterostomy will regard Mr. Lake's figure of 36 per cent. unsatisfactory results as much too high. Indeed, such a figure is undoubtedly a very strong reason for seeking some other operative procedure. In my experience the unsatisfactory results are not more than 10 per cent., and in many of these the symptoms are so slight and evanescent that the cases should be included under Mr. Lake's heading of "satisfactory." Again, it is not clear on reading this paper how many gastrectomies were done for duodenal ulcer and how many for gastric ulcer. It is essential to differentiate, for in many respects the two diseases are very unlike. The type of patient is not the same, gastric ulcer makes the patient much more ill as a rule, and duodenal ulcer is virtually never the precursor of malignant disease. It is a debatable point as to how often carcinoma becomes grafted on to gastric ulcer, but I think most surgeons allow that it happens sufficiently often to cause the possibility of any such change to pass through their minds on most of the occasions on which they deal with a gastric ulcer. The difference between the two types of ulcer (or perhaps one should say the types of patient) has a vital bearing on the statistics of anastomotic ulcer following gastrectomy. I have seen three cases where such an ulcer had formed after partial gastrectomy had been done for jejunal ulcer in which gastro-enterostomy had been done previously for duodenal ulcer; I have Sir Berkeley Moynihan's permission to say that he has had 12 such cases sent to him, and that he has never seen an anastomotic ulcer develop after a primary gastrectomy for gastric ulcer. Mr. Lake's explanation, that too little of the stomach was removed (that is to say, not all of the acid secreting part) does not apply to these cases.

Because of the difficulty of dealing directly with ulcers on the posterior surface of the duodenum, eroding the pancreas and causing marked deformity, I should regard these as the ulcers to be treated by gastrectomy, if this operation were ever necessary for duodenal ulcer; but gastro-enterostomy is very successful in these cases and the mortality is less than 1 per cent. I venture to say that in a series of this type gastrectomy would show a very much bigger mortality, and I presume this is the kind of ulcer Mr. Pannett has in mind when he finds it necessary to insert in his book on gastro-duodenal ulceration some paragraphs dealing with injury to the bile and pancreatic ducts as a complication which is observed in a certain percentage of cases of resection.

It is a great mistake to think that having performed the operation of gastro-enterostomy the business is finished. It is essential to deal with the ulcer itself at the time, and to treat the patient medically for long afterwards. I would suggest that the failure to take these two points into consideration in compiling statistics goes far to explain the high figures of unsatisfactory results sometimes given. This does not condemn gastro-enterostomy, or show the necessity to substitute gastrectomy; it is a reflection on the vision of the surgeon, for after all there is, or may be, still an ulcer present, and the operation only goes part of the way in promoting the patient's complete recovery.

I think if Mr. Lake could show that gastro-enterostomy gave the high percentage of unsatisfactory results which he quotes, in spite of a full measure of complementary treatment before, at, and after the operation, he would convince his readers that there were sound grounds for advocating gastrectomy for duodenal ulcer—even though it is followed by a higher mortality, and carries with it the risk of anastomotic ulceration, a risk which may prove to be as great as that after gastro-enterostomy, if no more.—I am, Sir, yours faithfully,

E. R. FLINT, F.R.C.S. Eng.

Leeds, August 15th, 1928.

THE HEART AND CIRCULATION IN BERI-BERI.

To the Editor of THE LANCET.

SIR,—May I refer Dr. Sutherland to the *Dublin Journal of Medical Science* for October, 1916, in which I draw attention to the negative pressure existing in the pericardium of a healthy person, and its tendency to disappear from the pericardia of persons in ill-health, especially those with serous effusion in the large cavities. This negative pressure results in a suction action whereby the pericardial fluid is kept at an equal thickness all over the surface of the heart and acts as a support to the working organ. A removal of that support affects the weaker-walled right ventricle at an earlier stage than the left. I have suggested the formula $F=(P+I)\div(T+S)$ where F=fibrillation, P=pressure, I=impulses, T=tone, and S=support; *from* which it is easy to see that if tone or support or both be diminished the tendency to fibrillation is increased. In beri-beri effusion occurs into the serous cavities, the general feebleness of the circulation implies that tone is less, consequently heart failure sets in. Prof. Wenckebach suggests the existence of a law of circulatory correlation between the right and left heart, working along simple mechanical lines. Does my formula help him in his contention?

I am, Sir, yours faithfully,

G. ARBOUR STEPHENS,

Consulting Cardiologist, King Edward VII. Welsh National Memorial.

Swansea, August 18th, 1928.

THE VITAMIN A CONTENT OF COD-LIVER OILS.

To the Editor of THE LANCET.

SIR,—In your issue of June 30th (p. 1353) Prof. J. C. Drummond attempts to counter statements made in an article published in the *Anglo-Norwegian Trade Journal* for May, 1928, which is based upon information which I have given the editor of that journal. Drummond's reply does not touch upon the crux of the matter, and is therefore unsatisfactory. As previous articles regarding this matter have appeared some years ago, a short résumé is necessary.

1. In 1924 Prof. Drummond (University College, London), jointly with Dr. S. S. Zilva (the Lister Institute, London) and Dr. Graham (The Fisheries Laboratory, Lowestoft), published in the *Biochemical Journal* (1924, XVIII., 178) a paper entitled: The Relation of the Vitamin A Potency of the Liver Oil to the Sexual Condition and Age of the Cod. In this very searching work they particularly treated the question whether the spawning of the cod had any influence on the vitamin content of the oil. Repeatedly, and in a most definite way, it is stated in the article referred to that no such influence could be demonstrated. For example: regarding the results of the four series of tests of cod from Flamborough and Scarborough during the months of January to June, it is stated that "even the liver oils from spent cod in March fish, which must have spawned just before being caught, and which had no time to recuperate, did not deviate in potency from the oils of fish before spawning, and several months after spawning and consequently after recuperation." The paper ends up with the following summary: "The sexual condition and age of the cod do not influence the vitamin A potency of the liver oil." In 1924 I myself carried out similar investigations, and came to the same conclusion, but in view of the paper in the *Biochemical Journal*, I considered any publication of my findings superfluous.

2. In 1925 Prof. Drummond published in THE LANCET (Sept. 26th, p. 679) a paper in which, without producing any fresh data, he says, with regard to oils produced in the important fishing district of Lofoten (Norway), that during spawning the oil becomes poor in vitamins and contains only one-tenth to one-fifth of the vitamin potency of that of oil from other places (Finmarken and Newfoundland), where the fisheries do not take place during the spawning period. The reason apparently being that, when the fish "are practically starving during the spawning period, and are at the same time transferring much fat and vitamin to the reproductive cells, the livers yield an almost white oil of relatively low potency." This is exactly opposite to the findings of Prof. Drummond and his collaborators in 1924: about the fish in this condition it is here said that "the relative potency of the residual liver oil is, however, not effected."

Drummond's paper of 1925 has during these years served as the basis for an exceedingly intense advertising of Newfoundland cod-liver oil, at the expense of the Norwegian oil and at great economic loss to the latter.

3. It was not until several months later that I became aware of Drummond's article in THE LANCET of Sept. 26th, 1925, and I thereupon wrote a rejoinder which appeared in your issue of Feb. 6th, 1926 (p. 320). Therein I expressed surprise that the Prof. Drummond of 1925 should contradict the Prof. Drummond (and his colleagues) of 1924. My paper was couched in the most moderate terms. I sent a copy of it to Drummond, and although it appeared necessary that he should furnish some explanation, he sent me no answer.

4. On the other hand, a reply was made by Dr. Zilva, who had previously collaborated with Prof. Drummond. This reply is now made use of in such a way by Drummond in your issue of June 30th (p. 1353) that the reader who has not kept fully in touch with developments may get the impression that Zilva supported Drummond. I do not believe others will agree with this interpretation. Zilva's reply leaves nothing to be desired in the way of explicitness:

> "As I did not see Prof. Drummond's article until it appeared in print I do not hold myself responsible for everything stated therein. Prof. Poulsson is quite right in asserting that the sexual condition of the cod during spawning has no bearing upon the activity of the oil, as was shown by my colleagues and myself, and I feel gratified that this work has been confirmed by our Norwegian colleague."

Prof. Drummond must be in a most unhappy frame of mind when he accepts this severe correction without a word of protest.

It appeared inevitable that Prof. Drummond should at this juncture explain himself, but no such explanation has been made, not even in his last letter. Instead of explaining upon what basis in 1925 he denies results achieved by himself and his colleagues in 1924, he devotes a lot of space to treating other subjects not relevant to the present issue. For example, a comparison is made between the biological and colorimetric tests, obviously in order to get an opportunity to point out that my tests of certain samples of cod-liver oil had been carried out according to a defective method. In this connexion I will content myself with pointing out that these assays had partly been completed already in 1923; the improved and now applicable method was described by Steenbock in 1924.

Summarising the above, we find ourselves faced with an instance of an author contradicting himself and his colleagues without communicating with them (one of them subsequently denying responsibility), without producing new data, and without offering any explanation. A situation of this kind is unparalleled in scientific discussion, and the situation is by no means clarified by Drummond's last letter, except in so far as he has now abandoned the contention which formed the chief basis of his paper in THE LANCET of Sept. 26th, 1925—namely, that the sexual condition of the cod during the spawning period influences the vitamin content of the liver oil.

I am, Sir, yours faithfully,

Oslo. E. POULSSON.

INSTRUCTION IN PSYCHIATRY.

To the Editor of THE LANCET.

SIR,—I should like in the first place to thank you for the kindly notice of my book on "Mental Disorders" in your issue of July 21st. My object in writing to you now is to comment on Dr. Estelle Cole's letter in your issue of August 11th. I hope that your review will be approved not only by "many of the older school of psychiatry," but also by those of some at least of the newer schools who realise the inchoate condition of much of modern psychological teaching regarding, for example, the psychoneuroses. So long as such a short period of time is allotted in the medical curriculum for the teaching of psychiatry in general, it seems to me that it would be unwise to employ more than a modicum of it in dealing with contentious psychological matters. When there is something approaching a settled doctrine I shall be only too glad to set it forth for those students and others who may care to read what I write. In conclusion, I find myself in complete agreement with what you say in your note that "so important and difficult a subject should be properly taught or left alone." It seems to me that there is a good deal of modern pseudo-psychology—or pseudo-psychopathology—which is not properly taught, but which is improperly practised.

I am, Sir, yours faithfully,

Wimereux, August 20th, 1928. HUBERT J. NORMAN.

"FUSSING OVER CANCER."

To the Editor of THE LANCET.

SIR,—Your correspondent "D.P.H.," in the course of an excellent letter, remarks that it is really a truism to say that "the earlier cancer is detected the better are the patient's chances of recovery." Having made this uncontroversial statement, he goes on to ask: "Why is there a certain hesitancy . . . in launching educational campaigns with regard to cancer?" and the inference would seem to be that "cancer campaigns throughout the world" have neglected this very useful part of what should be one of their primary activities. In order to attempt to prevent this inference being accepted as the whole truth of the matter, may I be allowed to draw the attention of your readers to some of the educational work undertaken by the Yorkshire Council of the British Empire Cancer Campaign?

Shortly after the Yorkshire Council was created, our leader, Sir Berkeley Moynihan, recognising that the education of the public was of prime importance, proposed that a propaganda subcommittee should be formed and financed. This was done, and the funds placed at its disposal were considerable in amount and were mainly derived from donations given by Insurance and Panel committees in the County. This subcommittee has done a great deal of work. It has issued a very comprehensive little book entitled "Notes on Cancer," prepared under the direction of the Medical and Scientific Committee of the Yorkshire Council. Free copies of this book have been sent to all practitioners in the county and many have been sent, by request, to almost all parts of the Empire. Any practitioner requiring the book may have it on application to our Secretary, at 47, Park-square, Leeds. The subcommittee has organised several courses of post-graduate lectures to practitioners by eminent authorities, the list of lecturers including the names of such well-known men as Sir Berkeley Moynihan, Prof. G. E. Gask, Prof. Grey Turner, Dr. Major Greenwood, and Prof. Sampson Handley. Most of these lectures have been very largely attended, and there is a demand for further courses which the subcommittee hopes shortly to be able to meet.

Having, in the above ways, attempted to assist practitioners by placing before them the latest available information, the subcommittee directed its attention to an effort to educate the public. It first succeeded in obtaining the services of a competent woman doctor who was well fitted to place facts before individuals which it felt they ought to know. It then organised a series of public demonstrations, called—for want of a better name—"cancer exhibitions." Each exhibition visits a selected town and is open to the public for, usually, one week. Various statistics, showing the number of deaths arising from cancer in different parts of the body are exhibited in graphical form. Large quantities of leaflets are used and visitors urged to take them home and show them to their friends. Information on various questions of health is given. Lectures by medical men and women of standing are delivered, and each day a local doctor gives a short talk, emphasising the necessity for early advice and treatment in all cases where the disease may be suspected. The woman demonstrator has personal interviews with visitors throughout each day and the burthen of her story is: "If you have anything wrong—or if you *fear* you have anything wrong—don't go on anxiously worrying, but consult your doctor and ask him to examine you and advise." These exhibitions have been attended by marked success. Thousands of people have visited them, and excellent reports of the lectures and addresses have been given in the public press. They are not easy to organise, for the difficulty in making them attractive to the public, whilst at the same time excluding all "gruesome" details is a very real one. None the less the subcommittee is very satisfied with the results. The deplorable experience of Dr. Stanley Reimann, as given in "D.P.H.'s" letter, has not been ours! When our work began I think most lay people agreed that a diagnosis of cancer—no matter where situated or how early or late it had been recognised—was tantamount to a sentence of death. This is not so now. The facts that some 50,000 people die annually from cancer in England and Wales; that getting on for 20,000 of these cases originally arise from superficial—and therefore get-at-able areas; that an enormous percentage of early cases have been shown by fully confirmed hospital reports to be alive 10 years after treatment, constitute, when proclaimed, a "message of hope" which the public is not slow in appreciating. Evidence supplied by surgeons and general practitioners in our county convinces us of this.

The fears of "frightening people to death," of "creating a nation of neurasthenics," do not impress the members of our Council. Our leader's happy phrase—"frightening them to *life*"—appeals to us more strongly, and it is a long time since I read so excellently logical an exposure of the futility of commonly used objections as that given in the letter of "D.P.H."

I am, Sir, yours faithfully,
G. B. HILLMAN,
Chairman, Medical Propaganda Subcommittee, Yorkshire Council, British Empire Cancer Campaign.

Wakefield, August 18th, 1928.

OSTEOCLASTOMA.

To the Editor of THE LANCET.

SIR,—I should be much obliged if you will correct an error which appears in THE LANCET of July 28th (p. 183) in the report of the proceedings of the recent International Conference on Cancer. In the discussion on bone sarcoma I spoke in favour of the view that the so-called giant-celled tumour or myeloid sarcoma is derived from the fibrous-tissue framework of bone and that the giant cells are osteoclastic (not osteoblastic) in nature. Osteoclastoma (not osteoblastoma) was suggested as a better name for this tumour than any of those at present in use, combining, as it does, brevity with precision of meaning.

I am, Sir, yours faithfully,
M. J. STEWART.

Leeds, August 15th, 1928.

PAYMENT FOR MOTOR ACCIDENT PATIENTS.—The governors of Folkestone Royal Victoria Hospital last week adopted the following resolution: "In cases provisionally admitted by the resident medical officer or by the matron for immediate treatment which has become obligatory as the result of a motor accident, each patient admitted shall pay for treatment at the rate of 11*s.* 4*d.* per day, subject, however, to the committee deciding subsequently that these charges be increased, reduced, or remitted." The resolution was the result of correspondence with the Central Bureau of Hospital Information.

Obituary.

WILLIAM SMITH SYME, M.D. EDIN., F.R.F.P.S. GLASG.

Mr. Syme, who died suddenly on August 14th, when on a holiday in North Wales, was well known in Cumberland and south-west Scotland as a specialist and writer on diseases of the nose, throat, and ear. Born in Harbour Grace, Newfoundland, in 1870, he was at an early age sent to school at Blair Lodge and continued his medical studies at Edinburgh, where he qualified M.B., C.M. in 1891. He then went as assistant to Dr. Charles Wilson, of Crewe, before starting general practice himself at Gamlingay, Cambs, where he remained till 1902. He had always enjoyed the life of the country and at that time he joined in the field sports of all kinds, being captain of the cricket team for some years. His return to Scotland was actuated by the desire to develop the more scientific professional side of his work, and after attending the clinics of Dr. Thomas Barr at the Ear Hospital and Dr. J. W. Downie at the Western Infirmary, and working on the former's staff, he decided to specialise in ear, nose and throat work, and in 1904 began consulting work in this specialty in Carlisle, and some years later in Dumfries. In 1913 the course at the Western Medical School was recognised by the University; in 1917 Mr. Syme was appointed surgeon to the Ear, Nose and Throat Hospital, and three years later to the Nose and Throat Western Infirmary. In the same year he became lecturer on diseases of the throat, later adding appointments and a lectureship in ear surgery to his other duties.

MR. W. S. SYME.

Photo by Annan, Glasgow

Mr. Syme was one of the founders of the Scottish Otological and Laryngological Society, and for many years its hon. secretary and treasurer. He was a ready and accurate writer on clinical subjects, his most considerable literary work being a handbook for students and practitioners, published in 1920, of which a new edition has recently appeared. His aim in this book was especially to stimulate the interest of students in a subject likely to concern them very closely, immediately on entering general practice. His oral teaching will be missed by Glasgow students who found in him the embodiment of good-humoured energy, and one who always showed an active interest in athletics, while the nursing staff were pleasantly aware of the uniform kindness and courtesy with which he treated both patients and their relatives. His devotion to duty and the heavy claim of detailed professional work are regarded by his friends as contributory to his early death. Few men, it is said, held such a place in the esteem and affection of their colleagues.

Mr. Syme married in 1895 a daughter of Thomas Paisley, J.P., of Greysouthen, Cumberland, and is survived by his wife, two sons, and four daughters.

MARY LAUCHLINE McNEILL, M.B. GLASG.

NEWS has been received from Kamali, Africa, of the death of Dr. Mary McNeill, on June 10th, from typhoid fever at Jinga Hospital. Dr. McNeill was born in 1874 at Holm in the Orkney Islands, eldest daughter of the Rev. Daniel McNeill, M.D. She went to school at Fochabers, studied music and languages in Germany and Switzerland, and later became a medical student at Queen Margaret College, Glasgow, where she graduated in 1905. She then returned to Orkney and practised there until 1914, when she went to Leicester to relieve her brother for service with the R.A.M.C. In 1916 Dr. McNeill held the appointment of resident physician in the Leicester Fever-Hospital for several months until she joined the staff of the Scottish Women's Hospital in Salonika. She remained there until early in 1919, when she moved with the hospital to Belgrade. In the autumn of the same year she went to Tiberias in Palestine to the U.F. Medical Mission under Dr. Torrance, and thence to the Central Provinces, India, until 1921. After a short holiday at home she became a member of the Church of Rome and joined the Catholic African Mission, first at Kampala, Uganda; latterly she worked single-handed with three Franciscan Sisters at a remote station in Kamali. She was looking forward to coming home on leave in November.

Prof. A. L. McIlroy writes: "Those who knew Dr. Mary McNeill loved her for her upright character, her unselfish life, and her devotion to her family. Her mysticism and joy in living was a source of wonder to her friends. She took a great interest in literature and art, and had a most marked gift for writing and for poetry. She was a loyal colleague, and always upheld the administration of those under whom she worked. Dr. McNeill never lost her youthful interest in people and places. She had travelled extensively, had absorbed new ideas and made friends wherever she journeyed. Her passing has left a great gap in the hearts of her friends."

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Committee 50 applications for assistance were considered and £825 5*s.* voted to 45 cases. Consideration of the following notes on a few of the applicants helped will show how sad some of the cases are and how urgent is the need of help, yet unfortunately the grant was small. The Fund appeals for subscriptions to enable it to make more adequate grants. Subscriptions and donations should be sent to the hon. treasurer, 11, Chandos-street, Cavendish square, W. 1.

L.R.C.S. Edin., aged 74, married; wife aged 72. The husband is completely broken down in health and is quite unfit to do any kind of work. This old couple have a total income of £82 a year, made up of Old Age Pension £52 and Epsom Pension £30. As their rent is £26, there remains only £56 for food and clothes. Voted £40, thus raising their income to £122 a year.

M.D., aged 75, bedridden. Has no private means, but was able to earn a little last year from literary work. Voted £10.

Widow, aged 80, of M.D. Bedridden and suffers from cerebral and anginal attacks, requires nursing day and night. Her only income is £50 being rent from a property which she has been unable to sell. Her two children have done all in their power to help and have contributed £42 a year. Voted £40.

Widow, aged 73, of L.R.C.P. On the death of her husband in 1925 her house was sold and the proceeds went to pay off existing debts, leaving the widow only £370 as capital. She is in receipt of Old Age Pension. Her relations have given some financial assistance this year but cannot continue to do so. Voted £26.

Widow, aged 52, of M.B. Since the death of her husband has supported herself and her invalid son by taking in paying guests, but owing to ill-health (diabetes) has been unable to take guests during the last 12 months. Her son has a congenital heart with marked cyanosis. Income during past year was investments £7 10*s.* and from a paying guest £6. Voted £26. The Fund is trying to get other charities to assist in this very sad case.

Medical News.

SOCIETY OF APOTHECARIES OF LONDON.—At recent examinations the following candidates satisfied the examiners in the undermentioned subjects:—

Surgery.—J. P. Collinson, Sheffield and London Hosp.; H. B. Blaker, St. Mary's Hosp.; E. C. Gross, Guy's Hosp.; I. G. Hardinge, Charing Cross Hosp.; G. L. Johnson, Columbia Univ., U.S.A.; C. K. McCoan, St. Mary's Hosp.; and C. F. C. White, Guy's Hosp.

Medicine.—T. A. Barnabas, Bristol; C. M. Brooks, Durham; J. S. Bury, Manchester; A. E. Gibbs, London Hosp.; K. Girgis, Manchester and Charing Cross Hosp.; I. G. Hardinge, Charing Cross Hosp.; H. H. Jackson, Manchester and Charing Cross Hosp.; G. L. Johnson, Columbia Univ. U.S.A.; H. C. Johnson, Minnesota, U.S.A.; J. H. Johnston and G. L. McDermott, St. Bart.'s Hosp.; M. T. Y. Selim, Liverpool; and H. D. K. Wright, St. Bart.'s Hosp.

Forensic Medicine.—N. Das, London Hosp.; E. C. Gross, Guy's Hosp.; I. G. Hardinge, Charing Cross Hosp.; A. H. Hennessy, Adelaide and London Hosp.; G. L. Johnson, Columbia Univ., U.S.A.; H. C. Johnson and K. R. Lundeberg, Minnesota, U.S.A.; C. P. Madden, St. Bart.'s Hosp.; S. M. Rahman, Calcutta and Middlesex Hosp.; M. T. Y. Selim, Liverpool; and H. D. K. Wright, St. Bart.'s Hosp.

Midwifery.—C. M. Brooks, Durham; H. C. Clifford-Smith, Charing Cross Hosp.; W. A. A. Collington, Guy's Hosp.; J. P. Collinson, Sheffield and London Hosp.; F. W. Crossley-Holland, St. Bart.'s Hosp.; L. P. Gregory, Bristol; I. G. Hardinge, Charing Cross Hosp.; A. H. Hennessy, Adelaide and London Hosp.; G. L. Johnson, Columbia Univ., U.S.A.; H. C. Johnson and K. R. Lundeberg, Minnesota, U.S.A.; R. Perkins, St. Bart.'s Hosp.; and T. A. P. Proctor, Birmingham.

The Diploma of the Society was granted to the following candidates entitling them to practise medicine, surgery, and midwifery: H. B. Blaker, H. C. Clifford-Smith, J. P. Collinson, I. G. Hardinge, A. H. Hennessy, G. L. Johnson, G. L. McDermott, S. M. Rahman, M. T. Y. Selim, and H. D. K. Wright.

DERMATITIS AMONG BAKERS.—At the Eighteenth Annual Congress of the Amalgamated Union of Operative Bakers and Confectioners held at Cardiff on August 20th, attention was called by the general secretary of the union (Mr. W. Anfield) to the alarming spread of dermatitis among bakers throughout the country. He asserted that there is a conspiracy of silence on the part of men suffering from the disease and also on the part of their employers. He believed that for every one man reported to be suffering from this disease there were three others unreported. It was suggested that since 1918 and 1919 something had been introduced into the raw material used by bakers which had caused a greater spread of this disease, and that the sole sufferers are the operative bakers. A resolution was passed stating that the conference viewed with alarm the spread of dermatitis among members of the union, and urged the Executive Committee to spare no expense in the matter, and to call for the assistance of the Government department together with the Master Bakers' Association and the millers and the medical profession.

THE LONDON HOSPITAL.—In 1927 the annual report records there were 16,840 in-patients who stayed, on an average, 15–19 days and cost £11 3*s.* 6*d.* each. New out-patients to the number of 114,509 made 567.525 attendances at a cost of 12*s.* each. The total ordinary income increased from £234,088 to £263.546, while ordinary expenditure fell from £262,900 to £250.419. The year's legacies totalled £51,315, nearly double the average.

CONTRIBUTIONS TO HOSPITALS FROM DOCKERS.—More than 10,000 dockers have agreed in writing to contribute to the Merseyside Voluntary Hospitals Penny-in-the-Pound scheme.—During the year ended on June 30th last Devonport Dockyard and its allied establishments, by means of a similar scheme, raised £5136, making a total for the last five years of £20,891.

MANCHESTER GUARDIANS AND CANCER FUND.—The Manchester board of guardians at its meeting on August 22nd again discussed the guardians' contribution of £1000 to the Lancashire, Cheshire, and North Wales Council of the British Empire Cancer Campaign, as the result of a letter from the Minister of Health intimating his inability to sanction the contribution. It was stated that the Minister was "unable to regard so considerable a donation to a fund of this kind as being within the spirit and intention of Section 36 of the Poor-law Act, 1927." He was, however, prepared to consider favourably applications from the guardians to subscribe reasonable amounts to the funds of the hospitals undertaking the treatment of cancer, in which persons receiving relief from the guardians are having, or are to have, assistance in cases of necessity.

MATERNITY HOSPITAL FOR SOUTHPORT.—The Southport Health Committee has accepted the offer of Miss Christiana Hartley, a former mayor of the town, to build a new maternity hospital. The present building was a temporary soldiers' hospital and last year, out of 1000 births in Southport, 300 took place within it. The new institution will be adjacent to the infirmary and will correspond, in design and material, with its main block.

THE LATE DR. S. W. GRIFFITH.—Samuel Wilbraham Griffith, of the Hermitage, Pwllheli, died suddenly on August 24th, aged 72. He began his medical studies in Dublin and continued them in Edinburgh, where he qualified L.R.C.P. and L.R.C.S. in 1884. He was one of the best-known medical practitioners in North Wales, a J.P. of Carnarvonshire, and senior magistrate of the shire, having officiated in the Pwllheli Court for nearly 40 years.

ROYAL WESTMINSTER OPHTHALMIC HOSPITAL.—This hospital, which has been under construction on its new site in Broad-street, Holborn, since November, 1926, is now completed and will be open for the admission of in-patients on Monday, Sept. 3rd. The out-patient and casualty departments were opened last Easter. In addition to the public wards, there are 14 single private rooms, which will be available in the autumn. The new hospital has cost, including the freehold site, about £150,000, towards which nearly £100,000 has been raised by the sale of the old site in King William-street, Strand, and by public appeal. The remaining £50,000 has yet to be found.

Medical Diary.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.1.

MONDAY, Sept. 3rd, to Saturday, Sept. 8th.—QUEEN MARY'S HOSPITAL, Stratford, E. Second week of Intensive Course in Medicine, Surgery and the Specialties. Syllabus on application to the Secretary.

Appointments.

BRECHIN, F., M.B., B.Ch. Glasg., D.P.H., has been appointed Medical Officer of Health, Renfrew.

DAVIDSON, M., M.D. Oxf., F.R.C.P. Lond. Consulting Physician to St. Luke's Hospital, Chelsea.

DUNSCOMBE, CLEMENT, M.B., B.Chir. Camb., D.P.H. Oxf., Medical Officer of Health for Mansfield Woodhouse, Notts., and Assistant School Medical Officer, Nottinghamshire County Council.

LOBBAN, G. M. D., M.B., Ch.B. Leeds, Assistant Schools Medical Officer, Oldham.

MITCHELL, L. M. V., M.B., Ch.B. Edin., to be one of the Medical Referees under the Workmen's Compensation Act, 1925, for Inverness (Mainland) District of the Sheriffdom of Inverness, Elgin, and Nairn.

ROWNTREE, S. J., M.R.C.S., L.R.C.P. Lond., Certifying Surgeon under the Factory and Workshop Acts for Islington.

STEVENS, W. G., L.R.C.P., L.R.C.S. Edin., Consultant Medical Officer of Health, Renfrew.

THOMSON, H. W., M.D. Glasg., a Specialist Medical Referee under the Workmen's Compensation Act for Ophthalmic Cases in the Sheriffdom of Lanark.

Surgeons under the Factory and Workshop Acts: BELLIS, T. M.B., Ch.B. Liverp. (Llanfairfechan); BRUCE, D. W. (Chagford, Devon); ELLIS, G. E., M.B., B.S. Lond. (Bourton, Dorset).

Vacancies.

For further information refer to the advertisement columns.

Albert Dock Hospital, Connaught-road, E.—Res. M.O. At rate of £110.

All Saints' Hospital, 49–55, Vauxhall Bridge-road, S.W.—H.S. At rate of £150.

Birmingham and Midland Eye Hospital, Church-street.—H.S. £110.

Bolingbroke Hospital, Wandsworth Common, S.W.—Res. M.O. £200.

Brighton Education Committee.—Asst. Sch. M.O. £600.

Cairo, Egyptian University.—Faculty of Medicine: Professor of Forensic Medicine. L.E. 1500. Also Prof. of Clin. Surg., &c.

Canterbury, Kent and Canterbury Hospital.—3rd Res. M.O. At rate of £125.

Cheltenham Borough.—M.O.H. and Sch. M.O. £850.

Chester Royal Infirmary.—H.P. £120.

Croydon General Hospital.—Cas. H.S. £125.

Dorchester, Dorset County Hospital.—H.S. At rate of £120.

Dreadnought Hospital, Greenwich.—H.P. and H.S. Each at rate of £110.

Eastbourne, Princess Alice Memorial Hospital.—Jun. H.S. At rate of £100.

Exeter, Wonford House.—Deputy Medical Supt.

Hull City and County of Kingston-upon-Hull.—Asst. M.O.H. £600.

Leeds City Hospitals.—1st Asst. Res. M.O. £450.

Lincoln County Hospital.—Jun. H.S. At rate of £150.

Lowestoft, St. Luke's Hospital.—Med. Supt. £800.

Manchester, Ancoats Hospital.—H.S. At rate of £100.

Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Res. M.O. At rate of £125.

Manchester, Monsall Hospital for Infectious Diseases.—Second Asst. M.O. Also Jun. M.O. At rate of £375 and £350 respectively.

Manchester, Royal Children's Hospital, Gartside-street.—Asst. M.O. At rate of £150.

Manchester, Royal Children's Hospital, Pendlebury.—Res. Surg. Officer. At rate of £125.

Metropolitan Ear, Nose and Throat Hospital, Fitzroy-square, W.—H.S. £150.

Miller General Hospital for South-East London, Greenwich-road, S.E.—Pathologist. £600. Also H.P. At rate of £125.

National Hospital for Diseases of the Heart, Westmoreland-street, W.—Res. M.O. At rate of £150.

Northampton General Hospital.—H.P., H.S., and two Asst. H.S.'s. Each at rate of £150.

Patna Medical College.—Prof. of Physiology. Rupees 1200.

Plymouth, Homœopathic and General Hospital.—H.S. At rate of £100.

Prince of Wales's General Hospital, Tottenham, N.—Res. Anæsthetist. At rate of £120.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Asst. Res. M.O. At rate of £80.

St. George's Hospital Medical School, S.W.—Pathologist and Lecturer in Pathology. £575.

St. Mary's Hospital, W.—Asst. Pathological Chemist. £300.

St. Peter's Hospital for Stone, &c., Henrietta-street, Covent Garden, W.C.—H.S. At rate of £75.

Salford Municipal Maternity Home and Babies' Hospital, Seedley-terrace, Pendleton.—Asst. Maternity and Child Welfare M.O. £600.

Salisbury General Infirmary.—H.S. £150.

Shrewsbury, Royal Salop Infirmary.—Res. H.S. At rate of £160.

Truro, Royal Cornwall Infirmary.—H.S. £170.

Tunbridge Wells and Counties General Hospital.—H.S. £160.

Weir Hospital, Grove-road, Balham, S.W.—Jun. Res. M.O. £150.

West London Hospital, Hammersmith-road, W.—H.P. and two H.S.'s. Each at rate of £100.

Westminster Hospital, Broad Sanctuary, S.W.—H.S. to Eye, Ear, Nose and Throat Depts. At rate of £102.

Wolverhampton and Staffordshire Hosp.—H.S. At rate of £150.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Langport (Somerset) and Aspatria (Cumberland).

The Home Secretary gives notice that in consequence of the death of Dr. A. Stuart, Medical Referee under the Workmen's Compensation Act for the Central District of the Sheriffdom of Perth, the appointment held by him is vacant. Applications for the post should be addressed to the Private Secretary, Scottish Office, Whitehall, London, S.W.1, and should reach him not later than Sept. 19th, 1928.

Births, Marriages, and Deaths.

BIRTHS.

BALTER.—On August 14th, at Avenue-road, N.W., the wife of David N. Balter, M.D., of a son.

HINGSTON.—On August 20th, at Uplands Cottage, Belvedere-drive, Wimbledon Hill, S.W., the wife of Major H. Hingston, I.M.S., of a son.

RICHARDS.—On August 15th, at Adelaide-road, N.W., the Hon. Noel Olivier, wife of W. Arthur Richards, F.R.C.S., of a daughter.

RUSSELL.—On August 24th, at "Bredon," Alverstoke, Hants, the wife of Dr. Norman L. Russell, of a son.

SKEGGS.—On August 26th, at Bicknor Lodge, Stevenage, the wife of Dr. B. Lyndon Skeggs, of a son.

SMALLEY.—On August 21st, the wife of Dr. L. Smalley, Montfort Cottage, Kenilworth, of a daughter.

TROTTER.—On August 27th, at "Braemar," Haslemere-road, London, N., the wife of Dr. G. Clark Trotter, M.O.H., Islington, of a daughter.

MARRIAGES.

SHELDRAKE—LANE.—On August 18th, at the Parish Church, Leamington Spa, William Donbavand Sheldrake, M.B., B.S. Lond., to Ida Frederica Lane, youngest daughter of the late Mr. and Mrs. W. Billings Lane, of Bottisford, Lincolnshire.

DEATHS.

GREENWAY.—On August 19th, at Alexandra-drive, Surbiton, Charles Melville Greenway, M.R.C.S., L.R.C.P. (late of Plumstead), aged 58.

HUGHES.—On August 23rd, at Bristol, following an operation, Frank Percival Hughes, M.B., B.S.

KEBBELL.—On August 8th, at a nursing home, Earl's Court, Charles Frederick Vivian Kebbell, M.R.C.S., L.R.C.P., in his 42nd year.

KHAN.—At Gaya, India, on 20th July, 1928, Major Abdus Sattar Khan, I.M.S., from heart failure, aged 46. Deeply mourned.

MCVINE.—On August 16th, at Hazelwood-lane, N., Dr. J. W. McVine.

MOORHOUSE.—On August 17th, at Melville-terrace, Stirling, Dr. James Ernest Moorhouse, aged 58 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

HOSPITAL LAW.

LIABILITY OF HOSPITALS AND THEIR PROFESSIONAL STAFFS FOR TORTS.*

BY CAPTAIN J. E. STONE, M.C., F.S.A.A.,
HON. SECRETARY, INCORPORATED ASSOCIATION OF HOSPITAL OFFICERS.

Operations.

No surgical operation can be performed on an adult patient without his or her consent if it is at all possible to obtain it. No operation, therefore, should be performed on a patient without the express consent of the patient, or if he is not in a position to give such consent, then of his nearest relative. Further, an operation must not be carried further than is warranted by the consent, and this consent should be founded on full knowledge of the nature and possible extent of the operation and the consequences which it may involve. Disregard of these precautions may cause the operation to be illegal, and to render the surgeon liable to an action for damages. In the case of a child similar precautions should be adopted except that instead of the patient's consent, the consent of a parent or guardian should be obtained. Even in the case of a child, it may be advisable to obtain his or her consent as well, especially if the child has attained years of discretion, for the power of the parent or guardian over the person of the child does not extend to the whole period of minority.

When a person has selected a surgeon to operate upon him, and has appointed no other person to represent him during the period of unconsciousness that constitutes a part of such operation, the law will by implication constitute such surgeon the representative of the patient, and will cast upon him the responsibility of so acting in the interests of the patient that the latter shall receive the full benefit of that professional judgment to which he is legally entitled. A surgeon undertook to perform a radical cure of a left inguinal hernia, and to do it gratuitously. When the patient was anæsthetised and ready for the operation to commence, a more serious rupture was found to exist on the right side. The surgeon accordingly dealt with the right hernia first, intending to deal with the left one afterwards. However, by the time the first operation was complete, the patient's condition was not so good and the second operation could not be commenced. The patient brought an action for assault and was awarded substantial damages; but a higher court set aside this decision on appeal. The grounds for this were that the use of anæsthesia modified the fundamental common law rule that consent must be given before an operation can be performed. Anæsthesia had postponed to the period of relaxation and unconsciousness the making of the complete and final diagnosis of the case, by which time consent could no longer be asked or obtained. These changed conditions are all for the benefit of the patient, and to allow them to be used as the basis of actions for assault or *mala praxis* would be contrary to the public interest. It will be noted that the decision is safeguarded by language which makes it safe from abuse, and confers no liberty upon the surgeon to carry out a more extensive or more dangerous operation than that for which he has obtained consent. A record of all professional staff in attendance at operations should be kept.

Who may Bring Action?

The only person who can properly bring an action for damages done to the person of the patient is the patient himself, even though a minor; otherwise in all cases of surgeons retained by any of the public establishments the patient would be without redress, for it could hardly be expected that the governors of a hospital would bring an action against the surgeon employed by them to attend the child of poor parents who may have suffered from his negligence and inattention (Pippin and Sheppard). Formerly, when a patient died as a result of the negligent treatment of a doctor or nurse, any right of action which he might have had in his lifetime ceased on the principle of the well-known maxim, *Actio personalis moritur cum persona*. By the Fatal Accidents Act, 1846, more commonly known as "Lord Campbell's Act," and called "an Act for compensating the families of persons killed by accidents," it was enacted that whenever the death of a person shall be caused by wrongful act, neglect or default, such as would (if death had not ensued) have entitled the party injured to maintain an action and recover damages, then the person who would have been liable if death had not ensued shall be liable to an action for damages, notwithstanding the death of the person injured, and although the death shall have been caused under such circumstances as amount in law to felony. Such actions must be for the benefit of the wife, husband, parent, or child of the deceased; be brought by his personal representative, and be commenced within 12 calendar months after the death of the deceased. If there is no legal representative, all or any of the persons for whose benefit such action would have been brought may themselves bring the action.

Rights and Obligations of Patients.

Voluntary hospitals are under no legal obligations to admit as patients persons who come to them for treatment. The fact that an institution is charitable is not in itself sufficient to entitle the public at large to demand free treatment, and cases can therefore be refused without any reasons being given. This right to refuse admission is, however, seldom exercised without some adequate ground for refusal, but such refusal would give the rejected applicant no cause of action against the governing body or the admitting officer.

A patient on admission to hospital submits himself to carry out any rules and regulations prescribed by the hospital with a view to enforcing on the part of the patients decent and orderly behaviour and obedience to orders. All hospitals have such rules, and the retention of a patient is conditional upon his observing such of the rules of the hospital as relate to his own conduct. A patient is entitled to expect to be treated with reasonable care and skill; this care, however, is so much and no more than a patient in that hospital would, according to its rules and practice, in the ordinary course receive. For instance, patients cannot complain at being attended by junior medical officers in the intervals of the visits of the physicians and surgeons, or because matters not requiring the personal attention of a qualified practitioner are left to the sister or nurse of the ward, or if in accordance with the ordinary practice of the hospital students or others accompany the physicians on their rounds. A patient so long as he remains in the hospital is bound to submit to the treatment bona fide ordered by the physician, and to its administration at the hands of the nurses or other agents employed by the hospital to carry out the treatment prescribed. A patient cannot be detained or treated against his will. If he does not comply with the rules of the hospital the proper remedy is not compulsion but expulsion. If it is found necessary to use force to a patient who exhibits violence or is insubordinate, the force employed should be reasonable and never be greater than is absolutely necessary.

Summary of Hospital's Position.

A hospital is *not liable* for:—

(*a*) The negligence of surgeons, physicians, nurses, or other officers in the exercise of their professional duties, provided it is shown that in the selection and appointment of such officers due and reasonable care was exercised. This as a practical proposition exonerates hospitals in most suits by patients, for in the ordinary case hospitals do exercise such care. (The exemption from liability does not follow the hospital because it is a charitable institution.)

(*b*) The negligence of a nurse (or other officer) assisting at an operation or in the carrying out of her purely professional duties.

A hospital *is liable* for the negligence of:—

(*a*) Nurses in the course of purely administrative duties over which the board has control.

(*b*) Other officers while under the control of the board.

(*c*) Its professional staff (surgeons, physicians, &c.) in the course of their professional duties, if it has not exercised due and reasonable care in their selection and appointment.

The mere fact that the officers are or are not remunerated is immaterial. The board are under no greater liability to a paying patient than to a non-paying patient.

Liability to Persons other than Patients.

Hospitals are liable for the negligent injury of those who do not bear to the hospital the relationship of patient—that is, those who are not beneficiaries of the hospital and its charitable purpose. In such suits hospitals are held by the law, as are all other concerns and individuals, to the use of due care—that is, such care as a prudent person would under like circumstances exercise, and failing in that would be liable in such damages as would fairly compensate the injured person. While, therefore, hospitals are held by the weight of judicial opinion to be exempt from liability for injuries to the recipients of their charity if they have selected their staffs with due care, no such exemption applies to injuries to others. Even though it has been proved that there was due care in the selection of the agents or servants where the relation of patient does not exist, and when the hospital would otherwise be liable, there is no exemption to the hospitals. Hospitals are bound to use ordinary care to have their premises in a reasonably safe condition. Cases coming under this heading would include injuries due to (1) defective lifts, (2) a lift shaft negligently left unprotected, (3) collision with hospital ambulance, (4) defective stairs, (5) falling roof slates or tiles, &c. The absence of reasonable care must, of course, be proved.

---

* Two previous articles on this subject were published in THE LANCET of April 28th, p. 895, and July 14th, p. 102.

This phase of a hospital's liability is not confined to what may be termed strangers—i.e., persons other than patients—but it also includes the employees of the hospital. For instance, injuries suffered by a laundry worker, if not properly instructed in operating the machinery which it was her duty to work, or if caused by insufficient protection or defective condition of the machinery, would give good grounds for maintaining an action against the hospital. The fact that employees receive no money for their services, but only lodging, board, and uniforms, does not defeat their right to bring an action. Nearly all hospitals contract out in respect of their liabilities falling under both the above headings; one or two undertake their own risks by the establishment of insurance funds, into which annual premiums are paid and out of which all accident claims are met.

St. Thomas's Hospital, London, S.E.

"THE WELL OF LONELINESS."

THE fact that "The Picture of Dorian Gray" is now available in cheap editions, while "The Well of Loneliness" has been withdrawn by Messrs. Jonathan Cape at the request of the Home Secretary, suggests that Miss Radcliffe Hall's book may at some future date be restored to circulation. It is not, of course, comparable in artistic merit with Wilde's work, nor even with Miss Radcliffe Hall's previous novel, but it is an honest attempt to portray the temptations, the emotional conflicts, and the social dilemmas of the homosexual woman. The author has considerable dramatic skill, though her emphasis is sometimes misplaced. The implication that the parents' desire to produce a son may alter the emotional affinities of the daughter born to them is difficult to accept; the origin of abnormal sex attractions cannot be so simply explained. The fallacy of the book lies in the failure to recognise that strong attachments between members of the same sex occur as a phase of normal development. Those who fail to outgrow this phase can be helped to divert their emotions into other channels. If their efforts are ineffectual their life must always be unhappy, for the race is bound to erect such barriers as will discourage the development of affinities dangerous to its existence. This duty is well recognised by Miss Radcliffe Hall. Her book, to which Mr. Havelock Ellis contributes a preface, is certainly not effective as a presentation of the case for social toleration of an abnormal habit of life, nor is there any evidence that the author holds a brief to this end.

JUNGLE AND MALARIA.

THE idea is widespread in the Federated Malay States that jungle causes malaria and that therefore ravines should be cleared of jungle and secondary growth. The Malaria Advisory Board states, however, in its report for 1927, that this is by no means always true, and many instances are known in which severe outbreaks of malaria have been caused by clearing jungle. An emphatic warning has therefore been issued against indiscriminate felling of jungle, and the attention of the public is invited to the following points: (1) If the health of those living close to a jungle-covered ravine is good, on no account do any clearing. (2) If the health is not good, owing to attacks of malaria, search thoroughly for other possible sources of mosquitoes before blaming the jungle. (3) Do not clear a ravine, unless you are prepared to drain and oil it thoroughly. (4) Sometimes jungle is dangerous, but before felling it you should seek the advice of your medical practitioner. The Health Department will be glad to coöperate with him in this important matter.

The Health Department of the F.M.S. states its willingness to coöperate with the local practitioner in coming to a decision.

REPORT OF THE IMPERIAL SOCIAL HYGIENE CONGRESS.

WE have received from the British Social Hygiene Council a copy of the proceedings of the Imperial Social Hygiene Congress held at Caxton Hall from Oct. 3rd to 7th, 1927. The Congress was reported at some length in our columns at the time (see THE LANCET, 1927, ii., 782, 829); and Mr. Neville Chamberlain in a preface expresses a hope that the record will have a wide circulation amongst those who are working to raise the moral and social standards throughout the Empire. The report deals in succession with the imperial, medical, and administrative aspects of social hygiene; a full index makes it possible to refer rapidly to work recorded in any part of the Empire. The report can be obtained from the Council at Carteret House, Carteret-street, London, S.W. 1.

NEW PREPARATIONS.

Atophan Balsam (Messrs. Schering, Ltd., 3, Lloyd's-avenue, London, E.C. 3. Manufacturers: Schering-Kahlbaum A.G. Berlin, N.39).—The use of atophan in facilitating the elimination of uric acid in gout and rheumatic affections, as well as its value in neuralgia and sciatica, are well known. It is now made in the form of a balsam, being an association of atophan-amylester 10 per cent., phenyl salicylate 10 per cent., and camphor 5 per cent., with a fatty soap base. The balsam can be used externally either per se or as a supplement to internal treatment by atophan. Experiments have shown that the preparation has high absorption qualities, confirmation being given here by the excretion of the components into the urine. The use of the preparation is particularly indicated where local and massage treatment are required simultaneously. It is put up in collapsible tubes. About ¼ oz. per day is recommended for use, and the tubes contain about 1¼ oz.

Zymocide (Messrs. Reed and Carnrick, Jersey City, N.J. Agents: Messrs. Coates and Cooper, 41, Great Tower-street, London, E.C. 3).—This is described as an antiseptic consisting of eucalyptol, thymol, menthol, methyl salicylate, boric, and benzoic acids with other aromatic ingredients and alcohol 20 per cent. by volume. It is non-irritating and non-poisonous, and is intended for use as a general antiseptic where it already enjoys popularity as a vaginal douche and a mouth wash. A 25 per cent. solution has been employed for cleansing the eyes following traumatism, and in the treatment of conjunctivitis, blepharitis, catarrh of the lacrymal passages and other ocular inflammations. It is put up in bottles containing 14 fluid ounces.

Robinson's "Patent" Barley in Powder.—Messrs. Keen, Robinson and Co., Ltd., Carrow Works, Norwich, have sent us a specimen of their well-known product, used as a food for infants and for making potable barley water and barley puddings. As a result of suggestions and criticisms from medical men they have now fixed on the tin, in addition to the directions, a table of food recipes specially designed for infants. The table gives in parallel columns the age of the infant for the first four weeks, and thereafter for the first nine months of its life, and the weight in pounds which is recognised as agreeing satisfactorily. Further columns give the quantity of the suggested foods and the number of feeds per day in accordance with the age and weight. A note on this table of recipes pointing out that infants should preferably be fed by weight rather than by age gives advice which might far more frequently be acted upon by the public—viz., that where the weight of an infant does not clearly correspond with the age the medical man should be consulted.

THE BUCKSTON-BROWNE PRIZE.

A CORRESPONDENT asks for details in regard to the Buckston-Browne prize to which he has found a reference in our columns. The prize was founded by Mr. Buckston-Browne, to whom the medical profession is indebted for his generosity in many directions, in memory of a son who lost his life in the war. The interest on a sum of money given for the purpose provides a cheque for £100 and a medal which are given for the best essay on some subject selected by the Council of the Harveian Society. The prize is awarded every two years, the first award having been made in 1927 to the late Mr. Lionel R. Fifield for his essay on new growths of the urinary bladder. An amplification of that excellent essay was reviewed in THE LANCET recently.

A BROCHURE ON TEA.

WE have received from the Mazawattee Tea Company, Ltd., an illustrated booklet setting out the connexion of the company with the history of tea in an interesting manner. Figures are given to show the vast increase in importation of tea which has been accompanied by the dramatic fall in prices, the figures really forming a commentary upon social developments in the United Kingdom during some 250 years. The Mazawattee Tea Company in their pamphlet point out that they were the first firm to bring home to the public that, as dealt with by experts in the fine art of blending, teas grown within the British Empire could present all the qualities which made those of China popular. We do not suppose that anyone who is a real amateur of China tea would suggest that the blends have all the qualities which personally appeal, but the blends are held on good ground to have other qualities which form satisfactory compensation; anyhow, those of this firm have earned their wide reputation.

THE address of the Deutsche Medizinische Wochenschrift is now Berlin W. 30, Viktoria Luise Platz 1.

Ingleby Lectures

ON

SOME RECENT ADVANCES IN OUR KNOWLEDGE OF RICKETS AND ALLIED DISEASES.

Delivered at the University of Birmingham

BY LEONARD G. PARSONS, M.D., F.R.C.P. LOND.,
PHYSICIAN TO THE CHILDREN'S AND GENERAL HOSPITALS, BIRMINGHAM.

LECTURE II.*

ACCORDING to most authorities the primary defect in uncomplicated human rickets is an impaired absorption of phosphorus from the bowel. Findlay and the Glasgow School do not accept this view and regard defective calcium absorption as the essential factor. To determine which view is the correct one is, however, a matter of extreme difficulty, because the relationship between these two elements in all phases of their metabolism is so intimate and reciprocal (Murdoch).

FACTORS INFLUENCING THE ABSORPTION OF CALCIUM AND PHOSPHORUS FROM THE BOWEL.

Excessive amounts of calcium in the diet tend to increase its absorption and retention but to impair phosphorus retention with the result that considerable amounts of phosphorus are diverted from the urine to the stools. Conversely, if the phosphorus in the diet is excessive, calcium metabolism is unfavourably influenced, there is an increase of calcium in the fæces, and its excretion in the urine becomes less. This retention of one element in the intestine by an excessive amount of the other is best explained by the formation of insoluble calcium phosphate. To obtain the maximum absorption of both elements the diet should, therefore, contain amounts of calcium and phosphorus sufficient in quality and properly balanced, the percentage of calcium being greater than that of phosphorus. Both these requirements are met if children take one pint of milk daily.

Another important factor in the absorption of calcium is the presence of certain fats in the dietary and their normal absorption from the intestine. Infants with a normal fat absorption must take from 2 to 6 g. of butter fat per kilo of body-weight to ensure the absorption of 0·1 g. of calcium oxide per kilo of body-weight. A child fed on a low fat dietary may, indeed, show a negative calcium balance. An infant whose diet, a milk mixture containing 2 per cent. of fat, contained 0·44 g. of calcium oxide per day, showed a percentage absorption of 34; whereas when fed for 17 days on a mixture containing 0·8 per cent. of fat, it showed a negative calcium balance, although the calcium intake was more than twice as much as on the previous diet (due to the addition of calcium caseinate). The presence of large amounts of unabsorbed fat in the intestine may also lead to a negative balance; thus a negative or low calcium retention is often found in cœliac disease. Again, in infantile biliary cirrhosis, owing to the exclusion of bile from the intestine, fat absorption is very defective. In one case of this disorder a negative calcium balance and in another a low retention was found. (See Table I.)

Telfer has produced evidence showing that the absorption of calcium only occurs in the upper part of the intestinal tract. The solution of the calcium salts in the food is effected by the acid of the gastric juice, and absorption proceeds until the acid mixture of lime and phosphoric acid is rendered alkaline by the intestinal secretions, when calcium phosphate is precipitated in insoluble form. It has, therefore, been suggested that an increased acidity in the upper part of the intestinal canal would increase the absorption of calcium. Bergeim maintains that acidity, and especially lactic acid fermentation, increases absorption of calcium, and has shown that lactose largely promotes its absorption, whereas maltose and glucose do so to a much lesser degree if at all. Breast milk contains much less calcium than cow's milk, but it is almost completely absorbed; this, he believes, is the result of a high proportion of lactose and of the acid intestinal reaction in breast-fed infants. My own observations lead me to believe that an increased acidity alone does not necessarily cause increased calcium—although it does produce increased phosphorus—absorption. Thus in the cases of biliary cirrhosis, to which I have referred, large amounts of fatty acid were present in the intestine, yet calcium absorption was very poor, and in one case there was a negative balance.

TABLE I.—*Infantile Atrophy.**

—	Calcium.		Phosphorus.	
	Intake.	Percentage absorbed.	Intake.	Percentage absorbed.
Cow's milk ..	1·04 (31 cases)	45·6	—	—
Lactic acid milk	1·32 (14 cases)	35·4	0·76 (11 cases)	71·3
HCl milk	1·22 (6 cases)	51·6	0·62 (1 case)	85·3
Almata	0·92 (6 cases)	72·5	0·63 (1 case)	46·5
Biliary cirrhosis.				
Cow's milk (M. C.)	0·98	0	1·07	92·1
	1·44	0	1·32	85·7
Lactic acid milk (A. J.)	1·35	13·9	0·66	94·9

We have carried out observations on a number of atrophic infants fed on varying dietaries, some being fed on acid milk. The average calcium absorption of 14 infants fed on lactic milk was considerably less than that in a group of 31 infants fed on ordinary cow's milk mixture. This may in part be due to the fact that children fed on lactic acid milk excrete more fat than those fed on ordinary milk mixtures. Four children fed on hydrochloric milk (prepared by adding one ounce of decinormal hydrochloric acid to four ounces of milk), however, showed a higher absorption of calcium, and although there was a marked increase in the amount of calcium excreted in the urine, the actual calcium retention was definitely higher than in children fed on cow's milk. Finally, a group of six infants fed on Almata, a food which has a buffer value similar to that of breast milk, showed the highest calcium absorption of all the children examined. Increased phosphorus absorption, as the result of increased intestinal acidity from excess of fatty derivatives in the intestine, is to be explained by the formation of large amounts of insoluble calcium soaps so that less calcium is available to bind phosphorus and the latter can be absorbed. (See Table I.)

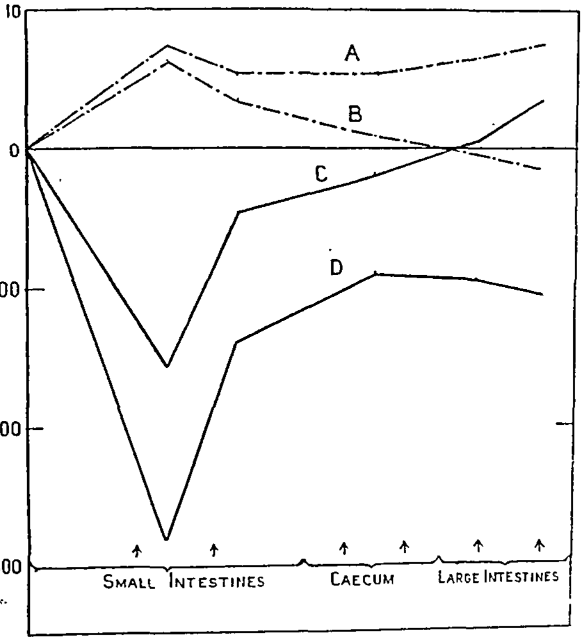
The absorption of calcium and phosphorus from the bowel can be increased by the oral administration of cod-liver oil, ostelin, irradiated ergosterol, or by exposing the skin to the sun's rays, or by artificial ultra-violet irradiation. Moreover, rats fed on a high-calcium, low-phosphorus, rickets-producing dietary develop a marked alkalinity of the fæces which can be reduced to the acid side of neutrality by any of those methods. Again, the child fed on a low fat dietary, having a low or negative calcium retention, can be made by such methods to absorb calcium well; and in cœliac disease the same results are obtained by irradiation or the administration of irradiated ergosterol in solid form. From all of these considerations it would appear that it is not intestinal acidity *per se* that is so important in absorption, but the presence of some factor (vitamin D), which directly increases absorption and also produces an acidity, and that the reason why some fats, such as cod-liver oil, are necessary for proper absorption of calcium and phosphorus is that they contain this vitamin.

---

* The figures given represent the amounts taken in grammes in 24 hours.

* Lecture I. appeared in THE LANCET of Sept. 1st.

New light has been shed on the question of calcium and phosphorus absorption by work carried out by Bergeim. Albino rats were fed for 25 days on a high-calcium, low-phosphorus dietary and rickets was produced. They were then divided into two groups; to one group were given ten drops of cod-liver oil daily for five days, to the other, ten drops of olive oil. The animals were then killed and estimations made of calcium and phosphorus in the small intestine, cæcum, and large intestine; the results are seen in the diagram. Both groups of animals showed considerable calcium absorption in the small intestine. On this diet, which produces a low phosphorus rickets (the analogue of human rickets), the rachitic condition could not therefore be due to a failure of calcium absorption. In the same area both groups also showed considerable excretion of phosphate—i.e., excretion of phosphate appeared to be an important factor in promoting calcium absorption. In the lower bowel, in the animals receiving cod-liver oil, there was an approximate balance between excretion and absorption of calcium and a high calcium balance resulted. Phosphorus was also reabsorbed so as to bring about a positive balance. In the other group calcium excretion was more marked than absorption, leading to a negative balance; also there was a failure of phosphate to be adequately reabsorbed so as to produce a positive balance. The re-excretion of absorbed calcium into the lower bowel, so that a negative balance results, must be due to the failure of the bones to fix calcium. This failure, as pointed out in the first lecture, is not due to defects in the bone cells but to low blood phosphate, which, in Bergeim's view, is the result of the inability of the tissues of the body to maintain the proper concentration of blood phosphate by breaking down the organic phosphates which they contain. Antirachitic vitamin, he believes, facilitates this action and therefore elevates blood phosphate, and the absorbed calcium is deposited in the bones. The absorbed calcium is hence not re-excreted in the lower bowel, phosphate absorption is unhindered, and the phosphate balance becomes positive. I am not convinced that Bergeim's explanation is correct in all its details, although his results appear to be incontrovertible. A reference to the diagram shows that, although it would appear as if excretion of phosphate favoured calcium absorption, yet in those animals receiving cod-liver oil the calcium absorption in the small intestine was higher with a smaller excretion of phosphate. Further, he states that in three non-rachitic rats which were fed on a milk diet which was high in calcium and phosphorus "an acid condition generally prevailed throughout the intestines, due presumably to lactic acid fermentation, and both calcium and phosphorus were absorbed to a considerable extent in the small intestines." Also, if phosphate excretion favours calcium absorption, it is not clear how calcium excretion hinders phosphorus absorption. Indeed, if his arguments are correct the reverse process would appear the more logical. It is, I think, much more probable that the antirachitic vitamin exerts its effect by an alteration of the pH of the intestinal canal rather than by any action such as Bergeim suggests. Reference has already been made to the influence of acidity of the intestinal canal on the absorption of calcium and phosphorus and to the fact that this acidity is largely due to the presence of the antirachitic factor. Recently Redman, Willimot, and Wokes have estimated the pH of contents of various sections of the gut of rodents by a method similar to that of Bergeim, and the curves they obtained on a low fat rachitogenic diet show that the fæcal alkalinity corresponds well with Bergeim's curve of calcium absorption. Administration of cod-liver oil or irradiated cholesterol to these animals restored the acidity of their intestinal tract.



Average absorption of calcium and phosphorus from intestines of rachitic animals and animals given cod-liver oil. A, cod-liver oil: calcium. B, rickets: calcium. C, cod-liver oil: phosphorus. D, rickets: phosphorus.

From this review it will be seen that it is almost impossible to say which of the two, calcium or phosphorus absorption, is actually at fault; probably both are, but perhaps on the whole the evidence favours the view that defective absorption of phosphorus is the more important.

TETANY.

Infantile tetany is very closely associated and frequently occurs with rickets, in fact, some authorities regard it as a nervous manifestation of rickets. In all cases of infantile tetany the serum calcium is low. The blood phosphorus may also be low, indeed it always is so if there are manifest symptoms of rickets, but the presence of low serum calcium is pathognomonic of infantile tetany and is the one characteristic sign of the disease. In manifest tetany the calcium may fall as low as 6 mg. per cent., and in latent tetany it is usually about 8 mg. per cent. Now calcium exists in the blood in both ionised and un-ionised forms. The un-ionised form is in part inorganic as bicarbonate and acid phosphate. Cameron and Moorhouse have suggested that the calcium content of the cerebro-spinal fluid, normally 5·3 mg. per cent., may be regarded as the amount of diffusible calcium —i.e. the inorganic and ionic calcium. In infantile tetany the calcium in the cerebro-spinal fluid is greatly reduced and may be entirely absent. From the results of experiments on the filterability of the blood calcium through collodion membranes under a negative pressure, and by means of the Rona-Takahashi equation, the amount of calcium present as ions in the blood in small children has been estimated to be 2·1 to 3·4 mg. per cent. with an average of 2·6 mg. All the methods of directly determining the amount of ionic calcium are open to considerable criticism; this is unfortunate, because the work of Loeb and others has shown that the excitability of the neuro-muscular mechanism depends on the relative concentration of the calcium, magnesium, sodium and potassium ions, according to the formula: $\frac{Na+K}{Ca+Mg}$. In infantile tetany potassium, magnesium, and sodium in the serum are all normal, and it is, therefore, the ionic calcium which is the determining factor in the onset of the disorder.

Tetany, of the same nature as infantile tetany, also occurs in cœliac disease. It may, however, appear without any diminution in blood calcium, as, for instance, in gastric tetany, a condition which may develop when there is continuous vomiting of acid gastric contents. This sometimes happens in pyloric stenosis of infants and is the explanation of the convulsions which occur in that disease, and which sometimes prove fatal. Examination of the blood in such cases reveals that there is a shift of the pH to the alkaline side—i.e., an alkalosis—as a result of which less calcium is ionised and tetany results.

> "During digestion the blood normally yields acid equivalents, especially HCl for the secretion of hydrochloric acid, and an excess of basic equivalents is formed. These are immediately neutralised by the carbon dioxide of the blood, the result being an increase in the BH CO_3 of the blood. The BH CO_3 content again falls, however, one to one and a half hours after the meal, as HCl is reabsorbed and replaces BH CO_3." (Drucker.)

The loss of hydrochloric acid by vomiting and the lack of reabsorption in pyloric stenosis produces an alkalosis. The occurrence of tetany after large doses of bicarbonate of soda is also due to alkalosis, as is that form known as superventilation tetany, which is brought about by forced respiration and in which the blood calcium is normal. This is undoubtedly the cause of the convulsions which are occasionally seen after rapid respirations in children suffering from post-encephalitic respiratory tic. (See Table II.)

TABLE II.—*Varieties of Tetany.*

—	Blood.		
	pH.	Calcium.	Phosphate.
Infantile ..	Normal.	Low.	Normal or low.
Parathyroid ..	"	"	" " high.
Bicarbonate ..	Alkaline.	Normal.	Normal.
Gastric ..	"	"	"
Superventilation ..	"	"	"
Phosphate ..	Normal.	Low.	High.

The threshold mechanism of blood calcium (of 10 mg. per cent.) appears to be a very delicate one. The calcium content can be raised above normal by intravenous injection of calcium salts, but the rise is a fleeting one and the extra calcium is soon excreted into the alimentary canal and the normal restored. Recently Collip has shown that the parathyroid glands contain a hormone which raises the blood calcium. Injection of large doses may produce hypercalcæmia and death, but even using this hormone it is necessary to repeat the injection frequently to maintain the blood calcium above threshold value. In tetany, as we have seen, blood calcium is diminished, but the parathyroid hormone raises it to normal and cures tetany, although only for a short time unless the dose is repeated. It is possible, in animals from whom the parathyroids have been removed so that tetany has been produced, not only to cure tetany by means of the hormone but also to produce hypercalcæmia and death. The parathyroid hormone, however, does not increase the absorption of calcium from the bowel, but actually mobilises the fixed calcium from the bones and other reservoirs, and its function appears to be to maintain the calcium of the blood at the normal level and to balance the distribution of calcium between the tissues and the blood. It is, therefore, useless in the treatment of tetany unless means are also taken to increase calcium absorption from the bowel.

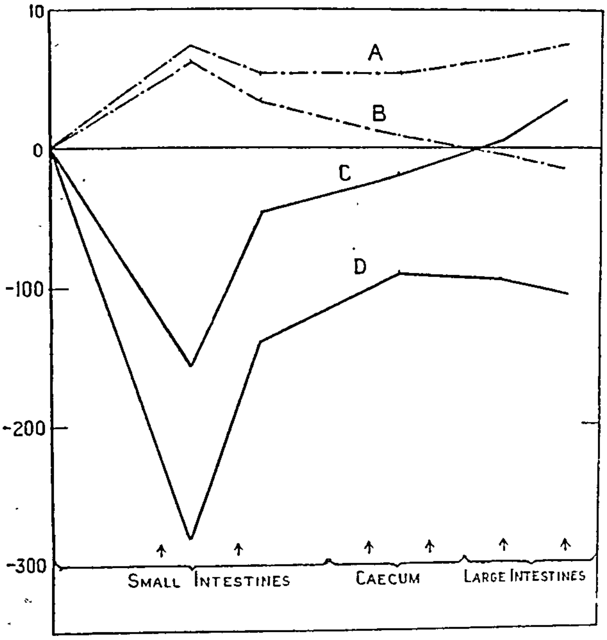
We must envisage rickets as usually primarily a functional disorder of the intestinal tract whereby calcium or phosphorus, or both, are not properly absorbed, either because there is an inefficient supply of these elements or because of the absence of vitamin D. Since this vitamin can act whether supplied from the skin by inunction or when taken by the mouth, it seems probable that it acts after absorption from the intestines and not, as suggested by some authorities, by a local action on the intestinal mucous membrane. The injection of cod-liver oil subcutaneously has been stated to have little or no effect on rickets, probably owing to the difficulty in dealing with fat that has not been through the processes of digestion. The antirachitic factor in cod-liver oil has been found to be contained in the unsaponifiable fraction of the oil, and by injecting intramuscularly a concentrate of this active fraction, Wilkins and Kramer produced a cure in two cases of active rickets. This is strong, although not conclusive, evidence that the antirachitic effect of the oral administration of cod-liver oil occurs as a result of absorption of the oil. The absorption of fats containing vitamin D should therefore be essential for the prevention of rickets, or, conversely, a child who is taking a fat-free diet, or who is not absorbing fat properly, should develop rickets. I have already mentioned the effect on the calcium balance of a diet of skimmed milk, and of the presence of large quantities of unabsorbed fat in the intestines, and also the occurrence of xerophthalmia in babies fed on a skim milk dietary.

There are certain conditions in childhood associated with defective fat absorption, of which the most important are severe and lasting jaundice, such as occurs with congenital obliteration of the bile ducts and some forms of cirrhosis of the liver; diarrhœa; cœliac disease. I have never seen xerophthalmia in any of these conditions, but Bloch and Wagner have described its occurrence in association with severe and lasting jaundice. The amount of unabsorbed fat in those forms of icterus is very great, yet, in spite of the fact that these infants have a low or negative calcium balance, they do not develop rickets. The probable explanation of this apparent anomaly is that growth in such conditions is practically inhibited, and in infants where there is no growth, there is no rickets. That these children may, however, develop rickets when growth starts is well illustrated by a case recorded by Bloch.

CŒLIAC RICKETS.

In cœliac disease of long standing all grades of severity of rickets are met with, and here again growth is, I believe, the activating cause. The bone is osteoporotic before any considerable degree of growth occurs, although rickets rarely develops before the age of 7. The child suffering from cœliac disease passes copious stools containing large amounts of undigested fat, for the treatment of which it is necessary to give a low fat dietary and therein lies the reason for the onset of cœliac rickets. Whilst this is correct, the amount of fat absorbed in cœliac disease on a full fat diet is often considerably higher than would be expected on clinical grounds, and very much greater than occurs in chronic jaundice; indeed, on a low fat dietary, such as skimmed protein milk, the absorption may reach the high figure of 94 per cent. Even with the deliberate addition of fat to the diet for short periods, although the amount present in the stool is increased, yet the amount absorbed is considerable and indeed, within limits, the higher the fat intake the greater the amount of fat is absorbed. Any attempt to prevent the onset of rickets by giving cod-liver oil, however, is unsuccessful because, as with any other extra fat, if continued for more than a short period, an increase in the diarrhœa, the size, offensiveness, and fat content of the stool is produced, and the child goes downhill. On the other hand, a low fat dietary improves the clinical condition and as a result growth may occur and rickets develop. Examination of the blood in cœliac rickets usually shows low serum phosphorus and calcium, and the condition can be cured by administration of dry irradiated ergosterol, or cholesterol, or by exposure to the ultra-violet rays. All this is evidence that the disease is due to fat-soluble vitamin deficiency, yet in spite of this xerophthalmia has so far not been reported, although growth is severely stunted. We have, therefore, acidity *per se* that is so important in absorption, but the presence of some factor (vitamin D), which directly increases absorption and also produces an acidity, and that the reason why some fats, such as cod-liver oil, are necessary for proper absorption of calcium and phosphorus is that they contain this vitamin.

New light has been shed on the question of calcium and phosphorus absorption by work carried out by Bergeim. Albino rats were fed for 25 days on a high-calcium, low-phosphorus dietary and rickets was produced. They were then divided into two groups; to one group were given ten drops of cod-liver oil daily for five days, to the other, ten drops of olive oil. The animals were then killed and estimations made of calcium and phosphorus in the small intestine, cæcum, and large intestine; the results are seen in the diagram. Both groups of animals showed considerable calcium absorption in the small intestine. On this diet, which produces a low phosphorus rickets (the analogue of human rickets), the rachitic condition could not therefore be due to a failure of calcium absorption. In the same area both groups also showed considerable excretion of phosphate—i.e., excretion of phosphate appeared to be an important factor in promoting calcium absorption. In the lower bowel, in the animals receiving cod-liver oil, there was an approximate balance between excretion and absorption of calcium and a high calcium balance resulted. Phosphorus was also reabsorbed so as to bring about a positive balance. In the other group calcium excretion was more marked than absorption, leading to a negative balance; also there was a failure of phosphate to be adequately reabsorbed so as to produce a positive balance. The re-excretion of absorbed calcium into the lower bowel, so that a negative balance results, must be due to the failure of the bones to fix calcium. This failure, as pointed out in the first lecture, is not due to defects in the bone cells but to low blood phosphate, which, in Bergeim's view, is the result of the inability of the tissues of the body to maintain the proper concentration of blood phosphate by breaking down the organic phosphates which they contain. Antirachitic vitamin, he believes, facilitates this action and therefore elevates blood phosphate, and the absorbed calcium is deposited in the bones. The absorbed calcium is hence not re-excreted in the lower bowel, phosphate absorption is unhindered, and the phosphate balance becomes positive. I am not convinced that Bergeim's explanation is correct in all its details, although his results appear to be incontrovertible. A reference to the diagram shows that, although it would appear as if excretion of phosphate favoured calcium absorption, yet in those animals receiving cod-liver oil the calcium absorption in the small intestine was higher with a smaller excretion of phosphate. Further, he states that in three non-rachitic rats which were fed on a milk diet which was high in calcium and phosphorus "an acid condition generally prevailed throughout the intestines, due presumably to lactic acid fermentation, and both calcium and phosphorus were absorbed to a considerable extent in the small intestines." Also, if phosphate excretion favours calcium absorption, it is not clear how calcium excretion hinders phosphorus absorption. Indeed, if his arguments are correct the reverse process would appear the more logical. It is, I think, much more probable that the antirachitic vitamin exerts its effect by an alteration of the pH of the intestinal canal rather than by any action such as Bergeim suggests. Reference has already been made to the influence of acidity of the intestinal canal on the absorption of calcium and phosphorus and to the fact that this acidity is largely due to the presence of the antirachitic factor. Recently Redman, Willimot, and Wokes have estimated the pH of contents of various sections of the gut of rodents by a method similar to that of Bergeim, and the curves they obtained on a low fat rachitogenic diet show that the fæcal alkalinity corresponds well with Bergeim's curve of calcium absorption. Administration of cod-liver oil or irradiated cholesterol to these animals restored the acidity of their intestinal tract.



Average absorption of calcium and phosphorus from intestines of rachitic animals and animals given cod-liver oil. A, cod-liver oil: calcium. B, rickets: calcium. C, cod-liver oil: phosphorus. D, rickets: phosphorus.

From this review it will be seen that it is almost impossible to say which of the two, calcium or phosphorus absorption, is actually at fault; probably both are, but perhaps on the whole the evidence favours the view that defective absorption of phosphorus is the more important.

TETANY.

Infantile tetany is very closely associated and frequently occurs with rickets, in fact, some authorities regard it as a nervous manifestation of rickets. In all cases of infantile tetany the serum calcium is low. The blood phosphorus may also be low, indeed it always is so if there are manifest symptoms of rickets, but the presence of low serum calcium is pathognomonic of infantile tetany and is the one characteristic sign of the disease. In manifest tetany the calcium may fall as low as 6 mg. per cent., and in latent tetany it is usually about 8 mg. per cent. Now calcium exists in the blood in both ionised and un-ionised forms. The un-ionised form is in part inorganic as bicarbonate and acid phosphate. Cameron and Moorhouse have suggested that the calcium content of the cerebro-spinal fluid, normally 5·3 mg. per cent., may be regarded as the amount of diffusible calcium —i.e. the inorganic and ionic calcium. In infantile tetany the calcium in the cerebro-spinal fluid is greatly reduced and may be entirely absent. From the results of experiments on the filterability of the blood calcium through collodion membranes under a negative pressure, and by means of the Rona-Takahashi equation, the amount of calcium present as ions in the blood in small children has been estimated to be 2·1 to 3·4 mg. per cent. with an average of 2·6 mg. All the methods of directly determining the amount of ionic calcium are open to considerable criticism; this is unfortunate, because the work of Loeb and others has shown that the excitability of the neuro-muscular mechanism depends on the relative concentration of the calcium, magnesium, sodium and potassium ions, according to the formula: $\frac{Na+K}{Ca+Mg}$. In infantile tetany potassium, magnesium, and sodium in the serum are all normal, and it is, therefore, the ionic calcium which is the determining factor in the onset of the disorder.

Tetany, of the same nature as infantile tetany, also occurs in cœliac disease. It may, however, appear without any diminution in blood calcium, as, for instance, in gastric tetany, a condition which may develop when there is continuous vomiting of acid gastric contents. This sometimes happens in pyloric stenosis of infants and is the explanation of the convulsions which occur in that disease, and which sometimes prove fatal. Examination of the blood in such cases reveals that there is a shift of the pH to the alkaline side—i.e., an alkalosis—as a result of which less calcium is ionised and tetany results.

"During digestion the blood normally yields acid equivalents, especially HCl for the secretion of hydrochloric acid, and an excess of basic equivalents is formed. These are immediately neutralised by the carbon dioxide of the blood, the result being an increase in the BH CO_3 of the blood. The BH CO_3 content again falls, however, one to one and a half hours after the meal, as HCl is reabsorbed and replaces BH CO_3." (Drucker.)

The loss of hydrochloric acid by vomiting and the lack of reabsorption in pyloric stenosis produces an alkalosis. The occurrence of tetany after large doses of bicarbonate of soda is also due to alkalosis, as is that form known as superventilation tetany, which is brought about by forced respiration and in which the blood calcium is normal. This is undoubtedly the cause of the convulsions which are occasionally een after rapid respirations in children suffering from post-encephalitic respiratory tic. (See Table II.)

TABLE II.—*Varieties of Tetany.*

—	Blood.

Phosphate ..	Normal.	Low.	High.

The threshold mechanism of blood calcium (of 10 mg. per cent.) appears to be a very delicate one. The calcium content can be raised above normal by intravenous injection of calcium salts, but the rise is a fleeting one and the extra calcium is soon excreted into the alimentary canal and the normal restored. Recently Collip has shown that the parathyroid glands contain a hormone which raises the blood calcium. Injection of large doses may produce hypercalcæmia and death, but even using this hormone it is necessary to repeat the injection frequently to maintain the blood calcium above threshold value. In tetany, as we have seen, blood calcium is diminished, but the parathyroid hormone raises it to normal and cures tetany, although only for a short time unless the dose is repeated. It is possible, in animals from whom the parathyroids have been removed so that tetany has been produced, not only to cure tetany by means of the hormone but also to produce hypercalcæmia and death. The parathyroid hormone, however, does not increase the absorption of calcium from the bowel, but actually mobilises the fixed calcium from the bones and other reservoirs, and its function appears to be to maintain the calcium of the blood at the normal level and to balance the distribution of calcium between the tissues and the blood. It is, therefore, useless in the treatment of tetany unless means are also taken to increase calcium absorption from the bowel.

We must envisage rickets as usually primarily a functional disorder of the intestinal tract whereby calcium or phosphorus, or both, are not properly absorbed, either because there is an inefficient supply of these elements or because of the absence of vitamin D. Since this vitamin can act whether supplied from the skin by inunction or when taken by the mouth, it seems probable that it acts after absorption from the intestines and not, as suggested by some authorities, by a local action on the intestinal mucous membrane. The injection of cod-liver oil subcutaneously has been stated to have little or no effect on rickets, probably owing to the difficulty in dealing with fat that has not been through the processes of digestion. The antirachitic factor in cod-liver oil has been found to be contained in the unsaponifiable fraction of the oil, and by injecting intramuscularly a concentrate of this active fraction, Wilkins and Kramer produced a cure in two cases of active rickets. This is strong, although not conclusive, evidence that the antirachitic effect of the oral administration of cod-liver oil occurs as a result of absorption of the oil. The absorption of fats containing vitamin D should therefore be essential for the prevention of rickets, or, conversely, a child who is taking a fat-free diet, or who is not absorbing fat properly, should develop rickets. I have already mentioned the effect on the calcium balance of a diet of skimmed milk, and of the presence of large quantities of unabsorbed fat in the intestines, and also the occurrence of xerophthalmia in babies fed on a skim milk dietary.

There are certain conditions in childhood associated with defective fat absorption, of which the most important are severe and lasting jaundice, such as occurs with congenital obliteration of the bile ducts and some forms of cirrhosis of the liver; diarrhœa; cœliac disease. I have never seen xerophthalmia in any of these conditions, but Bloch and Wagner have described its occurrence in association with severe and lasting jaundice. The amount of unabsorbed fat in those forms of icterus is very great, yet, in spite of the fact that these infants have a low or negative calcium balance, they do not develop rickets. The probable explanation of this apparent anomaly is that growth in such conditions is practically inhibited, and in infants where there is no growth, there is no rickets. That these children may, however, develop rickets when growth starts is well illustrated by a case recorded by Bloch.

CŒLIAC RICKETS.

In cœliac disease of long standing all grades of severity of rickets are met with, and here again growth is, I believe, the activating cause. The bone is osteoporotic before any considerable degree of growth occurs, although rickets rarely develops before the age of 7. The child suffering from cœliac disease passes copious stools containing lar amounts of undigested fat, for the treatment which it is necessary to give a low fat dietary an therein lies the reason for the onset of cœliac ricket Whilst this is correct, the amount of fat absorbe in cœliac disease on a full fat diet is often considerabl higher than would be expected on clinical grounds and very much greater than occurs in chronic jaundice; indeed, on a low fat dietary, such as skimmed protein milk, the absorption may reach the high figure of 94 per cent. Even with the deliberate addition of fat to the diet for short periods, although the amount present in the stool is increased, yet the amount absorbed is considerable and indeed, within limits, the higher the fat intake the greater the amount of fat is absorbed. Any attempt to prevent the onset of rickets by giving cod-liver oil, however, is unsuccessful because, as with any other extra fat, if continued for more than a short period, an increase in the diarrhœa, the size, offensiveness, and fat content of the stool is produced, and the child goes downhill. On the other hand, a low fat dietary improves the clinical condition and as a result growth may occur and rickets develop. Examination of the blood in cœliac rickets usually shows low seru phosphorus and calcium, and the condition can b cured by administration of dry irradiated ergosterol, or cholesterol, or by exposure to the ultra-violet rays. All this is evidence that the disease is due to fat-soluble vitamin deficiency, yet in spite of this xerophthalmia has so far not been reported, although growth is severely stunted. We have, therefore, in cœliac disease the converse of the condition described by Bloch in infants fed on a skimmed milk dietary. In cœliac disease there is rickets but no xerophthalmia; in dystrophia alipogenetica there is xerophthalmia but no rickets. The explanation of this anomaly seems to be that after the period of infancy the child is more susceptible to a diminution in the supply of D- than of A-vitamin. Rickets occurs in cœliac disease only when the latter is severe and of long standing. It seems that, although as a result of defective fat absorption, normal amounts of vitamin D are not absorbed, yet enough is absorbed to enable the child to obtain sufficient calcium and phosphorus to ossify a fragile osteoporotic bone during the period whilst growth is slow, but that this subnormal absorption of vitamin D is quite insufficient to ossify growing bone, and so rickets results. A low fat dietary seems to ensure a better percentage absorption of fat, and, therefore, probably ensures the absorption of any fat-soluble vitamin that may be present in the diet, but here again the amount of vitamin D is so small as to be totally inadequate when growth occurs. From what has been said it is obvious that I regard the osteoporotic bone as a prerachitic stage, only awaiting a period of growth actually to declare itself as frank rickets.

It is not very unusual to meet with cases of rickets which appear to resist treatment by cod-liver oil but which respond to treatment by light or by the administration of ergosterol. One such case was reported to have been under treatment with cod-liver oil for years, but at the age of 7 was unable to walk because of severe and progressive rickets. Radiograms showed an extreme degree of osteoporosis and a large rachitic metaphysis. Treatment by light and ergosterol has, however, completely healed the bones, and the child is now able to walk. In another case, in spite of a life spent under ideal conditions, most careful dieting and the administration of cod-liver oil, a girl presented, when 3 years old, evidence of rickets of moderate degree, which has increased slowly until her present age of 8 years. There was a history of mild digestive disturbances, and examination of her stools showed a higher fat content than usual, and therein, in my opinion, lies the cause of her rickets, which I believe can be cured by light and ergosterol. Both these children were smaller than normal children of the same age, and although they could not be classed as cases of cœliac disease they are, in my opinion, examples of a subnormal absorption of fat—particularly the fat-soluble vitamin D—extending over a long period of time. Cases of cœliac rickets and those to which I have just referred require treatment for much longer periods than ordinary rickets in order to effect complete cure.

Diarrhœa, another cause of defective fat absorption in childhood, is of little importance in producing rickets because, unless the condition is one of cœliac disease, it is usually only transitory and, indeed, leads to starvation which produces arrest of growth and therefore absence of rickets.

RICKETS OCCURRING AS A RESULT OF DEFECTIVE EXCRETION

As already pointed out, there does not appear to be any bone disorder associated with defective calcium excretion, but a very different state of affairs exists with defective excretion of phosphate. The latter occurs in chronic interstitial nephritis, a disease which in children produces marked infantilism and not infrequently severe bone deformities ranging from a mild degree of genu valgum to the severest manifestations of rickets—"renal rickets." In these children the defect does not lie in the intake of calcium and phosphorus, nor is it due to the absence of vitamin D, or sunshine, but is purely a defective excretion of phosphate by the kidneys. Examination of the blood reveals nitrogen and phosphate retention, an acidosis, and frequently a high degree of lipæmia. The phosphorus values are often even higher than would appear at first sight, because, although 5 mg. per cent. is the normal concentration in infants, many of these children have reached an age when the normal blood phosphorus is considerably below that figure. Blood calcium in comparison with blood phosphorus is always low but in actual values is frequently at or above the normal figure of 10–11 mg. per cent., a very different state of affairs from that found in azotæmic nephritis of adults and after the injection of phosphate into animals or children.

In azotæmic nephritis of adults the higher the retention of phosphorus the lower is the calcium in the serum. Injection of phosphate into animals or children raises blood phosphorus, lowers blood calcium, and in some cases produces tetany. Why, therefore, does not blood calcium become low and tetany occur in renal rickets? I think the answer may be that the increased blood calcium is an effort on the part of the child to prevent tetany. Tetany is a serious disease, and to prevent it I suggest that the child mobilises calcium from the bones, producing osteoporosis and rickets, an action similar to that produced by the injection of parathyroid hormone. If that suggestion is true, administration of the hormone should definitely make renal rickets worse. In one case the bone condition was reported by my radiologist colleague (Dr. Teall) to be worse after administration of the hormone, but the variations in the state of the rickets are so marked in the ordinary clinical course of renal rickets that too much importance cannot be attached to this observation. Tetany does not occur in chronic azotæmic nephritis of adults in spite of the fact that the blood calcium is diminished; the explanation usually accepted is that advanced by de Wesselow, that in this form of nephritis there is an acidosis and usually a diminution of the bicarbonate content of the plasma, which conditions favour an increased ionisation of calcium. There is, however, another factor of importance in explaining the immunity of the adult from tetany. It has been shown that if the blood plasma is subjected to ultra-filtration under negative pressure there is a considerable diminution in the calcium content of the filtrate in tetany but not in chronic nephritis. In the latter, therefore, the diminution of calcium in the plasma is largely due to diminution in non-diffusible calcium, or, in other words, is chiefly due to diminution in calcium bound to protein. In renal rickets there is no diminution in the calcium of the filtrate. Indeed, as would be expected if my theory is correct, in some cases there is an increase. Occasionally, however, tetany does occur in renal rickets, but so far I have not been able to investigate a case. Acidosis occurs in renal rickets, and not only does it increase ionisation of calcium, but it also washes out calcium from the calcium reservoirs, and presumably from the bones (Ross and Scriver), and therefore helps to produce rickets.

There are, therefore, two factors which contribute to the causation of osteoporosis and rickets in these kidney conditions in childhood: (1) some mechanism, probably a protective one, which keeps the blood calcium at a higher level than is usual in an azotæmic nephritis; (2) acidosis.

There is, however, a third and much more important factor to be considered—namely, the defective excretion of phosphorus. It is possible to see rickets develop in a case of renal infantilism, heal, and then relapse. Thus there is produced a flux between healing and relapse, and this can be correlated with periods in which the blood-phosphorus waxes and wanes. If estimations of blood-urea or non-protein nitrogen are made, it is found that the curve of phosphorus retention parallels the curve of nitrogen retention. "Renal" infants pass through many attacks of uræmia before the final one closes their chequered career. Such attacks, I believe, make their rickets worse by increasing the disparity between calcium and phosphorus, whereas in the periods of improvement the phosphorus may even return to normal limits, with the result that the calcium-phosphorus ratio becomes normal and the rickets heals. Contributory factors in this healing are a lessened degree of acidosis, and a lessened depressing effect of phosphorus on calcium and of the resulting need to call on the calcium reservoirs.

I would also draw attention to the fact that anything which increases phosphorus absorption from the alimentary tract may make the condition worse. Definite evidence has, I think, been produced by Teall and myself showing that ultra-violet irradiation, far from ameliorating, actually increases the rachitic manifestations. Let me add in passing that in renal rickets we have another illustration of the effect of growth in the development of rickets, because in those rare cases which survive until the later 'teens, when the growth period has ceased and the epiphyses joined up, rickets does not occur, although the bone is still osteoporotic to some degree and the calcium phosphorus ratio is abnormal.

From what has been said it will be gathered that I regard renal rickets as belonging, like cœliac rickets, to the low calcium category. The occurrence of renal rickets also proves the importance of the calcium-phosphorus ratio, since if the calcium-phosphorus product were a correct guide it would put these deformities far outside the rachitic range. It may well be asked, therefore, what is the proof that the condition is rickets? I think no one will question the fact that some of the cases show a radiographic appearance absolutely indistinguishable from rickets (the "rachitic type"), but, on the other hand, there are radiographic manifestations which we have called the "woolly," "honeycomb," or "stippled type," which are totally unlike that seen in ordinary rickets. There is another type, which we have called the "atrophic type," which resembles cœliac rickets, and although I have never seen the rachitic change into the atrophic type I think they can do so, just as at times we see in uncomplicated rickets a radiological picture absolutely identical with the atrophic type and with cœliac rickets. In the "woolly, stippled, or honeycomb type" osteoporosis is present, the diaphysis is straight but there is a long metaphysis, and it is in the latter that the severe deformities so characteristic of the condition occur. The metaphysis shows irregular ossification, giving the appearance of honeycombing, stippling, or woolliness, and under the periosteum the bone may appear to be eroded. The changes do not appear to the same degree in all the long bones. As the change advances the absence of subperiosteal bone becomes so marked that the end of the bone collapses, and since this absence of bone is usually more marked on one side than the other the collapse usually occurs sideways, with the result that the most extreme deformities are produced. The skull in some cases of this type shows most extraordinary changes, marked stippling being present. In the severest case that I have observed all trace of inner and outer tables of the cranial bones had disappeared and the bone was much thickened, the whole presenting an appearance indistinguishable from Paget's disease. Post-mortem examination of the long bones shows that the woolliness or stippling is due to the presence of islets of cartilage deep down in the long metaphysis, and that the appearance of subperiosteal erosion is also due to unossified cartilage. The metaphysis itself, although long, is not broad and splayed out as in the rachitic type. Although this type cannot be recognised radiographically as due to rickets, and microscopical examination shows that the changes present differ from those ordinarily seen in rickets, the proliferative cartilage being much more irregular and broken, yet Prof. Haswell Wilson, who has examined the sections for me, pronounces them as definitely rachitic in nature—a view also held by Shipley.

CONCLUSION.

I hope that in these lectures I have made clear that recent advances in our knowledge have shown that rickets is a disorder of calcium and phosphorus salt metabolism, usually the result of defective absorption of these elements from the bowel; further, that this defective absorption is due either to an inefficient supply of these elements, or of some activating body in the tissue fluids; that this body is probably vitamin D, which in its turn is derived from the alimentary canal, or synthesised by the action of ultra-violet rays on sterols in the skin; but that occasionally the faulty metabolism may be entirely endogenous in origin, as occurs in renal rickets; and finally, that growth is an essential for the development of rickets.

Although rickets existed before Glisson's time it certainly increased markedly after his day, and became almost universal in some grades of urban society, especially in districts like our own Black Country and Glasgow. We must, however, remember that except for the empirical discovery of the curative effects of cod-liver oil some hundred years ago, our knowledge of the disease advanced very little until the last few years. Although there are still many gaps in our complete knowledge of the disorder, recent researches have put us in possession of information that should allow us completely to eradicate all ordinary rickets. Already its incidence and severity are declining, and we can look forward with sure and certain hope to the day, perhaps no further distant than the tercentenary of Glisson's work, when rickets will have become one of that small but increasing number of diseases which possess a great interest for the historian but happily present no terrors of ill-health for the patient and no cause for anxiety on the part of the doctor.

BONE FORMATION AND THE OSTEOBLAST.

By H. A. HARRIS, B.Sc. Cardiff, M.B. Lond.,
ASSISTANT PROFESSOR OF ANATOMY, UNIVERSITY COLLEGE, LONDON; ASSISTANT TO THE MEDICAL UNIT, UNIVERSITY COLLEGE HOSPITAL.

> "Quid dicam de ossibus? quae subjecta corpori, mirabiles commissuras habent, et ad stabilitatem aptas, et ad artus finiendos accommodatas, et ad motum, et ad omnem corporis actionem."
>
> —*Cicero, De Natura Deorum.*

> "Scrape a bone, and its vessels bleed; cut or bore a bone, and its granulations sprout up; break a bone, and it will heal; or cut a piece away, and more bone will readily be produced; burn it, and it dies."
>
> —*Charles Bell, Anatomy.*

Cicero and Charles Bell have given pithy descriptions of the marvels of bone, the tissue which, in common with bone-marrow, displays the highest powers of regeneration and repair in the whole human economy. Sir Arthur Keith[1] has recently asked "Quid dicam de ossificatione?" The answer to the problem of ossification has not yet been found, and to review the search for the mode of ossification is to review the history of morbid anatomy. No subject has been attacked more vigorously, no subject has been deserted more frequently. When Monro Secundus and William Hewson were pleading a priority suit, in relation to their discoveries in the lymphatic system, with Benjamin Franklin as assessor, Abernethy said: "All our knowledge of the absorbing vessels has been obtained by fragments, and our future acquisitions must be made in the same manner." This is equally true of bone development. Our knowledge of the histological structure of bone is a memorial to three Englishmen: Clopton Havers (1650–1702), John Howship (d. 1841), and William Sharpey (1802–1880), who are familiarised in the canals, lacunæ, and fibres which bear their names. The bone corpuscles were first described by Purkinje and Deutsch in 1834. The specific terms "osteoblast" and "osteoclast" as applied to cells actively engaged in depositing or absorbing bone respectively were introduced by Gegenbaur and Kölliker and came into general use 60 years ago. It is of interest to note that as early as 1689, just after the invention of the Huyghens eye-piece, Gagliardi, a professor of medicine in Rome, had described certain "claviculi" or "small nails," which are identical with the fibres of Sharpey. Moreover, as Sharpey maintains, the ossification in membrane without the intervening stage of cartilage formation had been described by Nesbitt in 1736. Coincidently with the slow unfolding of the microscopic structure of bone, the experimental method was pursued by Stephen Hales, Nehemiah Grew, John Belchier, and John Hunter in this country, by Duhamel in Paris, and by Haller in Göttingen. Their methods consisted largely of actual measurements of growing bones and of the feeding of madder to experimental animals. Hales and Grew were activated by the search for vegetable processes in the development of the animal world. The madder experiments of Belchier and Hunter have been repeated on innumerable occasions, the most recent being the work of Prof. Brash,[2] of Birmingham, on the growth of the mandible. It is interesting to note how most modern investigators have failed to appreciate Hunter's description of the sites of deposition of the dye. Hunter[3] insisted on the fact that the whole of the bone was stained by madder, and that the depth of the staining was proportional to the rate of deposition and absorption of the earthy salts.

> "But in the full-grown state, it would appear from the circumstances of reddening a *whole* bone by feeding the animal with madder, that a bone, although completely formed, yet is changing its earth, and probably every other part. This effect, however, is much slower than in the growing bone. This would show that the madder does not act as a dye upon the earth which is already deposited in the bone, but only upon that matter which is every day deposited; and as there is a great deal more deposited in a young bone than in an old one in a given time, in the same proportion must it dye sooner than an old one. The new matter that is deposited in an old bone is to make up for the waste that is daily going on in it; but in a very old bone the waste is more than the repair."

This is the first clear expression of the fact that the calcium of the bones is not permanently fixed as a deposit account but can be brought into the circulation as a current account. The recent brilliant work of Collip[4] with parathyroid extract indicates the ease with which the extract can raise the blood calcium to abnormally high values by calling upon the calcium in the bones and muscles.

Grew, Duhamel, and the other botanists regarded bone as the product of the deeper layers of the periosteum, which they regarded as a "cambium" layer, by analogy with the actively proliferating zone of plants. Haller regarded bone as a product of the arteries, which could lay down bone anywhere. Hunter favoured this view, and Sir Arthur Keith[1] has recently attributed to the perithelial cells of the capillaries the power of conversion into osteoblasts. Goodsir, differing from Hunter, believed that the cartilage cells gave rise to "bone-forming corpuscles."

The present-day teaching of the formation of bone in membrane, in cartilage, and in the deep layer of the periosteum represents a consolidation of the views of Sharpey, Kölliker, and Virchow. The source of the osteoblast is, however, still a problem. Stump[5] traces the cartilage cell, the subperiosteal osteoblast, the endochondral osteoblast, the osteoclast, the endothelial cells of the growing capillaries, the primitive blood cells and the "hæmoblasts" to the same young connective tissue cells. This is an extreme statement of the monophyletic origin. Fell,[6] in a study of osteogenesis in the domestic fowl, claims, on the other hand, that the chondroblasts suffer a triple fate. They may give rise to osteoblasts, as described by Ranvier, Retterer, Macewen, and Van der Stricht, or they may give rise to the reticulum of the bone-marrow, or they may degenerate and disappear. Experiments on animals, such as those of Bast, Sullivan, and Geist[7] on the repair of fractured bones, show that the "cambium" layer of the periosteum, the osteogenetic cells lining the Haversian canals, and the cells of the endosteum are all active in the production of new bone. They found that the only site of formation of cartilage in the repair of bones was at the cut edge of the fibrous part of the periosteum. They saw fibrous tissue cells giving rise to cartilage cells. Carey and Zeit,[8] as a result of the study of the ossifying patella in the dog, emphasise the dual origin of the osteoblast, and depict both osteoblasts arising from the subendothelial mesenchyme cells accompanying the invading blood-vessels, and osteoblasts formed directly from the embryonic chondroblasts in the neighbourhood of the capillaries.

Nerve-supply of Bone.

The problem of the nerve-supply of bone has remained in abeyance. The innervation of the two tissues of the body which exhibit the greatest power of regeneration and repair, bone and its marrow, still awaits adequate description. Sir G. Thane, in Quain's Anatomy (tenth edition), mentions the fact that distinct nerves can be seen entering the nutrient foramina of the long bones. D. Goering[9] has studied the influence of the nervous system on bones and joints. She concludes that bone has a somatic and a sympathetic innervation by means of medullated and non-medullated nerve-fibres. Numerous investigators have found that trophic changes in bone follow nerve-section, such as loss of size and weight, diminution of inorganic material, and, in growing animals, defective development. Numerous observations have been recorded upon the influence in bone of nerve lesions and diseases in man. Here again, especially in leprosy, regressive changes seem to be the rule. In general, lesions of mixed nerves produce more bony changes than those of purely motor nerves, and irritative lesions of sensory nerves seem to be the most potent, as in leprosy. Goering concludes, on clinical grounds, that there are special trophic fibres of sympathetic origin passing to bones, with corresponding spinal centres. A general controlling centre, so it is claimed, is situated in the brain in the region of the floor of the third ventricle. It is obvious that there is much room for anatomical and clinical research in this field, and that the bony changes of anterior poliomyelitis and tabes dorsalis offer abundant material.

Problem of Calcium Metabolism.

The vast literature relating to bone formation was admirably summarised by Gideon Wells[10] in the Harvey lecture of 1911. Since that date biochemistry and the intensive study of the vitamins have revealed the complexity of the whole problem of calcium metabolism. Wells stated that the questions to be answered are:—

1. Why is calcium deposited in the tissues at all?
2. Why is it deposited in some tissues and not in others?
3. How is the calcium carried in the blood?
4. How is it held in the tissues where deposited?
5. Why is the composition of calcified deposits so constant, qualitatively and quantitatively?
6. What are the causes of rickets and osteomalacia?

These questions still await concise answers. The first question involves the whole problem of senescence and death. Calcification occurs not only in certain cartilages but also in tumours, such as fibroids and granulomata, in the meninges, and in tendons, ligaments, and arteries. The second question brings to mind the fact that the tissues which undergo calcification in senescence are the tissues which afford examples of vegetative reproduction, with or without mitotic division of nuclei, in relatively bloodless areas. Cartilage, which most readily undergoes calcification, is a tissue in which the cells live by the imbibition of tissue juice, removed from an active blood-supply. There is undoubtedly a limit to the size of the mass of cartilage which any animal can grow, just as there is a limit to the size of a granuloma. When the limit of growth is reached certain of the cells degenerate and the matrix calcifies or caseates. Thus in cartilage proliferation, degeneration and calcification are closely related to the vegetative processes of proliferation without specialisation of function and without differentiation of structure, leading to old age and death of the tissue. On the other hand, bone formation is an active process, distinct from calcification. It occurs in the presence of a rich blood-supply and is accompanied by differentiation of the primitive cells for function, as distinct from mere proliferation. In short, bone is a live tissue, actively growing or functioning in an area richly endowed with blood. Calcified cartilage is so senescent as to be virtually a dead tissue in an area relatively poor in blood-supply.

The question of the carriage of calcium in the blood has been attacked with great vigour by the chemist. Howland, Shipley, and Marriott and Kramer [11] have stated that bone normally contains bicalcium phosphate, that different bones of the same individual have the same inorganic percentage, that the ratio of calcium phosphate to calcium carbonate is greater in normal than in rachitic bones, and, further, that the bone contains the phosphate and carbonate of calcium in the same proportion as the serum. R. Robison [12] has disagreed with these views and has emphasised the significance of the hexose phosphoric esters. He states that the osteoblasts and the hypertrophic cartilage cells of the growing animal secrete an active phosphatase which, by hydrolysing the phosphoric esters of the blood, brings about a local increase of the tricalcium phosphate concentration. This concentration exceeds the solubility product of the salt and leads to its deposition in the ossifying zone. Howland and his co-workers do not favour simple precipitation as the explanation, but regard the process as a chemico-physical one, depending on the activity of the living tissue in a medium in which the concentration of calcium and phosphate in the serum and tissue juice exceed a certain minimum value. J. B. Collip [4] in Canada, and C. P. Stewart and J. H. Percival [13] in this country, have dealt in particular with the changes in serum calcium under administration of Collip's parathyroid hormone. The diffusible calcium is markedly increased thereby. These experiments indicate the ease with which calcium passes into the blood from bone and other tissues, and this is a brilliant confirmation of Hunter's precocious statement about the continuous absorption and deposition of alkaline earths in old bone as well as in young bone.

Several attempts have been made to imitate in colloidal solutions the actual deposition of tricalcium phosphate and calcium carbonate. Barillé [14] in France and J. C. Watt [15] in Canada have come to the conclusion that the salts in bone are deposited by the activity of the osteoblasts as a secretory phenomenon. Crétin,[16] in particular, has contributed much to our knowledge of the staining reaction of bone and of the possible conditions of deposition of the calcium salts. He regards the actual areas of muscular attachment to be of great significance in determining cartilage formation and ossification. The sterno-mastoid and trapezius muscles in relation to the clavicle and the occipital bone are differentiated before the cartilage or bone appears. The point of cartilage formation and of bone formation is always related to the muscular attachment. The transportation of phosphorus in combination with alkali metals converts the primitive tissue into cartilage by producing a modification in the albumenoids of the matrix. Whereas cartilage is rich in sodium, growth ceases when calcium disturbs the equilibrium between phosphate on the one hand and sodium and potassium on the other. Calcium carbonate is now precipitated, redissolved in the presence of alkalies, and then reprecipitated by phosphate in the form of basic phosphate or phosphocarbonate.

Tissue Culture Experiments.

The results of tissue culture experiments have so far been disappointing. A. Carrel and M. T. Burrows [17] cultivated conjugal cartilage as early as 1910, but the first detailed experiments were those of A. Fischer [18] in 1922. He cultivated the cartilage cells from the sclera of the chick embryo “in vitro,” and found that the cells would not grow in the substance but would grow on the surface of a clot of plasma. In the implant the hyaline substance liquefies, the cells migrate, increase in size, and continue to live. No division of the cells was seen. T. S. Strangeways [19] succeeded in producing multiplication of the cartilage cells in vitro, with typical mitoses. Policard and Boucharlat [20] implanted periosteum and perichondrium of chicks, but in vitro they gave rise to connective tissue cells without the formation of cartilage or bone. A. O. Wjerinski [21] reports the same results in vitro, though a homoplastic transplant in vivo led to strong mitotic multiplication of the cells of the periosteum and actual conversion into osteoblasts. Thus, so far, osteoblasts have not been grown or propagated in vitro by the technique of tissue culture. This suggests that the osteoblast is a purposively differentiated cell which may easily regress into a fibroblast, but will only redifferentiate in the presence of the blood-borne exudate of a living capillary.

The nerve cell of the young embryo has been grown in tissue culture, but the growth has been localised almost entirely in the axone—i.e., in the part of the cell which was shown capable of growth in the adult by Waller's classical experiments on nerve regeneration. The osteoblast, as Burrows [22] has pointed out for the fully matured lymphocyte, polymorphonuclear leucocyte, and many other mononuclear cells, will not grow in a tissue culture. Neither the nerve cell nor the osteoblast can be propagated. Thus these cells seem to exhibit an extreme degree of differentiation.

R. G. Harrison,[23] in 1914, pointed out that cells will not grow in tissue cultures in clotted plasma unless some form of support is afforded, such as the surface of the cover-glass, the surface of the fluid film, or a framework of spider-web, silk gauze, or cotton-thread. In cultures in which the tissue floats free in a fluid medium no outgrowth occurs and the cell succumbs. This phenomenon whereby a cell in the free rounded stage, devoid of support, is unable to grow was described by Leo Loeb and Fleischer [24] under the name of stereotropism. It involves a most fundamental conception of a skeletal support for the cell, and may account for the failure to grow osteoblasts and fully differentiated blood cells such as lymphocytes. Kidney and liver are grown with ease because of their associated connective tissue stroma. Cartilage cells die when they round up near the epiphysis. Osteoblasts apparently require the support of a connective tissue stroma and the adequate supply of blood-borne substances such as vitamin A and ergusia. Only those animals which have a blood vascular system and a cœlom are able to produce an active osteoblast.

Bone Pathology.

The pathology of bone, like the pathology of the blood-vessels, has been so obscured by diverse classifications and a multitude of strange names that certain simple facts escape observation. Chondrodystrophies, osteochondrites, and osteites have been subdivided without end, and dysostoses, aclasias, and dysclasias have been added thereto. Vrolik's term of “ osteogenesis imperfecta ” is one of the few safe terms in the pathology of growing bone. H. A. Harris's [25] tentative scheme, as a simple working basis for the analysis of bone growth, serves also as a basis for the interpretation of bone pathology. He states that cartilage grows vegetatively by the imbibition of tissue juice in much the same way as bacteria, yeasts, tumour cells, and granulomata. This vegetative proliferation of the cell is largely under the control of the water-soluble vitamins and of those substances which workers in the realm of tissue culture have designed as “ archusia ” (M. T. Burrows)[26] or “ trephones ” (A. Carell).[27] The process of proliferation of the undifferentiated cartilage cell is limited by the size of the mass and by the adequacy of nutrition. When the mass of cartilage reaches a certain limit, as in the case of a granuloma, the cells within the mass become senescent, degenerate, and gradually pass into a resting stage which in many cases leads to death. This process of degeneration is accompanied by calcification of the matrix, and is comparable to the phenomenon of caseation and calcification in a tubercle, gumma, or fibroid, or to hyalinisation and the formation of cell nests in a stage of cartilage formation had been described by Nesbitt in 1736. Coincidently with the slow unfolding of the microscopic structure of bone, the experimental method was pursued by Stephen Hales, Nehemiah Grew, John Belchier, and John Hunter in this country, by Duhamel in Paris, and by Haller in Göttingen. Their methods consisted largely of actual measurements of growing bones and of the feeding of madder to experimental animals. Hales and Grew were activated by the search for vegetable processes in the development of the animal world. The madder experiments of Belchier and Hunter have been repeated on innumerable occasions, the most recent being the work of Prof. Brash,[2] of Birmingham, on the growth of the mandible. It is interesting to note how most modern investigators have failed to appreciate Hunter's description of the sites of deposition of the dye. Hunter[3] insisted on the fact that the whole of the bone was stained by madder, and that the depth of the staining was proportional to the rate of deposition and absorption of the earthy salts.

> "But in the full-grown state, it would appear from the circumstances of reddening a *whole* bone by feeding the animal with madder, that a bone, although completely formed, yet is changing its earth, and probably every other part. This effect, however, is much slower than in the growing bone. This would show that the madder does not act as a dye upon the earth which is already deposited in the bone, but only upon that matter which is every day deposited; and as there is a great deal more deposited in a young bone than in an old one in a given time, in the same proportion must it dye sooner than an old one. The new matter that is deposited in an old bone is to make up for the waste that is daily going on in it; but in a very old bone the waste is more than the repair."

This is the first clear expression of the fact that the calcium of the bones is not permanently fixed as a deposit account but can be brought into the circulation as a current account. The recent brilliant work of Collip[4] with parathyroid extract indicates the ease with which the extract can raise the blood calcium to abnormally high values by calling upon the calcium in the bones and muscles.

Grew, Duhamel, and the other botanists regarded bone as the product of the deeper layers of the periosteum, which they regarded as a "cambium" layer, by analogy with the actively proliferating zone of plants. Haller regarded bone as a product of the arteries, which could lay down bone anywhere. Hunter favoured this view, and Sir Arthur Keith[1] has recently attributed to the perithelial cells of the capillaries the power of conversion into osteoblasts. Goodsir, differing from Hunter, believed that the cartilage cells gave rise to "bone-forming corpuscles."

The present-day teaching of the formation of bone in membrane, in cartilage, and in the deep layer of the periosteum represents a consolidation of the views of Sharpey, Kölliker, and Virchow. The source of the osteoblast is, however, still a problem. Stump[5] traces the cartilage cell, the subperiosteal osteoblast, the endochondral osteoblast, the osteoclast, the endothelial cells of the growing capillaries, the primitive blood cells and the "hæmoblasts" to the same young connective tissue cells. This is an extreme statement of the monophyletic origin. Fell,[6] in a study of osteogenesis in the domestic fowl, claims, on the other hand, that the chondroblasts suffer a triple fate. They may give rise to osteoblasts, as described by Ranvier, Retterer, Macewen, and Van der Stricht, or they may give rise to the reticulum of the bone-marrow, or they may degenerate and disappear. Experiments on animals, such as those of Bast, Sullivan, and Geist[7] on the repair of fractured bones, show that the "cambium" layer of the periosteum, the osteogenetic cells lining the Haversian canals, and the cells of the endosteum are all active in the production of new bone. They found that the only site of formation of cartilage in the repair of bones was at the cut edge of the fibrous part of the periosteum. They saw fibrous tissue cells giving rise to cartilage cells. Carey and Zeit,[8] as a result of the study of the ossifying patella in the dog, emphasise the dual origin of the osteoblast, and depict both osteoblasts arising from the subendothelial mesenchyme cells accompanying the invading blood-vessels, and osteoblasts formed directly from the embryonic chondroblasts in the neighbourhood of the capillaries.

Nerve-supply of Bone.

The problem of the nerve-supply of bone has remained in abeyance. The innervation of the two tissues of the body which exhibit the greatest power of regeneration and repair, bone and its marrow, still awaits adequate description. Sir G. Thane, in Quain's Anatomy (tenth edition), mentions the fact that distinct nerves can be seen entering the nutrient foramina of the long bones. D. Goering[9] has studied the influence of the nervous system on bones and joints. She concludes that bone has a somatic and a sympathetic innervation by means of medullated and non-medullated nerve-fibres. Numerous investigators have found that trophic changes in bone follow nerve-section, such as loss of size and weight, diminution of inorganic material, and, in growing animals, defective development. Numerous observations have been recorded upon the influence in bone of nerve lesions and diseases in man. Here again, especially in leprosy, regressive changes seem to be the rule. In general, lesions of mixed nerves produce more bony changes than those of purely motor nerves, and irritative lesions of sensory nerves seem to be the most potent, as in leprosy. Goering concludes, on clinical grounds, that there are special trophic fibres of sympathetic origin passing to bones, with corresponding spinal centres. A general controlling centre, so it is claimed, is situated in the brain in the region of the floor of the third ventricle. It is obvious that there is much room for anatomical and clinical research in this field, and that the bony changes of anterior poliomyelitis and tabes dorsalis offer abundant material.

Problem of Calcium Metabolism.

The vast literature relating to bone formation was admirably summarised by Gideon Wells[10] in the Harvey lecture of 1911. Since that date biochemistry and the intensive study of the vitamins have revealed the complexity of the whole problem of calcium metabolism. Wells stated that the questions to be answered are:—

1. Why is calcium deposited in the tissues at all?
2. Why is it deposited in some tissues and not in others?
3. How is the calcium carried in the blood?
4. How is it held in the tissues where deposited?
5. Why is the composition of calcified deposits so constant, qualitatively and quantitatively?
6. What are the causes of rickets and osteomalacia?

These questions still await concise answers. The first question involves the whole problem of senescence and death. Calcification occurs not only in certain cartilages but also in tumours, such as fibroids and granulomata, in the meninges, and in tendons, ligaments, and arteries. The second question brings to mind the fact that the tissues which undergo calcification in senescence are the tissues which afford examples of vegetative reproduction, with or without mitotic division of nuclei, in relatively bloodless areas. Cartilage, which most readily undergoes calcification, is a tissue in which the cells live by the imbibition of tissue juice, removed from an active blood-supply. There is undoubtedly a limit to the size of the mass of cartilage which any animal can grow, just as there is a limit to the size of a granuloma. When the limit of growth is reached certain of the cells degenerate and the matrix calcifies or caseates. Thus in cartilage proliferation, degeneration and calcification are closely related to the vegetative processes of proliferation without specialisation of function and without differentiation of structure, leading to old age and death of the tissue. On the other hand, bone formation is an active process, distinct from calcification. It occurs in the presence of a rich blood-supply and is accompanied by differentiation of the primitive cells for function, as distinct persists in the molar teeth of the rat after eruption. The crown continues to increase in both dimensions; as much as 10 per cent. is added to its length and breadth during the first two years, and the growth takes place in the dentine. This startling observation compels us to regard dentine, like bone, as a tissue subject to prolonged growth, peculiarly susceptible to changes in the blood calcium, and revealing the same processes of absorption and deposition as bone. The rapid development of caries and the fragmentation of the enamel in pregnant and nursing mothers may be due to the inroad made on the calcium of the dentine and the resulting shrinkage.

Still more numerous are the problems afforded by comparative anatomy, and it is surprising that so little has been added to the original observations of John Goodsir (1814–1867), who inaugurated the study of calcification in sponges and molluscs. Pearl and Surface[37] in 1909 performed a classical experiment. They anastomosed the gut to the oviduct of the fowl and showed that the fæces were covered with a shell. The domestic fowl, with its active metabolism and great powers of repair, appears to be an ideal animal for the study of calcification and ossification. Considering the extent to which the costochondral junction and the costal cartilages have figured in the literature of rickets and respiratory diseases, it is evident that a detailed study of the comparative anatomy of these structures offers a promising field for research. The costal cartilages calcify in old age in man, in adolescence in sheep and goats, and they become really ossified in birds.

It seems that until the chemist explains the colloidal processes which lead to the deposition of the salts of calcium in two tissues so fundamentally distinct as dying cartilage on the one hand and living bone on the other, we must continue to regard the osteoblast as a splendid being, endowed with genius, sensibility, and intelligence, ever ready to perform the work at hand.

CANCER OF THE INTESTINE.

A CLINICAL STUDY.

BY RICHARD WARREN, M.D., M.CH. OXF.,
F.R.C.S. ENG.,

SURGEON TO THE ALEXANDRA MEMORIAL HOSPITAL, WESTON-SUPER-MARE; LATE SURGEON TO THE LONDON HOSPITAL.

THIS account is based on observations of 69 cases of cancer of the bowel (excluding the rectum) verified by operation. In all except two cases the cancer was of the large intestine. Although distinctly a disease of middle and old age, no stage of life affords immunity to it. The youngest in this series was a boy of 15 (much younger cases are on record) and the oldest a man of 78. Cancer of the small gut is rare; only two cases were noted. In the colon the distribution was as follows: cæcum to hepatic flexure, 12; transverse colon, 4; splenic flexure and descending colon, 20; sigmoid, 31. It is, therefore, much more common at the two ends of the colon, especially the lower.

The onset is usually insidious, taking the form of a vague dyspepsia or abdominal discomfort which may be regarded lightly by the patient until the crisis arrives with a well-marked attack of intestinal obstruction. The commonest symptoms and signs are: (*a*) in the earlier quiet period—pain, flatulence, and meteorism or distension with gas, alteration in the motions such as constipation and diarrhœa, and occasionally a local tumour; (*b*) the urgent condition—signs of acute intestinal obstruction and of local or general peritoneal irritation. Most of the early signs are those of early intestinal obstruction and must be weighed carefully before being regarded as trivial.

Early Stages.

In the early stages a mild degree of obstruction is apt to be the only significant sign. Rarely a local tumour can be felt. A woman of 50 who had suffered from metrorrhagia for some years was brought up for examination. In addition to the enlarged nodular fibroid uterus there was a small mobile lump on the left of, and not definitely attached to, the uterus, but sufficiently close to lead to the conclusion that it was a very mobile subperitoneal fibroid. At operation the small lump proved to be a cancer of the sigmoid. The cæcum is the part where a cancerous tumour is most commonly noted early.

1. *The pain* tends to be intermittent and varies from abdominal discomfort to fairly severe colic as the obstruction becomes more advanced. It may have a relation to meals and is, in fact, one of the forms of dyspepsia. The time relation is not, however, constant, like that of peptic ulcer, and the associated flatulence renders it more likely to be confused with gall-bladder dyspepsia. In a great many instances the pain is not enough to make the patient seek advice before acute obstruction supervenes. More rarely there is pain of a different type in the vicinity of the growth, as in one case where there was a large growth of the cæcum simulating a renal tumour, but not reducible into the loin. In other patients spread of the growth from the splenic flexure along the lieno-renal ligament gave severe pain, which in one instance preceded any signs of obstruction by some weeks and drew attention to the kidney rather than the bowel. Localised pain from ulceration of, and peritonitis over, the distended cæcum is discussed later.

2. *Flatulence* is a word covering various conditions. It may refer to eructation of gas associated with pain or discomfort, or to a feeling of full[illegible] which is relieved by [illegible] tion with gurgling and tinkling noises known as borborygmi. Such noises and eructations are so commonly due to errors in diet, neurosis, &c., that unless they are of recent development and recur frequently, accompanied by pain which is relieved by the passage of gas, they have little significance.

carcinoma. Lastly, the propinquity of a rapidly growing capillary system in the bone-marrow brings into the region a new set of factors which lead to tissue differentiation as distinct from cell proliferation. The capillaries of the bone-marrow proceed to remove the dead calcified cartilage as they would proceed to remove any other foreign dead body, such as a caseated granuloma or a ligature. The cells of the calcified cartilage that are not quite dead, but rather in a resting or " spore " stage, respond to the approach of the blood capillaries by active amitotic division to form osteoblasts. Any primitive connective tissue cell in the vicinity of the actively proliferating capillary can give rise to osteoblasts, whether this cell be periosteal, perivascular, or reticular. This process of cell differentiation for function is in part attributable to the arrival in the area, via the blood stream, of fat-soluble blood-borne substances. These fat-soluble, blood-borne substances correspond to the " ergusia " or differentiating, energy-producing substance of Burrows, and to vitamin A proper. The osteoblasts are cells designed for work, not for proliferation, and a failure of ergusia or vitamin A leads to the formation of imperfectly differentiated osteoblasts. The degree of differentiation may be so low that the osteoblast is little more than a fibroblast; it may be more advanced, so that the cells deserve the name of " osteoidoblast," but only in the presence of an adequate supply of the blood-borne vitamin A does one see the fully differentiated osteoblast with deeply staining nucleus and numerous basophilic granules in the cytoplasm. This conception of the vegetative proliferative process in cartilage, in contradistinction to the differentiating and functional process in bone, is not entirely new. Its formulation in terms of archusia and ergusia on the one hand, or in terms of water-soluble and fat-soluble vitamins on the other hand, is but an experimental and clinical statement of a long-established teleological fact. Richard Owen,[28] when Curator of the Royal College of Surgeons of England, said, as far back as 1843 :—

> " Organic forms result from the antagonistic working of two principles, of which one brings about a vegetative repetition of structure, while the other, a teleological principle, shapes the living thing to its functions. . . . In every species these two forces are at work, and the extent to which the general polarising or ' vegetative repetition force ' is subdued by the teleological is an index of the grade of the species."

Evolution is measured by the extent of the triumph of ergusia and the fat-soluble vitamins over archusia and the water-soluble vitamins.

The term metastatic calcification was applied by Virchow to the occurrence of deposits of calcium salts in abnormal sites. There is hardly a tissue in the body which does not present numerous examples of abnormal calcification, from ganglion cells and skin on the one hand, to kidney, liver, lungs, and gastric mucosa on the other. Most of the cases of calcification occur in an area of senile or necrosed tissue, with a poor blood-supply and a slow lymph stream. There are, however, three marked exceptions, for calcification has been repeatedly reported in the lungs, kidneys, and gastric mucous membrane. These three areas are the sites of excretion or secretion of acid substances, and the tendency to calcification in these areas may be an expression of this fact. Cartilage, when calcifying, stains deeply with basophilic dyes, and has an acid reaction. Wells[29] has stated that the well-known tendency of muscle-fibres to calcify in the vicinity of recent wounds, including laparotomy wounds, may be due to the precipitation of calcium salts by lactic acid, set free by the injury to the muscle-fibres during the process of degeneration. The question whether a site of calcification shall also become a site of bone formation is apparently a question of blood-supply. Tendons, ligaments, the media of arteries and caseating granulomata rarely produce true bone, but muscle, kidney, lung, suprarenal, and tonsil frequently do, by reason of the association of primitive connective tissue cells with a rich capillary network. Cushing and Weed,[30] in their experimental studies on the cerebro-spinal fluid of cats, observed numerous instances of calcification and ossification of the arachnoid membrane. Calcification occurred in non-vascular areas, for the nutrition of the arachnoid is obtained through the cerebro-spinal fluid rather than through the blood stream. On the other hand, every case of true bone formation was vascularised and could be attributed to the proliferation of mesothelial cells in a vascularised area, as distinct from the calcification of aged cells in an avascular area. In the aged cadaver of the dissecting-room, calcification of the membranes, both dura and arachnoid, is common. True bone formation, on the other hand, is rare.

For a considerable time it was thought that the secret of calcification would be found in the formation of calcium soaps with fatty acids, for the early pathologists had described calcification by soap formation in degenerating lipomata as early as 1850. The absence of any appreciable amount of calcium soaps from areas of normal calcification has negatived this idea, and the presence of large quantities of calcium soaps in certain stages of the digestion of fat without associated calcification is also against the theory. We seem to be confronted with the need for a new chemical concept. The hydrogen-ion concentration and the salt content must be known, not only for the arterial and venous streams but also for the contents of the lymphatics, for the tissue juice, and for the interior of the cell. The high percentage of calcium which can be absorbed in a cartilage designed for later calcification was shown by Wells.[10] He showed that pieces of epiphysial cartilage, tracheal cartilage, and costal cartilage absorb decreasing amounts of calcium salts, irrespective of whether the cells in the transplant be alive or dead. Moreover, decalcified bone-grafts are known to be less efficient than normal bone-grafts, so that a preliminary calcification or power of calcium absorption in the tissue seems to be advantageous for subsequent ossification. Pathological ossification, no less than normal ossification, seems to require preliminary calcification of the cartilage or of the necrosed tissue.

Since no chemical ion or soap in cartilage can be proved to be an adequate agent in producing the deposition of calcium phosphate and carbonate, it is interesting to note that Jan Wolf[31] has returned to the problem of chondroitin-sulphuric acid. This substance is a normal constituent of cartilage; it is increased in calcifying cartilage; it occurs in the amyloid deposits of the spleen, liver, and arteries; its calcium salt is very soluble. Jan Wolf has shown that the small veins draining the costal cartilage contain a measurable amount of chondroitin-sulphuric acid, and that this can be stained in situ by mucicarmin or basophilic stains. The acid is not found in the arteries. This suggests that the continuous removal of chondroitin-sulphuric acid from the matrix of a cartilage is necessary to preserve it from calcification. As yet no one has studied the effects on the solubility product of this acid or its calcium salt in the presence of other ions. Even as long ago as 1891, Schmiedeberg[32] suggested that one of the functions of cartilage was the production of chondroitin-sulphuric acid and that this acid served as a mordant and possibly as a regulator of the processes of nutrition in other tissues. A chemical study of cartilage from this point of view may throw some light upon the metabolism of mucin, which hitherto has been unsolved.

Dentine and the Odontoblast.

Closely associated with the problem of the osteoblast and bone is the problem of the odontoblast and dentine. The metabolic processes involved are closely related, and the pathological processes are parallel in craniotabes, in dysostosis cleidocranialis, in osteomalacia, and in experimental rickets. The problem has been discussed recently by Mrs. Mellanby,[33] W. Fish,[34] and D. Stewart,[35] and attention must be drawn to the disturbing evidence adduced by Donaldson and French,[36] who claim that growth persists in the molar teeth of the rat after eruption. The crown continues to increase in both dimensions; as much as 10 per cent. is added to its length and breadth during the first two years, and the growth takes place in the dentine. This startling observation compels us to regard dentine, like bone, as a tissue subject to prolonged growth, peculiarly susceptible to changes in the blood calcium, and revealing the same processes of absorption and deposition as bone. The rapid development of caries and the fragmentation of the enamel in pregnant and nursing mothers may be due to the inroad made on the calcium of the dentine and the resulting shrinkage.

Still more numerous are the problems afforded by comparative anatomy, and it is surprising that so ittle has been added to the original observations of ohn Goodsir (1814–1867), who inaugurated the study f calcification in sponges and molluscs. Pearl and urface[37] in 1909 performed a classical experiment. hey anastomosed the gut to the oviduct of the fowl nd showed that the fæces were covered with a shell. he domestic fowl, with its active metabolism and eat powers of repair, appears to be an ideal animal the study of calcification and ossification. Con- dering the extent to which the costochondral junction and the costal cartilages have figured in the literature of rickets and respiratory diseases, it is evident that a detailed study of the comparative anatomy of these structures offers a promising field for research. The costal cartilages calcify in old age in man, in adolescence in sheep and goats, and they become really ossified in birds.

It seems that until the chemist explains the colloidal processes which lead to the deposition of the salts of calcium in two tissues so fundamentally distinct as dying cartilage on the one hand and living bone on the other, we must continue to regard the osteoblast as a splendid being, endowed with genius, sensibility, and intelligence, ever ready to perform the work at hand.

CANCER OF THE INTESTINE.

A CLINICAL STUDY.

BY RICHARD WARREN, M.D., M.CH. OXF.,
F.R.C.S. ENG.,
SURGEON TO THE ALEXANDRA MEMORIAL HOSPITAL, WESTON-SUPER-MARE; LATE SURGEON TO THE LONDON HOSPITAL.

THIS account is based on observations of 69 cases of cancer of the bowel (excluding the rectum) verified by operation. In all except two cases the cancer was of the large intestine. Although distinctly a disease of middle and old age, no stage of life affords immunity to it. The youngest in this series was a boy of 15 (much younger cases are on record) and the oldest a man of 78. Cancer of the small gut is rare; only two cases were noted. In the colon the distribution was as follows: cæcum to hepatic flexure, 12; transverse colon, 4; splenic flexure and descending colon, 20; sigmoid, 31. It is, therefore, much more common at the two ends of the colon, especially the lower.

The onset is usually insidious, taking the form of a vague dyspepsia or abdominal discomfort which may be regarded lightly by the patient until the crisis arrives with a well-marked attack of intestinal obstruction. The commonest symptoms and signs are: (*a*) in the earlier quiet period—pain, flatulence, and meteorism or distension with gas, alteration in the motions such as constipation and diarrhœa, and occasionally a local tumour; (*b*) the urgent condition—signs of acute intestinal obstruction and of local or general peritoneal irritation. Most of the early signs are those of early intestinal obstruction and must be weighed carefully before being regarded as trivial.

Early Stages.

In the early stages a mild degree of obstruction is apt to be the only significant sign. Rarely a local tumour can be felt. A woman of 50 who had suffered from metrorrhagia for some years was brought up for examination. In addition to the enlarged nodular fibroid uterus there was a small mobile lump on the left of, and not definitely attached to, the uterus, but sufficiently close to lead to the conclusion that it was a very mobile subperitoneal fibroid. At operation the small lump proved to be a cancer of the sigmoid. The cæcum is the part where a cancerous tumour is most commonly noted early.

1. *The pain* tends to be intermittent and varies from abdominal discomfort to fairly severe colic as the obstruction becomes more advanced. It may have a relation to meals and is, in fact, one of the forms of dyspepsia. The time relation is not, however, constant, like that of peptic ulcer, and the associated flatulence renders it more likely to be confused with gall-bladder dyspepsia. In a great many instances the pain is not enough to make the patient seek advice before acute obstruction supervenes. More rarely there is pain of a different type in the vicinity of the growth, as in one case where there was a large growth of the cæcum simulating a renal tumour, but not reducible into the loin. In other patients spread of the growth from the splenic flexure along the lieno-renal ligament gave severe pain, which in one instance preceded any signs of obstruction by some weeks and drew attention to the kidney rather than the bowel. Localised pain from ulceration of, and peritonitis over, the distended cæcum is discussed later.

2. *Flatulence* is a word covering various conditions. It may refer to eructation of gas associated with pain or discomfort, or to a feeling of fullness and distension, which is relieved by passage of the gas past the obstruction with gurgling and tinkling noises known as borborygmi. Such noises and eructations are so commonly due to errors in diet, neurosis, &c., that unless they are of recent development and recur frequently, accompanied by pain which is relieved by the passage of gas, they have little significance.

Careful inquiry into the smaller happenings of a patient's abdomen will often be helpful. Meteorism or considerable distension of the abdomen with gas may be regarded as the acme of flatulence; it is hardly an early symptom but is evidence that intestinal obstruction is already well developed and that the case has passed into stage (*b*).

3. *Irregular action of the bowels*, if of recent origin in a middle-aged or elderly patient who has previously been normal, is one of the most suggestive symptoms. Less frequent, smaller, and perhaps thin and tape-like motions suggest an obstructive growth low down in the large intestine. Obstruction higher up, where the motion is soft or liquid, will not have the same effect in causing constipation and alteration in the shape of the motions. Diarrhœa is less frequent and is usually associated with constipation, though it may be the initial symptom. Two quite different conditions are classed together as diarrhœa.

(*a*) The first is the liquefaction of fæces above an obstruction which has perhaps become temporarily blocked with a scybalous mass, the pouring out of secretion by the mucosa irritated by the retained fæces, and, still more, the inability of the mucosa to perform its normal function of extracting water from the fæcal porridge. The result is a great mass of peasoup-like material above the stenosed part. The temporary block gives way and the flood of liquid fæces pours down as diarrhœa or, if the dam does not yield naturally, persists until the surgeon lets out many pints of liquid fæces through a Paul's tube to relieve acute obstruction.

(*b*) The second is the irritation of a fungating growth by the passage of fæces which causes an outpouring of mucus, pus, sloughs, and perhaps blood, and irritates the bowel below, causing tenesmus and small, frequent, slimy stools. Diarrhœa of this type is a special feature of cancer of the lower part of the large gut, especially the rectum, and is common in the early morning. In the former class we find large intermittent stools of liquid fæces, and in the latter small, frequent stools with plenty of mucus, perhaps blood and occasionally sloughs.

A palpable tumour is not common, and when present is, in my experience, of evil significance. The larger number of cases are those of annular stricture, which can only be felt when the abdomen is opened. A cancer is most often palpable in the cæcal region. Unfortunately, the tumours that can be palpated are apt to be secondaries in the glands, mesentery, and omentum, and indicate that the stage for radical removal has passed.

To sum up, the only early signs of cancer of the bowel, except tumour, which is uncommon, are those of intestinal obstruction. The difficulty consists in distinguishing in time obstruction from other abdominal conditions of less serious or, at any rate, of less urgent import.

Later Stages.

The signs at this period are those suggesting what is commonly known as the "acute abdomen," and are of two types, (*a*) the obstructive, and (*b*) the peritonitic, though a combination is not uncommon.

The signs of acute obstruction hardly need repetition here; the severe colicky pain, the rising pulse, the vomit turning from green to brown, then acquiring a foul odour and finally consisting of liquid fæces, and the inability to pass flatus form a very definite picture. This is the class of case where true fæcal vomiting is best seen; it simply denotes that the obstruction is low in the bowel. Visible peristalsis and marked meteorism, without tenderness or rigidity, complete the picture.

The less frequent but more obviously acute type is where the bowel above the obstruction is so distended that it has become ulcerated with inflammation spreading to its peritoneal coat. It may be gangrenous, or perforation may have taken place. The abdomen will then show marked tenderness and rigidity, which may be general where leaking of fæces through a perforation has taken place, or localised, especially in the right iliac fossa, because the cæcum is the place of maximum distension where gangrene and perforation most commonly occur. This last type of case gives a picture closely resembling acute appendicitis and has caused difficulty in diagnosis.

X Rays in Diagnosis.

Since almost the only signs are those of oncoming intestinal obstruction, it behoves us to get any help we can in distinguishing this from other varieties of "dyspepsia." Careful following of an opaque meal downwards and, still better, of an opaque enema upwards with the fluorescent screen, is of great help in early and doubtful cases, but more often results in proving a negative and saving an exploratory laparotomy than in finding and locating an intestinal growth. Most commonly, in my experience, by the time the patient and doctor realise that anything serious is the matter, it is sufficiently obvious that operation is urgent and that X ray examination will only take up time which might be better employed. There can be no doubt, however, that if this means of investigation were used more frequently for patients with obscure abdominal symptoms, a good many cases would be diagnosed with sufficient probability to warrant operation at an earlier period.

Complications.

These are, unfortunately, only too frequent, and they may be :—

1. Direct sequelæ of the growth: (*a*) Spread of the cancer to omentum, glands, peritoneum, or liver, rendering radical removal impossible. (*b*) Distension of the bowel above a constricting growth, ending in localised ulceration, gangrene, and perforation, and leading to local or generalised peritonitis.

2. Association with totally distinct diseases such as appendicitis, suppurating ovarian cyst, or fibroids of the uterus, any of which may render radical removal of the growth much more difficult.

Treatment.

Out of 69 cases preliminary drainage by colostomy (including cæcostomy) or lateral anastomosis was done in 57; in the other 12 the operation was primary excision and anastomosis. Of the 43 cases which survived colostomy or anastomosis excision of the growth was done in 24, and 16 recovered. As far as possible the rule was followed of not resecting at the primary operation when any obstruction was present. In some special circumstances this rule was broken, and not always with bad results. Taking it all round, patients did far better after secondary than primary excision, the mortality being 30 per cent. as against nearly 60 per cent. There is a great temptation to try to get the matter finished with as few operations as possible, especially in aged patients, but experience shows that people over 70 stand the extra time in bed, needed for a second and third operation (excision and closure of colostomy), quite well. Colostomy, though a relatively minor operation, has quite a sufficiently high mortality; in this series it was 20 per cent. This may seem high, but it is partly caused by complications. For instance, a middle-aged woman was admitted to hospital with well-marked signs of appendicitis. A large, red, swollen appendix surrounded with lymph was removed and the abdomen closed. The patient made a good recovery for 14 days and was about to get up when she was suddenly seized with severe abdominal pain and rigidity with collapse. Immediate laparotomy revealed thrombosis of the inferior mesenteric vessels, early gangrene of the sigmoid and descending colon, and a small annular cancer of the sigmoid. Whether the appendicitis was a pure coincidence or a sequel to septic absorption from the ulcerated growth, as well as a source for thrombosis, is a matter for conjecture.

In several other cases the cæcum has been gangrenous or perforated; not all these cases succumbed, but those who survive are fortunate. In another patient a suppurating ovarian cyst rendered the preliminary colostomy and excision difficult and presumably inadequate, as recurrence took place. About a year later another inflamed ovarian cyst on the opposite side further complicated the condition.

Primary Excision of Cancer.

Cases in which primary excision seems enticing are:—

(*a*) Those in which no obstruction is present—i.e., those in which a palpable tumour is the leading sign, especially growths of the cæcum.

(*b*) Growths of the cæcum and ascending colon, because of the technical difficulties of an enterostomy in or above the cæcum followed by excision in the vicinity of such a fæcal fistula.

(*c*) Where sepsis, peritonitis, and possibly abscess about the growth without much obstruction lead the surgeon to think that if the cases recover from colostomy and drainage of pus the resulting adhesions will make removal of the growth later on impossible. My impression is that cases of the last group are such bad operative risks that as little as possible should be done at first, provided that good drainage be established. For example, after draining an abdomen the lower part of which was full of fæculent pus from the bursting of an over-distended cæcum, and making a cæcostomy, I was able three months later to remove a cancer of the transverse colon with comparative ease and success. One can afford to wait quite a considerable time after establishing bowel drainage.

Cases of group (*b*) have most often tempted me to a primary excision, and though the results are poor they are no worse than those of secondary resection following anastomosis or drainage by enterostomy. The mortality either way is about 50 per cent. Where there is no obstruction there seems no reason why primary resection should not be done; nevertheless, we shall probably get better results by preliminary drainage.

Sites for Temporary Colostomy.

There are three sites where the colon has a suitably long mesocolon—viz., the sigmoid, the transverse colon, and the cæcum. The sigmoid is seldom available for growths above the rectum, and it is surprising how often it is too short to bring up to the surface. In some cases the sigmoid loop is long enough to use the upper part for a left inguinal colostomy for cancer of the lower sigmoid; more often, however, the colostomy must be made in the transverse colon or cæcum. The cæcum is the place most generally suitable and its great advantage is accessibility. In the course of operation for intestinal obstruction the cæcum is the first thing to look for, and therefore by the time one has decided on the local condition and diagnosis (provisional or complete) it is ready to hand and can readily be brought out through a small grid-iron incision in the right iliac fossa, well away from the future field of operation in the middle line. Moreover, the fæces here are liquid and escape readily, so that the Paul's tube does not get blocked with scybalæ, as may happen lower down. The disadvantages are more apparent than real. (1) The cæcostomy is not an artificial anus but a fæcal fistula—i.e., the current of fæces is tapped but not entirely diverted so that we cannot avoid letting fæces pass the growth, and operation later cannot be rendered aseptic. As a matter of fact, even if the fæcal stream be diverted, it is often impossible to get all the fæcal masses out of the bowel, especially as they are often below the growth. (2) The fluidity of the fæces is a great advantage for a temporary colostomy, but owing to irritation of the skin is a serious drawback for one which is intended to be permanent. Therefore one must try to make sure that the growth is removable before doing a cæcostomy. In urgent cases this may be too difficult and dangerous, and, of course, it is possible to make a permanent colostomy lower down after the obstruction is relieved and close the cæcostomy. To perform three operations in a patient condemned to death is not a very satisfactory procedure, but it may be unavoidable.

The transverse colon has the disadvantages (1) that it may be pushed up by the distended guts and may be difficult to bring to the surface; (2) that the attachment of the omentum renders it hard to make a neat colostomy opening, although when there is time the bowel can be freed from the omentum; (3) that it comes up most easily in the mid-line, where colostomy is rather in the way of further proceedings. The transverse colon is more useful for a permanent colostomy.

Where the cancer is in a long loose loop of colon the loop and growth may be simply pulled up outside the abdomen and a colostomy made above the growth. A few days later, when the obstruction has subsided, the loop of bowel with the growth can be resected without anæsthetic close to the abdominal wall. Still later the two ends of colon can be freed, sutured end to end, and replaced. The last operation is practically extraperitoneal, as the adhesions about the abdominal opening usually stretch sufficiently to allow of manipulation and suturing without opening the peritoneum. This method of Greig-Smith is the one for debilitated subjects, but is only suitable in a few instances, especially for growths of the sigmoid. The disadvantage is that, although a good length of colon can be removed, the amount of mesocolon and glands available may be inadequate to make the resection sufficiently radical. Usually 10 to 20 days were allowed to elapse after the preliminary colostomy before removal of the cancer was attempted, but occasionally, owing to complications, as much as three months passed with quite successful results.

Resection of the Cancer.

The work of Jameson and Dobson has given us a standard of the amount of bowel, mesentery, and glands that should be removed if possible for growths of the various parts of the colon, and I have had this standard in mind in operating on these cases. It happens, however, fairly often that the condition of the patient or the complications involving the growth render it impossible for a classical excision to be carried out in its entirety. Fortunately, these growths are mostly of a sclerosing, slow-growing type with late secondary spread, and what seems on anatomical and pathological grounds an inadequate operation often proves quite successful. End-to-end anastomosis was most frequently employed and occasionally end to side. This saves material where there is not too much length to spare and has, in my experience, given better results than the lateral method. If a cæcostomy had not been made at a previous operation one was always provided when resection and anastomosis was done, to act as a safety-valve for flatus and to prevent tension on the suture line.

Table of Operations and Results.

—	Colostomy.		Anastomosis.		Primary resection.		Secondary resection following—			
							(*a*) colostomy.		(*b*) anastomosis.	
	L.	D.	L.	D.	L.	D.	L.	D.	L.	D.

L. = Lived. D. = Died.

Conclusions.

About half the cases come to hand at a sufficiently early stage to warrant an attempt at radical removal. Few cases are thought to need surgical advice until

Careful inquiry into the smaller happenings of a patient's abdomen will often be helpful. Meteorism or considerable distension of the abdomen with gas may be regarded as the acme of flatulence; it is hardly an early symptom but is evidence that intestinal obstruction is already well developed and that the case has passed into stage (*b*).

3. *Irregular action of the bowels*, if of recent origin in a middle-aged or elderly patient who has previously been normal, is one of the most suggestive symptoms. Less frequent, smaller, and perhaps thin and tape-like motions suggest an obstructive growth low down in the large intestine. Obstruction higher up, where the motion is soft or liquid, will not have the same effect in causing constipation and alteration in the shape of the motions. Diarrhœa is less frequent and is usually associated with constipation, though it may be the initial symptom. Two quite different conditions are classed together as diarrhœa.

(*a*) The first is the liquefaction of fæces above an obstruction which has perhaps become temporarily blocked with a scybalous mass, the pouring out of secretion by the mucosa irritated by the retained fæces, and, still more, the inability of the mucosa to perform its normal function of extracting water from the fæcal porridge. The result is a great mass of peasoup-like material above the stenosed part. The temporary block gives way and the flood of liquid fæces pours down as diarrhœa or, if the dam does not yield naturally, persists until the surgeon lets out many pints of liquid fæces through a Paul's tube to relieve acute obstruction.

(*b*) The second is the irritation of a fungating growth by the passage of fæces which causes an outpouring of mucus, pus, sloughs, and perhaps blood, and irritates the bowel below, causing tenesmus and small, frequent, slimy stools. Diarrhœa of this type is a special feature of cancer of the lower part of the large gut, especially the rectum, and is common in the early morning. In the former class we find large intermittent stools of liquid fæces, and in the latter small, frequent stools with plenty of mucus, perhaps blood and occasionally sloughs.

A palpable tumour is not common, and when present is, in my experience, of evil significance. The larger number of cases are those of annular stricture, which can only be felt when the abdomen is opened. A cancer is most often palpable in the cæcal region. Unfortunately, the tumours that can be palpated are apt to be secondaries in the glands, mesentery, and omentum, and indicate that the stage for radical removal has passed.

To sum up, the only early signs of cancer of the bowel, except tumour, which is uncommon, are those of intestinal obstruction. The difficulty consists in distinguishing in time obstruction from other abdominal conditions of less serious or, at any rate, of less urgent import.

Later Stages.

The signs at this period are those suggesting what is commonly known as the "acute abdomen," and are of two types, (*a*) the obstructive, and (*b*) the peritonitic, though a combination is not uncommon.

The signs of acute obstruction hardly need repetition here; the severe colicky pain, the rising pulse, the vomit turning from green to brown, then acquiring a foul odour and finally consisting of liquid fæces, and the inability to pass flatus form a very definite picture. This is the class of case where true fæcal vomiting is best seen; it simply denotes that the obstruction is low in the bowel. Visible peristalsis and marked meteorism, without tenderness or rigidity, complete the picture.

The less frequent but more obviously acute type is where the bowel above the obstruction is so distended that it has become ulcerated with inflammation spreading to its peritoneal coat. It may be gangrenous, or perforation may have taken place. The abdomen will then show marked tenderness and rigidity, which may be general where leaking of fæces through a perforation has taken place, or localised, especially in the right iliac fossa, because the cæcum is the place of maximum distension where gangrene and perforation most commonly occur. This last type of case gives a picture closely resembling acute appendicitis and has caused difficulty in diagnosis.

X Rays in Diagnosis.

Since almost the only signs are those of oncoming intestinal obstruction, it behoves us to get any help we can in distinguishing this from other varieties of "dyspepsia." Careful following of an opaque meal downwards and, still better, of an opaque enema upwards with the fluorescent screen, is of great help in early and doubtful cases, but more often results in proving a negative and saving an exploratory laparotomy than in finding and locating an intestinal growth. Most commonly, in my experience, by the time the patient and doctor realise that anything serious is the matter, it is sufficiently obvious that operation is urgent and that X ray examination will only take up time which might be better employed. There can be no doubt, however, that if this means of investigation were used more frequently for patients with obscure abdominal symptoms, a good many cases would be diagnosed with sufficient probability to warrant operation at an earlier period.

Complications.

These are, unfortunately, only too frequent, and they may be:—

1. Direct sequelæ of the growth: (*a*) Spread of the cancer to omentum, glands, peritoneum, or liver, rendering radical removal impossible. (*b*) Distension of the bowel above a constricting growth, ending in localised ulceration, gangrene, and perforation, and leading to local or generalised peritonitis.

2. Association with totally distinct diseases such as appendicitis, suppurating ovarian cyst, or fibroids of the uterus, any of which may render radical removal of the growth much more difficult.

Treatment.

Out of 69 cases preliminary drainage by colostomy (including cæcostomy) or lateral anastomosis was done in 57; in the other 12 the operation was primary excision and anastomosis. Of the 43 cases which survived colostomy or anastomosis excision of the growth was done in 24, and 16 recovered. As far as possible the rule was followed of not resecting at the primary operation when any obstruction was present. In some special circumstances this rule was broken, and not always with bad results. Taking it all round, patients did far better after secondary than primary excision, the mortality being 30 per cent. as against nearly 60 per cent. There is a great temptation to try to get the matter finished with as few operations as possible, especially in aged patients, but experience shows that people over 70 stand the extra time in bed, needed for a second and third operation (excision and closure of colostomy), quite well. Colostomy, though a relatively minor operation, has quite a sufficiently high mortality; in this series it was 20 per cent. This may seem high, but it is partly caused by complications. For instance, a middle-aged woman was admitted to hospital with well-marked signs of appendicitis. A large, red, swollen appendix surrounded with lymph was removed and the abdomen closed. The patient made a good recovery for 14 days and was about to get up when she was suddenly seized with severe abdominal pain and rigidity with collapse. Immediate laparotomy revealed thrombosis of the inferior mesenteric vessels, early gangrene of the sigmoid and descending colon, and a small annular cancer of the sigmoid. Whether the appendicitis was a pure coincidence or a sequel to septic absorption from the ulcerated growth, as well as a source for thrombosis, is a matter for conjecture.

In several other cases the cæcum has been gangrenous or perforated: not all these cases succumbed, but those who survive are fortunate. In another patient a suppurating ovarian cyst rendered the preliminary colostomy and excision difficult and

Plasmoquine-compound.

Subsequently Schulemann and Memmi showed that the therapeutic action of plasmoquine was greatly enhanced by the addition of quinine, and that the specific plasmoquine cyanosis was thereby avoided. In other words, the therapeutic actions of plasmoquine and quinine are antagonistic. It was found, moreover, that the addition of small quantities of quinine greatly increased its parasitotropic action upon subtertian infections and that the clinical results were, as a rule, superior to those of plasmoquine alone. Schulemann and his fellow workers have shown that one-tenth of the daily amount of plasmoquine taken is excreted in the urine. The presence of the drug in the urine can be ascertained by chloranil, which gives an intense blue colour with plasmoquine, but not with quinine.

The combination of quinine sulphate with plasmoquine is now known as "plasmoquine-compound." It is put up in tablets of 0·01 g. (gr. 1/6) plasmoquine with 0·125 g. (gr. 2) quinine sulphate. The following scheme of dosage and treatment is the one I generally advise:—

For Benign Tertian and Quartan Malaria.

1st week, 7 days, 2 tablets plasmoquine-compound three times daily (0·06 g. (gr. 1): plasmoquine plus 0·75 g. (grs. 12) quinine three times daily).

Treatment should extend over a further 44 days, composed of four separate weeks' treatment (making five weeks in all) of 12 tablets of plasmoquine-compound daily with four days' interval between each week. It is necessary to follow this scheme closely in order to prevent relapses.

In subtertian malaria it has been found advisable to alter the periods during which the drug is administered. The first period should be one of five days followed by a four days' break, and the subsequent five courses of administration should be five days each, instead of seven, as given in the above table. It is necessary to be explicit about the dosage of plasmoquine-compound, as confusion is apt to arise on this point. Recently the size of the individual tablet has been altered to contain twice the amount formerly dispensed. Up to a month ago each tablet contained 0·005 g. plasmoquine and 0·0625 g. quinine.

In a recent communication I have been able to show that plasmoquine-compound has a striking effect upon the gametocytes of both subtertian and benign tertian malaria. Disintegration of crescents takes place after the exhibition of 8 tablets of plasmoquine compound (i.e., 0·08 g. plasmoquine plus 1·0 g. quinine), while with pure quinine these crescents sometimes persist in the circulation for a month.

Recent Experiences in the Treatment of Malaria with Plasmoquine-compound.

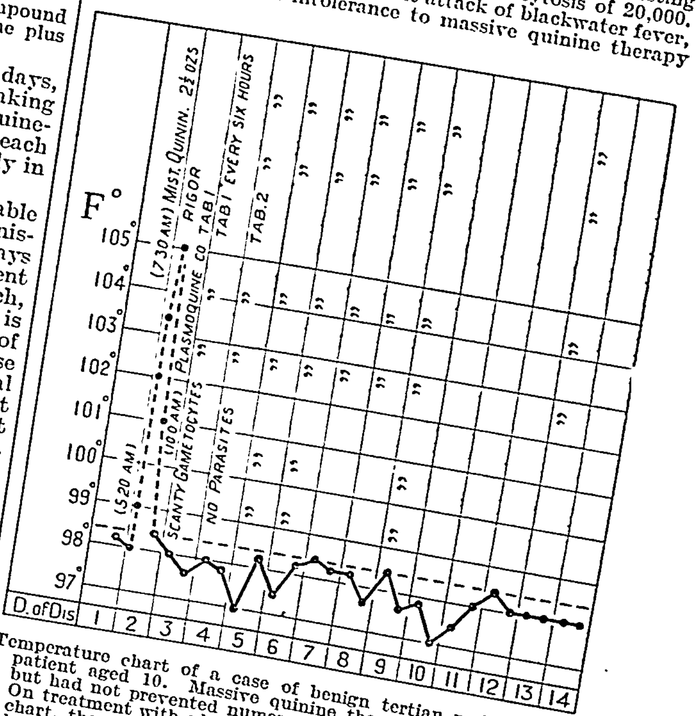
During the year 1927 and the early portion of 1928 I have discontinued the use of plasmoquine for that of plasmoquine-compound, and the results have been on the whole satisfactory, both clinically and parasitologically. The cases here described were treated in hospital where prolonged and accurate observations could be made.

Of 18 benign tertian cases 12 were in men and 6 in women; the youngest was a boy of 8 years of age. The average length of stay in hospital was 11 days and the parasites disappeared from the blood stream after an average amount of 13½ tablets of plasmoquine-compound (i.e., 0·135 g. plasmoquine + 1·687 g. quinine). As a rule the patient received a total amount of 25 tablets (i.e., 0·25 g. plasmoquine, 3·125 g. quinine) while in hospital.

In one case only was a slight cyanosis observed after the sixth day of administration of the drug. The only other untoward symptoms noted were dyspepsia, occasionally abdominal pains, and, in one case only, dizziness. Subsequent experience has shown that these could be removed by glucose ʒi., given daily, either in powder or liquid form. As with pure plasmoquine, a rapid contraction in the size of the spleen took place and a corresponding clinical improvement in the condition of the patient was noticed. In three cases, in which considerable blood destruction had taken place, there was an increase of red blood corpuscles of 1,000,000 within a week. In only one case did a rigor or secondary rise of temperature take place. Two of the best clinical cases of the series had previously exhibited intolerance to quinine, both by immediate dyspepsia and vomiting and later by tinnitus and cerebral irritability. In both the subsequent course of plasmoquine-compound was well tolerated.

Relapses.—No doubt relapses do occur, just as they do after prolonged quinine therapy. I have records of two clinical relapses within six months of the cessation of treatment in the above series of 18. Probably further experiences of plasmoquine-compound will indicate that a still more prolonged constant therapy is necessary to stamp out the infection from the body.

The 11 cases of *subtertian malaria* were all in males. Amongst them were five cases which, from the severity of the symptoms, could be legitimately regarded as of the pernicious form. One, from the acuteness of onset and the persistence of diarrhœa and vomiting, could be classified as a genuine case of abdominal malaria, and it was interesting to note that he showed a persistent leucocytosis of 20,000. One had recovered from a recent attack of blackwater fever, a third showed an intolerance to massive quinine therapy and had suffered from relapses in spite of it, while a fourt had been previously diagnosed on clinical grounds as tuberculosis. Very large numbers of crescents were found in the peripheral blood (132 to every 200 leucocytes). Crescents were present in three cases and ring-forms were found in eight. In one instance the appearance of scanty crescents in the peripheral blood was noted during the course of treatment with plasmoquine-compound (i.e., after 0·29 g. plasmoquine and 3·6 g. quinine). The length of treatment in hospital was 14 days and the average amount of plasmoquine-compound required to banish the infection was 13½ tablets (0·135 g. plasmoquine and 1·68 g. quinine). The average amount of the drug taken was 27½ tablets (or 0·27 g. plasmoquine and 3·37 g. quinine).



Temperature chart of a case of benign tertian malaria in a patient aged 10. Massive quinine therapy had been tried but had not prevented numerous relapses on alternate days. On treatment with plasmoquine-compound, as shown on the chart, the malaria was apparently cured, no relapses having been recorded since cessation of treatment six months ago. (The dosage is that of the smaller size tablet as describ above.)

On the whole the results were not so satisfactory as in benign tertian malaria. In two cases, owing to the severity of the symptoms—vomiting and pyrexia—the action of plasmoquine-compound had to be reinforced by two intramuscular injections of quinine, grs. 5 each. Nevertheless, in three very severe cases the clinical improvement was striking and quite as satisfactory as after intensive quinine treatment.

intestinal obstruction is becoming obvious. Earlier investigation with opaque enemata should help to separate this class of "dyspepsia" from other less serious conditions. It is largely delay which makes the mortality of colostomy so high.

A certain number of cases are beyond radical operation, from secondary spread, before any symptoms are noted by the patient. A preliminary colostomy (cæcostomy) is a wise precaution even where there is no obvious obstruction.

There is no need for great haste after the colostomy is established; weeks or even months may be needed before the patient is fit to undergo the more radical operation of resection of the cancerous growth.

THE THERAPEUTIC ACTION OF PLASMOQUINE AND PLASMOQUINE-COMPOUND* IN MALARIA.

BY PHILIP MANSON-BAHR, D.S.O., M.D. CAMB., F.R.C.P. LOND.,

PHYSICIAN TO THE HOSPITAL FOR TROPICAL DISEASES, LONDON.

ONE of the first specifics in medicine to be discovered, quinine has held the premier place in the treatment of malaria for nearly 300 years, and, in spite of a vast amount of research upon the action of the alkaloids of cinchona during the last 14 years, no striking improvement has been made in its therapeutic qualities. No one can doubt the instantaneous and selective effect of quinine upon the malaria parasite, but the drug does not entirely extirpate the infection from the body; there usually remain trophozoites which migrate to some secure spot and there multiply and produce a relapse whenever conditions become favourable. Effective quinine therapy is based upon the belief that it is necessary to continue its administration in gradually decreasing dosage until two months from the time of the last appearance of the malaria parasites in the circulation; in other words, it is believed that only by constantly assailing the parasite with repeated doses of quinine is it possible to prevent it from multiplying and producing further relapses. This is especially true of the benign tertian parasite, *Plasmodium vivax*, which may produce an infection that it is almost impossible to eradicate with quinine until the natural life-span of the parasite has been run and it dies out from inanition. This may take from one to three years.

We have no really conclusive evidence that quinine —for instance the bihydrochloride salt—when injected intramuscularly or intravenously, is able to extirpate an infection more effectively or speedily than when it is absorbed by the alimentary tract. The drug is excreted equally rapidly from the body, and, although injection has its legitimate uses when quinine by the mouth cannot be tolerated, yet it is cumbrous, painful, and sometimes even dangerous. Some people, especially women, have an insufferable intolerance to the drug. In different subjects it may provoke intractable dyspepsia, vomiting, and diarrhœa, the most irritating tinnitus, or a toxic urticaria, while in some it is a powerful cerebral depressant. Research upon the various salts of quinine has not demonstrated that any particular combination has special curative or preventive virtue. The other alkaloids of cinchona bark—cinchonine, cinchonidine, and quinidine—possess no greater parasiticidal action than quinine itself. Obviously some alternative specific drug for malaria is eminently desirable.

Plasmoquine.

The chemical formula of quinine is complicated, but it is known to be a combination of a quinoline ring with piperidine. The former appears to be a protoplasmic poison. Many unsuccessful attempts have been made to synthesise quinine in the laboratory and other compounds have been elaborated in the process. Schulemann, Schönhöfer, and Wingler have synthesised a derivative of quinoline (ethylamino-quinoline-hydrochloride) which is now known as plasmoquine and which was found to exert a toxotropic effect upon the plasmodium of birds (*Plasmodium præcox*). According to Hörlein, its exact constitution is the salt of alkylamino-methoxyquinoline. Kopanaris, the brothers Sergent in Algiers, and Giemsa in Hamburg had already shown that quinine exerts an effect upon the plasmodium of canaries which is comparable to its effect upon the malaria parasites of man.

Estimation of Therapeutic Action.

The treatment of bird malaria with the various derivatives of the quinoline ring afforded a means of comparison of these compounds with the salts of quinine. Further extensive experiments upon canaries artificially infected with *P. præcox* were carried out by Roehl in the Chemotherapeutic Laboratories at Elberfeld. Difficulty was at first experienced in assessing the correct therapeutic action, as plasmoquine caused too violent a local reaction when injected into the breast muscles of these delicate creatures, and the exact amount ingested could not be estimated when it was mixed with their food. Finally Roehl devised a pipette about the size of a ureteric catheter, through which an exact amount of plasmoquine could be injected directly into the stomach of the canary and its effect upon the parasite accurately estimated. By calculating the amount of quinine necessary to cause a permanent disappearance of *P. præcox* from the blood of infected canaries, it was found that plasmoquine exerted a parasitotropic action 60 times greater than that of quinine. Another remarkable observation resulting from these experiments was that plasmoquine exercises an especially destructive action upon the sexual stages, or gametocytes, upon which quinine is almost inert. The next step was to test the effect of plasmoquine upon human malaria. A dose of 0·25 g. daily was found to exert toxic effects; the patient developed a blue lividity of the skin and nails, the blood became a peculiar chocolate-brown colour, due to the conversion of hæmoglobin into methæmoglobin, while partial collapse and sometimes vomiting was produced. This cyanosis, which, when intensive, is extremely alarming both to patient and physician, is now generally recognised as indicating that the dosage of plasmoquine is too large and that it is exerting a toxic effect. At first Mühlens and Sioli advocated a dose of 0·1 g. plasmoquine daily for three days after the disappearance of the malaria parasites from the circulation. Later it was found that even this dose was too large for general use and that 0·06 g. daily was sufficient to extirpate the infection without producing cyanosis. Plasmoquine is practically tasteless, but when chewed produces a curious anæsthetic effect on the tongue and pharynx. When tested by Sioli in therapeutic malaria for general paralysis and by Mühlens in a series of 134 naturally acquired infections, it was found that plasmoquine exerted the same lethal action upon the gametocytes of benign and subtertian malaria as it had already been shown to exert upon the *P. præcox* of birds. The gametocytes, or crescents, of the subtertian parasite disappeared after four days. The action of the drug upon trophozoites of the subtertian was much less satisfactory than upon similar stages of the benign tertian parasite. These observations I was able to confirm in a series of 28 cases of malaria treated in London in 1926. In addition I noted the rapid reduction in the size of the spleen; in some instances the shrinkage was so rapid as to cause very considerable pain over the splenic area, and in others the administration of the drug had to be discontinued on account of the acute abdominal pain it produced. It was found necessary to interrupt the course of plasmoquine to allow of the total excretion of the drug from the body. The drug could be given in full therapeutic doses (0·06–0·08 g.) daily for seven consecutive days for six separate weeks if a break of five days were allowed between each course.

---

* Identical with plasmochin and plasmochin-compound.

Plasmoquine-compound.

Subsequently Schulemann and Memmi showed that the therapeutic action of plasmoquine was greatly enhanced by the addition of quinine, and that the specific plasmoquine cyanosis was thereby avoided. In other words, the therapeutic actions of plasmoquine and quinine are antagonistic. It was found, moreover, that the addition of small quantities of quinine greatly increased its parasitotropic action upon subtertian infections and that the clinical results were, as a rule, superior to those of plasmoquine alone. Schulemann and his fellow workers have shown that one-tenth of the daily amount of plasmoquine taken is excreted in the urine. The presence of the drug in the urine can be ascertained by chloranil, which gives an intense blue colour with plasmoquine, but not with quinine.

The combination of quinine sulphate with plasmoquine is now known as "plasmoquine-compound." It is put up in tablets of 0·01 g. (gr. 1/6) plasmoquine with 0·125 g. (gr. 2) quinine sulphate. The following scheme of dosage and treatment is the one I generally advise:—

For Benign Tertian and Quartan Malaria.

1st week, 7 days, 2 tablets plasmoquine-compound three times daily (0·06 g. (gr. 1); plasmoquine plus 0·75 g. (grs. 12) quinine three times daily).

Treatment should extend over a further 44 days, composed of four separate weeks' treatment (making five weeks in all) of 12 tablets of plasmoquine-compound daily with four days' interval between each week. It is necessary to follow this scheme closely in order to prevent relapses.

In subtertian malaria it has been found advisable to alter the periods during which the drug is administered. The first period should be one of five days followed by a four days' break, and the subsequent five courses of administration should be five days each, instead of seven, as given in the above table. It is necessary to be explicit about the dosage of plasmoquine-compound, as confusion is apt to arise on this point. Recently the size of the individual tablet has been altered to contain twice the amount formerly dispensed. Up to a month ago each tablet contained 0·005 g. plasmoquine and 0·0625 g. quinine.

In a recent communication I have been able to show that plasmoquine-compound has a striking effect upon the gametocytes of both subtertian and benign tertian malaria. Disintegration of crescents takes place after the exhibition of 8 tablets of plasmoquine compound (i.e., 0·08 g. plasmoquine plus 1·0 g. quinine), while with pure quinine these crescents sometimes persist in the circulation for a month.

Recent Experiences in the Treatment of Malaria with Plasmoquine-compound.

During the year 1927 and the early portion of 1928 I have discontinued the use of plasmoquine for that of plasmoquine-compound, and the results have been on the whole satisfactory, both clinically and parasitologically. The cases here described were treated in hospital where prolonged and accurate observations could be made.

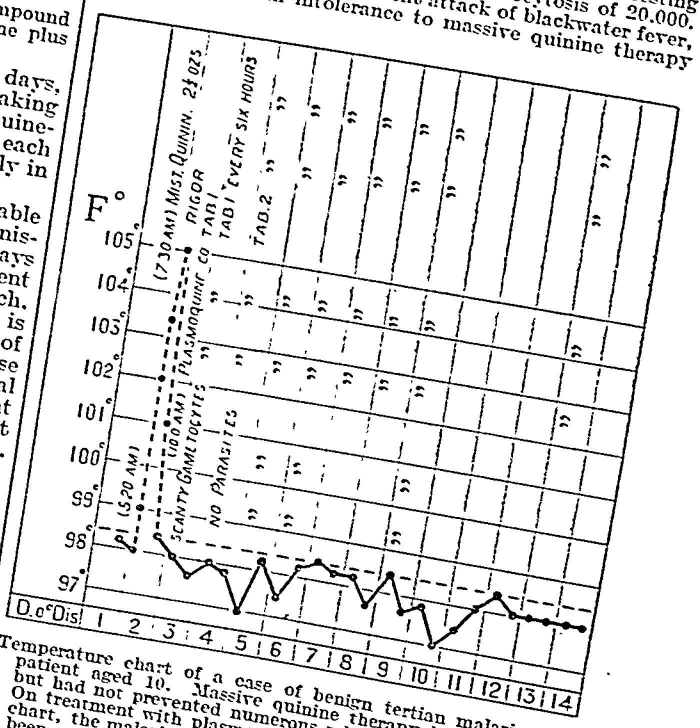
Of 18 benign tertian cases 12 were in men and 6 in women: the youngest was a boy of 8 years of age. The average length of stay in hospital was 11 days and the parasites disappeared from the blood stream after an average amount of 13½ tablets of plasmoquine-compound (i.e., 0·135 g. plasmoquine + 1·687 g. quinine). As a rule the patient received a total amount of 25 tablets (i.e., 0·25 g. plasmoquine, 3·125 g. quinine) while in hospital.

In one case only was a slight cyanosis observed after the sixth day of administration of the drug. The only other untoward symptoms noted were dyspepsia, occasionally abdominal pains, and, in one case only, dizziness. Subsequent experience has shown that these could be removed by glucose ʒi., given daily, either in powder or liquid form. As with pure plasmoquine, a rapid contraction in the size of the spleen took place and a corresponding clinical improvement in the condition of the patient was noticed. In three cases, in which considerable blood destruction had taken place, there was an increase of red blood corpuscles of 1,000,000 within a week. In only one case did a rigor or secondary rise of temperature take place. Two of the best clinical cases of the series had previously exhibited intolerance to quinine, both by immediate dyspepsia and vomiting and later by tinnitus and cerebral irritability. In both the subsequent course of plasmoquine-compound was well tolerated.

Relapses.—No doubt relapses do occur, just as they do after prolonged quinine therapy. I have records of two clinical relapses within six months of the cessation of treatment in the above series of 18. Probably further experiences of plasmoquine-compound will indicate that a still more prolonged constant therapy is necessary to stamp out the infection from the body.

The 11 cases of *subtertian malaria* were all in males. Amongst them were five cases which, from the severity of the symptoms, could be legitimately regarded as of the pernicious form. One, from the acuteness of onset and the persistence of diarrhœa and vomiting, could be classified as a genuine case of abdominal malaria, and it was interesting to note that he showed a persistent leucocytosis of 20,000. One had recovered from a recent attack of blackwater fever, a third showed an intolerance to massive quinine therapy and had suffered from relapses in spite of it, while a fourth had been previously diagnosed on clinical grounds as tuberculosis. Very large numbers of crescents were found in the peripheral blood (132 to every 200 leucocytes). Crescents were present in three cases and ring-forms were found in eight. In one instance the appearance of scanty crescents in the peripheral blood was noted during the course of treatment with plasmoquine-compound (i.e., after 0·29 g. plasmoquine and 3·6 g. quinine). The length of treatment in hospital was 14 days and the average amount of plasmoquine-compound required to banish the infection was 13½ tablets (0·135 g. plasmoquine and 1·68 g. quinine). The average amount of the drug taken was 27½ tablets (or 0·27 g. plasmoquine and 3·37 g. quinine).

On the whole the results were not so satisfactory as in benign tertian malaria. In two cases, owing to the severity of the symptoms—vomiting and pyrexia—the action of plasmoquine-compound had to be reinforced by two intramuscular injections of quinine, grs. 5 each. Nevertheless, in three very severe cases the clinical improvement was striking and quite as satisfactory as after intensive quinine treatment.



Temperature chart of a case of benign tertian malaria in a patient aged 10. Massive quinine therapy had been tried but had not prevented numerous relapses on alternate days. On treatment with plasmoquine-compound, as shown on the chart, the malaria was apparently cured, no relapses having been recorded since cessation of treatment six months ago. (The dosage is that of the smaller size tablet as described above.)

intestinal obstruction is becoming obvious. Earlier investigation with opaque enemata should help to separate this class of "dyspepsia" from other less serious conditions. It is largely delay which makes the mortality of colostomy so high.

A certain number of cases are beyond radical operation, from secondary spread, before any symptoms are noted by the patient. A preliminary colostomy (cæcostomy) is a wise precaution even where there is no obvious obstruction.

There is no need for great haste after the colostomy is established; weeks or even months may be needed before the patient is fit to undergo the more radical operation of resection of the cancerous growth.

THE THERAPEUTIC ACTION OF PLASMOQUINE AND PLASMOQUINE-COMPOUND* IN MALARIA.

BY PHILIP MANSON-BAHR, D.S.O., M.D. CAMB., F.R.C.P. LOND.,
PHYSICIAN TO THE HOSPITAL FOR TROPICAL DISEASES, LONDON.

ONE of the first specifics in medicine to be discovered, quinine has held the premier place in the treatment of malaria for nearly 300 years, and, in spite of a vast amount of research upon the action of the alkaloids of cinchona during the last 14 years, no striking improvement has been made in its therapeutic qualities. No one can doubt the instantaneous and selective effect of quinine upon the malaria parasite, but the drug does not entirely extirpate the infection from the body; there usually remain trophozoites which migrate to some secure spot and there multiply and produce a relapse whenever conditions become favourable. Effective quinine therapy is based upon the belief that it is necessary to continue its administration in gradually decreasing dosage until two months from the time of the last appearance of the malaria parasites in the circulation; in other words, it is believed that only by constantly assailing the parasite with repeated doses of quinine is it possible to prevent it from multiplying and producing further relapses. This is especially true of the benign tertian parasite, *Plasmodium vivax*, which may produce an infection that it is almost impossible to eradicate with quinine until the natural life-span of the parasite has been run and it dies out from inanition. This may take from one to three years.

We have no really conclusive evidence that quinine—for instance the bihydrochloride salt—when injected intramuscularly or intravenously, is able to extirpate an infection more effectively or speedily than when it is absorbed by the alimentary tract. The drug is excreted equally rapidly from the body, and, although injection has its legitimate uses when quinine by the mouth cannot be tolerated, yet it is cumbrous, painful, and sometimes even dangerous. Some people, especially women, have an insufferable intolerance to the drug. In different subjects it may provoke intractable dyspepsia, vomiting, and diarrhœa, the most irritating tinnitus, or a toxic urticaria, while in some it is a powerful cerebral depressant. Research upon the various salts of quinine has not demonstrated that any particular combination has special curative or preventive virtue. The other alkaloids of cinchona bark—cinchonine, cinchonidine, and quinidine—possess no greater parasiticidal action than quinine itself. Obviously some alternative specific drug for malaria is eminently desirable.

Plasmoquine.

The chemical formula of quinine is complicated, but it is known to be a combination of a quinoline ring with piperidine. The former appears to be a protoplasmic poison. Many unsuccessful attempts have been made to synthesise quinine in the laboratory and other compounds have been elaborated in the process. Schulemann, Schönhöfer, and Wingler have synthesised a derivative of quinoline (ethylamino-quinoline-hydrochloride) which is now known as plasmoquine and which was found to exert a toxotropic effect upon the plasmodium of birds (*Plasmodium præcox*). According to Hörlein, its exact constitution is the salt of alkylamino-methoxyquinoline. Kopanaris, the brothers Sergent in Algiers, and Giemsa in Hamburg had already shown that quinine exerts an effect upon the plasmodium of canaries which is comparable to its effect upon the malaria parasites of man.

Estimation of Therapeutic Action.

The treatment of bird malaria with the various derivatives of the quinoline ring afforded a means of comparison of these compounds with the salts of quinine. Further extensive experiments upon canaries artificially infected with *P. præcox* were carried out by Roehl in the Chemotherapeutic Laboratories at Elberfeld. Difficulty was at first experienced in assessing the correct therapeutic action, as plasmoquine caused too violent a local reaction when injected into the breast muscles of these delicate creatures, and the exact amount ingested could not be estimated when it was mixed with their food. Finally Roehl devised a pipette about the size of a ureteric catheter, through which an exact amount of plasmoquine could be injected directly into the stomach of the canary and its effect upon the parasite accurately estimated. By calculating the amount of quinine necessary to cause a permanent disappearance of *P. præcox* from the blood of infected canaries, it was found that plasmoquine exerted a parasitotropic action 60 times greater than that of quinine. Another remarkable observation resulting from these experiments was that plasmoquine exercises an especially destructive action upon the sexual stages, or gametocytes, upon which quinine is almost inert. The next step was to test the effect of plasmoquine upon human malaria. A dose of 0·25 g. daily was found to exert toxic effects; the patient developed a blue lividity of the skin and nails, the blood became a peculiar chocolate-brown colour, due to the conversion of hæmoglobin into methæmoglobin, while partial collapse and sometimes vomiting was produced. This cyanosis, which, when intensive, is extremely alarming both to patient and physician, is now generally recognised as indicating that the dosage of plasmoquine is too large and that it is exerting a toxic effect. At first Mühlens and Sioli advocated a dose of 0·1 g. plasmoquine daily for three days after the disappearance of the malaria parasites from the circulation. Later it was found that even this dose was too large for general use and that 0·06 g. daily was sufficient to extirpate the infection without producing cyanosis. Plasmoquine is practically tasteless, but when chewed produces a curious anæsthetic effect on the tongue and pharynx. When tested by Sioli in therapeutic malaria for general paralysis and by Mühlens in a series of 134 naturally acquired infections, it was found that plasmoquine exerted the same lethal action upon the gametocytes of benign and subtertian malaria as it had already been shown to exert upon the *P. præcox* of birds. The gametocytes, or crescents, of the subtertian parasite disappeared after four days. The action of the drug upon trophozoites of the subtertian was much less satisfactory than upon similar stages of the benign tertian parasite. These observations I was able to confirm in a series of 28 cases of malaria treated in London in 1926. In addition I noted the rapid reduction in the size of the spleen; in some instances the shrinkage was so rapid as to cause very considerable pain over the splenic area, and in others the administration of the drug had to be discontinued on account of the acute abdominal pain it produced. It was found necessary to interrupt the course of plasmoquine to allow of the total excretion of the drug from the body. The drug could be given in full therapeutic doses (0·06–0·08 g.) daily for seven consecutive days for six separate weeks if a break of five days were allowed between each course.

---

* Identical with plasmochin and plasmochin-compound.

Culture showed a coliform bacillus, probably a contamination. The liver gave evidence of early nutmeg changes, but no evidence of cirrhosis was noted. Adherent ante-mortem clot was present in the splenic, portal, and mesenteric veins. The post-mortem note stated: "The phlebitis and thrombosis have presumably spread from the splenic pedicle along the splenic vein, but no proof of bacterial infection was obtained." No explicit note was made either at operation or at the post-mortem examination on the size of the splenic vein or the condition of its wall. The spleen was unfortunately not examined microscopically.

CASE 2. *Recovery.*—A man, aged 23, was admitted to hospital complaining of black stools. Four months previously he had had hæmatemesis, for which he had been treated at another hospital with Lenhartz diet and ultra-violet rays. On examination the spleen was palpable; jaundice and ascites were absent and there were no palpable lymph nodes. A blood count showed: Hæmoglobin, 48 per cent.; red cells, 3,200,000; white cells, 5600; colour-index, 0·75. The Wassermann and sigma reactions were negative, and so was van den Bergh's test. There was no history of malaria. A diagnosis of splenic anæmia was made and splenectomy performed.

Morbid Anatomy.—The spleen weighed 25 oz., and was firm and fibrous. Perisplenitis was absent, and there were no infarcts. Microscopically, it showed a rather a-cellular generalised fibrosis. There was no uniform congestion, but a few small scattered hæmorrhages were present, due possibly to operative trauma. The sinuses were not dilated and contained very few cells. There was no evidence of endothelial proliferation or the deposition of pigment. The picture was quite unlike that described by Tansini and Morone in splenomegaly due to portal thrombosis,[6] where the splenic sinuses were transformed into "large lakes of blood," and the pulp infiltrated with macrophages and pigment.

The patient recovered from the immediate effects of the operation, and eight days later a blood count showed: Red cells, 2,800,000; white cells, 8600; polymorphs, 6620; lymphocytes, 1030. An estimation of the hæmoglobin was not done. Thirteen days later the figures were: Hæmoglobin, 44 per cent; red cells, 3,400,000; white cells, 14,000; colour-index, 0·7.

On the fourteenth day after splenectomy the patient had a sudden attack of severe abdominal pain and vomited. His temperature dropped to 96°; the pulse-rate rising to 135. The abdomen become distended and free fluid was noted. No leucocyte count was done at this time. Intraperitoneal hæmorrhage was suspected, and it was decided to perform a suprapubic exploratory puncture. This was done, and two pints, not of blood but of clear yellow fluid, were withdrawn. A drainage-tube was left in, and the patient transfused with 400 c.cm. of blood. He vomited afterwards, and was rather restless. However, his temperature gradually improved, reaching normal on the third day, and he made a good recovery. Six months later a blood count showed: Red cells, 4,090,000; hæmoglobin, 50 per cent.; white cells, 9000. In spite of this, there can be little doubt that acute portal thrombosis supervened on the fourteenth day after splenectomy. The exact site must remain uncertain, but two facts—the ascites and the sudden severe pain—make it probable, as will appear later, that both portal and mesenteric veins were involved.

Signs and Symptoms of Portal Thrombosis.

The signs and symptoms of portal thrombosis are fairly well known and have been described exhaustively by Langdon-Brown.[7] They are more or less invariable, and include abdominal pain, ascites, diarrhœa with or without blood, vomiting with or without hæmatemesis, enlargement of the spleen and, if of acute onset, general shock. All these were present in the two cases described in this paper. Langdon-Brown suggests that the signs and symptoms may bear some relation to the site of thrombosis. "Broadly speaking, in any case of pylethrombosis, if ascites is present, the trunk of the vein is probably occluded; if hæmatemesis occurs, the splenic vein is probably involved; and if pain, vomiting, diarrhœa, and collapse are the leading symptoms, there is probably obstruction of the superior mesenteric vein." The onset is not always acute; it may be slow and progressive, though interrupted by critical episodes corresponding to fresh attacks of thrombosis. Frick [8] and Frugoni [9] emphasise this irregularity in progress as an important point of distinction between primary splenomegaly and that due to portal thrombosis. This point will be referred to later.

Acute thrombosis of the coronary vessels is well known to give rise to an emphatic leucocytosis. A leucocyte count in direct response to the acute abdominal condition was done in only two cases, in Case 1 of this paper, and in another case of acute portal thrombosis not described here. In the latter the count rose from 18,000 to 34,000 with the onset of symptoms. In Case 1 splenectomy had been performed 13 days previously, and splenectomy per se causes a leucocytosis. In fact, however, the appearance of acute symptoms introduces a figure of a different order from that anticipated on physiological grounds, so that this may be taken to represent leucocytosis of thrombogenic origin. Before splenectomy the leucocyte count was 1200; seven days afterwards it was 9500. With the onset of acute symptoms on the thirteenth day after operation it rose to the quite unexpected figure of 63,400. Further leucocyte counts in patients with portal thrombosis are to be desired, but the evidence of these two cases suggests that leucocytosis may occur.

Classification of the Two Cases.

It is clear that all these signs and symptoms, with the exception of a possible leucocytosis, are common both to portal thrombosis and (if they have any separate existence) to splenic anæmia and Banti's disease. The two cases under discussion are presented as examples of primary splenomegalic anæmia rather than of thrombosis, on the following grounds:—

1. That thrombosis was here the initial cause is improbable, as acute signs and symptoms attributable to thrombosis only occurred well within the course of an already established "splenomegalic anæmia."

2. The contention that this pre-established splenomegaly was itself the result of a slowly progressive thrombosis is difficult to maintain in view of three facts: (*a*) The absence in the past history of exacerbations similar to the one observed. Reference has already been made to the importance of this point, emphasised by Frick. (*b*) The absence in the records of the surgical procedure of any mention of such thrombosis or thrombophlebitis in situ. (*c*) The fact that Case 2 made such a complete and rapid recovery from his post-operative attack. If this had been merely the culmination of a slowly progressive thrombotic process extending over one year, such a rapid remission would seem most improbable, with or without splenectomy.

If these points be admitted, then Warthin's theory of an initial and invariable portal thrombosis as the underlying condition in both splenic anæmia and Banti's disease seems clearly inapplicable to these two cases. It is not maintained that portal thrombosis never gives rise to a picture indistinguishable from Banti's syndrome; it seems certain that it can, and does. But it is maintained that thrombosis seems peculiarly liable to develop during the course of a primary splenomegalic anæmia without lymphatic enlargements and with or without ascites. To argue in the reverse way would be on all fours with the attempt to show that portal thrombosis is the cause of hepatic cirrhosis, since Langdon-Brown [7] has shown that this is the commonest condition associated with portal thrombosis in general.

Rosenthal,[10] in a recent study of the platelets in Banti's disease, has shown that cases can be divided into two groups, thrombocytic and thrombopenic. The former he considers particularly liable to severe hæmorrhages; the latter to thromboses, especially post-operative. Unfortunately, platelet counts were not done on either of the cases considered here, but it is clear that the idea opens up a fresh field for investigation and offers a possible explanation of the frequency with which thrombosis occurs. The post-operative tendency to it may further be related to the fact that the red cells are apt to rise very rapidly after splenectomy, and Leon-Kindberg [11] reports transient polycythæmia on several occasions. This was present in Case 1 (red cells 6,890,000), although

Quartan Malaria.—I have had only one opportunity of observing the effects of plasmoquine-compound in quartan malaria.

The patient had suffered almost continuously for four years from persistent relapses of a peculiarly intractable form of fever which did not yield to quinine. She had a large and painful spleen and a scanty infection of quartan parasites in the peripheral blood. A full course of plasmoquine-compound was followed by a slight cyanosis, which was transitory and unaccompanied by any other alarming symptoms. The clinical results, as far as could be ascertained, were satisfactory and no more relapses have occurred. The physical condition is satisfactory.

Conclusions.

The time is not yet ripe to draw a final conclusion upon the rôle which plasmoquine is destined to play in the therapeutics of malaria. I am not suggesting that it is going to replace quinine in the treatment of every case, but I submit that sufficient evidence has now been accumulated to show that, under certain circumstances, it can act as an efficient substitute in patients who have been susceptible to, or intolerant of, large doses of quinine. Its most important property is that it affords an alternative treatment and is undoubtedly tolerated in severe cases with persistent vomiting when pure quinine is not. The amount of the drug necessary to banish the parasites from the blood is much smaller—a very important point—the taste is not disagreeable, the effects upon digestion are negligible, and it is well tolerated by children.

Occasional signs of relative intolerance to plasmoquine and plasmoquine-compound are slight cyanosis, dyspepsia, colic, and splenic pain.

SPLENIC ANÆMIA AND PORTAL THROMBOSIS.

BY J. CONWAY DAVIES, M.B. CAMB.,
M.R.C.P. LOND.,
PHYSICIAN TO THE SEAMEN'S HOSPITAL, GREENWICH; DEMONSTRATOR OF PATHOLOGY, ST. BARTHOLOMEW'S HOSPITAL.

THE relation between splenic anæmia, Banti's disease, and portal thrombosis has been the subject of much controversy in medical literature. The current orthodox view applies the term "splenic anæmia" to a condition of primary splenomegalic anæmia of unknown origin, without enlargement of lymph nodes or cirrhosis of the liver and having a striking tendency to gastro-intestinal hæmorrhage; the expression "Banti's disease" is confined to cases in the above group which terminate in atrophic hepatic cirrhosis with ascites. Therefore cases of splenic anæmia which progress without showing any tendency to cirrhosis, or which develop a late hæmolytic jaundice—again without cirrhosis—as described by Banti himself,[1] would be excluded from this group. On the other hand, cases of splenic anæmia exhibiting later the signs of Banti's syndrome would be regarded after the event as early cases of Banti's disease. The latter, it is held, is a terminus towards which certain cases of splenic anæmia progress. They do not all do so, and therefore the terms can only be synonymous in certain cases, and then only retrospectively. Splenomegalic anæmia associated with syphilis, malaria, tuberculosis, or kala-azar should also, on this view, be grouped separately. According to this classification it will be seen that any case exhibiting Banti's *syndrome*, attributable to a hitherto recognised cause, ceases to be one of Banti's *disease*; this applies also to splenic anæmia. Both are essentially expectant groups awaiting nomination. This is the view taken by Leon-Kindberg, amongst others, in his admirably clear and discriminating article on the sclerotic splenomegalies.[2]

Differing Interpretations.

Many writers, however, chiefly French and American, disagree with this conception, and wish to classify the conditions under the general headings of (1) hepatic congestion or cirrhosis, (2) syphilis, and (3) malaria. Gilbert and Lereboullet,[3] in 1904, pointed out that a condition indistinguishable from Banti's disease can be produced by portal congestion of hepatic origin. The spleen, in their view, is the satellite of the liver, and splenomegaly of this type is merely an episode of portal hypertension. Persistence of the umbilical vein, so that excessive amounts of blood are carried to the portal sinus, has also been described as a cause. Oettinger and Fiessinger,[4] and Warthin,[5] consider that Banti's disease as such is an illusion, and describe a group of splenomegalic anæmias associated with portal thrombosis. Warthin is particularly out-spoken, and says: "Until it has been shown that the splenic anæmia of Banti's complex can exist without any evidence of obstruction in the portal or splenic veins, then my contention must hold that the complex is no disease-entity. Until this is done, splenic anæmia and Banti's disease must be regarded as coördinated symptom-complexes and not individual disease-entities." Elsewhere he says that an infective thrombophlebitis of the portal or splenic veins is the essential feature of all these cases, no matter under what head reported—splenic or portal thrombosis, splenic anæmia or Banti's disease. The importance of this view is further emphasised by the fact that of the six cases diagnosed clinically as either splenic anæmia or Banti's disease in the post-mortem register at St. Bartholomew's Hospital since 1920, portal thrombosis was present in every one. The facts, then, are not in question. What seems doubtful is the interpretation to be placed upon them, whether such thrombosis is primary or secondary, and the exact discrimination of the causal sequences at work. Relation in point of time is notoriously difficult to establish by post-mortem methods, and it is difficult to see how this question can be settled other than by an analysis of events occurring within the course of the disease itself. Two cases, occurring recently at St. Bartholomew's Hospital, seem to go some way towards meeting Warthin's challenge and supplying a solution to this problem.

Two Cases Related.

CASE 1. *Fatal Termination.*—A woman of 50 was admitted to hospital complaining of breathlessness, palpitation, epigastric pain after food, and pain in the left side of the chest, all of one year's duration. She was pale and sallow. The spleen was palpable, and both it and the liver were described as being "three fingers-breadth below the costal margin." Ascites was absent. There had been no hæmatemesis. The Wassermann and sigma reactions were negative, and the fragility of the red cells was within normal limits. Van den Bergh's test was not done, but there was no obvious jaundice. A blood count showed: Hæmoglobin, 35 per cent.; red cells, 2,540,000; white cells, 3800 (polymorphs, 2508; lymphocytes, 1216); colour-index, 0·7. No nucleated red cells or megaloblasts were seen.

The patient had never had malaria or jaundice, and there were no enlarged lymph nodes. A diagnosis of splenic anæmia was made, and three blood transfusions were given, which raised the hæmoglobin to 40 per cent. and the red blood cells to 4,900,000. Splenectomy was then performed. The patient progressed uneventfully until the fourteenth day after operation, when she suddenly felt faint and her temperature dropped from 99° to 95° F.; pulse-rate, 100; respirations, 20. The abdomen was distended, but no pain, tenderness, rigidity, or shifting dullness was noticed. The patient passed two stools containing bright-red blood. Early the next morning the pulse-rate suddenly rose to 150; temperature, 95°; respirations, 20. A blood count at this time showed: Red cells, 6,890,000; hæmoglobin, 85 per cent.; white cells, 63,400. (Six days after operation a leucocyte count showed only 6900.) The striking rise in the number of red cells and in the hæmoglobin content was evidently due to sudden concentration of the blood, associated with shock. The patient was considered too ill for operation, but a further transfusion was done, one hour after which the temperature rose to 102°. The patient died the following morning with a temperature of 107°.

Post-mortem Examination.—The peritoneal cavity contained much clear yellowish fluid. The lower three feet of the ileum were congested and œdematous. The ligatures on the splenic pedicle were intact and there was no evidence of suppuration. A film made from the tissues of the pedicle and stained by Gram's method showed no organisms

Culture showed a coliform bacillus, probably a contamination. The liver gave evidence of early nutmeg changes, but no evidence of cirrhosis was noted. Adherent ante-mortem clot was present in the splenic, portal, and mesenteric veins. The post-mortem note stated: "The phlebitis and thrombosis have presumably spread from the splenic pedicle along the splenic vein, but no proof of bacterial infection was obtained." No explicit note was made either at operation or at the post-mortem examination on the size of the splenic vein or the condition of its wall. The spleen was unfortunately not examined microscopically.

CASE 2. *Recovery.*—A man, aged 23, was admitted to hospital complaining of black stools. Four months previously he had had hæmatemesis, for which he had been treated at another hospital with Lenhartz diet and ultraviolet rays. On examination the spleen was palpable; jaundice and ascites were absent and there were no palpable lymph nodes. A blood count showed: Hæmoglobin, 48 per cent.; red cells, 3,200,000; white cells, 5600; colour-index, 0·75. The Wassermann and sigma reactions were negative, and so was van den Bergh's test. There was no history of malaria. A diagnosis of splenic anæmia was made and splenectomy performed.

Morbid Anatomy.—The spleen weighed 25 oz., and was firm and fibrous. Perisplenitis was absent, and there were no infarcts. Microscopically, it showed a rather a-cellular generalised fibrosis. There was no uniform congestion, but a few small scattered hæmorrhages were present, due possibly to operative trauma. The sinuses were not dilated and contained very few cells. There was no evidence of endothelial proliferation or the deposition of pigment. The picture was quite unlike that described by Tansini and Morone in splenomegaly due to portal thrombosis,[6] where he splenic sinuses were transformed into "large lakes of lood," and the pulp infiltrated with macrophages and igment.

The patient recovered from the immediate effects of the eration, and eight days later a blood count showed: ed cells, 2,800,000; white cells, 8600; polymorphs, 6620; nphocytes, 1030. An estimation of the hæmoglobin s not done. Thirteen days later the figures were: moglobin, 44 per cent; red cells, 3,400,000; white cells, 00; colour-index, 0·7. n the fourteenth day after splenectomy the patient had dden attack of severe abdominal pain and vomited. His erature dropped to 96°; the pulse-rate rising to 135. abdomen become distended and free fluid was noted. No leucocyte count was done at this time. Intraperitoneal hæmorrhage was suspected, and it was decided to perform a suprapubic exploratory puncture. This was done, and two pints, not of blood but of clear yellow fluid, were withdrawn. A drainage-tube was left in, and the patient transfused with 400 c.cm. of blood. He vomited afterwards, and was rather restless. However, his temperature gradually improved, reaching normal on the third day, and he made a good recovery. Six months later a blood count showed: Red cells, 4,090,000; hæmoglobin, 50 per cent.; white cells, 9000. In spite of this, there can be little doubt that acute portal thrombosis supervened on the fourteenth day after splenectomy. The exact site must remain uncertain, but two facts—the ascites and the sudden severe pain—make it probable, as will appear later, that both portal and mesenteric veins were involved.

Signs and Symptoms of Portal Thrombosis.

The signs and symptoms of portal thrombosis are fairly well known and have been described exhaustively by Langdon-Brown.[7] They are more or less invariable, and include abdominal pain, ascites, diarrhœa with or without blood, vomiting with or without hæmatemesis, enlargement of the spleen and, if of acute onset, general shock. All these were present in the two cases described in this paper. Langdon-Brown suggests that the signs and symptoms may bear some relation to the site of thrombosis. "Broadly speaking, in any case of pylethrombosis, if ascites is present, the trunk of the vein is probably occluded; if hæmatemesis occurs, the splenic vein is probably involved; and if pain, vomiting, diarrhœa, and collapse are the leading symptoms, there is probably obstruction of the superior mesenteric vein." The onset is not always acute; it may be slow and progressive, though interrupted by critical episodes corresponding to fresh attacks of thrombosis. Frick[8] and Frugoni[9] emphasise this irregularity in progress as an important point of distinction between primary splenomegaly and that due to portal thrombosis. This point will be referred to later.

Acute thrombosis of the coronary vessels is well known to give rise to an emphatic leucocytosis. A leucocyte count in direct response to the acute abdominal condition was done in only two cases, in Case 1 of this paper, and in another case of acute portal thrombosis not described here. In the latter the count rose from 18,000 to 34,000 with the onset of symptoms. In Case 1 splenectomy had been performed 13 days previously, and splenectomy per se causes a leucocytosis. In fact, however, the appearance of acute symptoms introduces a figure of a different order from that anticipated on physiological grounds, so that this may be taken to represent leucocytosis of thrombogenic origin. Before splenectomy the leucocyte count was 1200; seven days afterwards it was 9500. With the onset of acute symptoms on the thirteenth day after operation it rose to the quite unexpected figure of 63,400. Further leucocyte counts in patients with portal thrombosis are to be desired, but the evidence of these two cases suggests that leucocytosis may occur.

Classification of the Two Cases.

It is clear that all these signs and symptoms, with the exception of a possible leucocytosis, are common both to portal thrombosis and (if they have any separate existence) to splenic anæmia and Banti's disease. The two cases under discussion are presented as examples of primary splenomegalic anæmia rather than of thrombosis, on the following grounds:—

1. That thrombosis was here the initial cause is improbable, as acute signs and symptoms attributable to thrombosis only occurred well within the course of an already established "splenomegalic anæmia."

2. The contention that this pre-established splenomegaly was itself the result of a slowly progressive thrombosis is difficult to maintain in view of three facts: (*a*) The absence in the past history of exacerbations similar to the one observed. Reference has already been made to the importance of this point, emphasised by Frick. (*b*) The absence in the records of the surgical procedure of any mention of such thrombosis or thrombophlebitis in situ. (*c*) The fact that Case 2 made such a complete and rapid recovery from his post-operative attack. If this had been merely the culmination of a slowly progressive thrombotic process extending over one year, such a rapid remission would seem most improbable, with or without splenectomy.

If these points be admitted, then Warthin's theory of an initial and invariable portal thrombosis as the underlying condition in both splenic anæmia and Banti's disease seems clearly inapplicable to these two cases. It is not maintained that portal thrombosis never gives rise to a picture indistinguishable from Banti's syndrome; it seems certain that it can, and does. But it is maintained that thrombosis seems peculiarly liable to develop during the course of a primary splenomegalic anæmia without lymphatic enlargements and with or without ascites. To argue in the reverse way would be on all fours with the attempt to show that portal thrombosis is the cause of hepatic cirrhosis, since Langdon-Brown[7] has shown that this is the commonest condition associated with portal thrombosis in general.

Rosenthal,[10] in a recent study of the platelets in Banti's disease, has shown that cases can be divided into two groups, thrombocytic and thrombopenic. The former he considers particularly liable to severe hæmorrhages; the latter to thromboses, especially post-operative. Unfortunately, platelet counts were not done on either of the cases considered here, but it is clear that the idea opens up a fresh field for investigation and offers a possible explanation of the frequency with which thrombosis occurs. The post-operative tendency to it may further be related to the fact that the red cells are apt to rise very rapidly after splenectomy, and Leon-Kindberg[11] reports transient polycythæmia on several occasions. This was present in Case 1 (red cells 6,890,000), although

Quartan Malaria.—I have had only one opportunity of observing the effects of plasmoquine-compound in quartan malaria.

The patient had suffered almost continuously for four years from persistent relapses of a peculiarly intractable form of fever which did not yield to quinine. She had a large and painful spleen and a scanty infection of quartan parasites in the peripheral blood. A full course of plasmoquine-compound was followed by a slight cyanosis, which was transitory and unaccompanied by any other alarming symptoms. The clinical results, as far as could be ascertained, were satisfactory and no more relapses have occurred. The physical condition is satisfactory.

Conclusions.

The time is not yet ripe to draw a final conclusion upon the rôle which plasmoquine is destined to play in the therapeutics of malaria. I am not suggesting that it is going to replace quinine in the treatment of every case, but I submit that sufficient evidence has now been accumulated to show that, under certain circumstances, it *can act as an efficient substitute* in patients who have been susceptible to, or intolerant of, large doses of quinine. Its most important property is that it affords an alternative treatment and is undoubtedly tolerated in severe cases with persistent vomiting when pure quinine is not. The amount of the drug necessary to banish the parasites from the blood is much smaller—a very important point—the taste is not disagreeable, the effects upon digestion are negligible, and it is well tolerated by children.

Occasional signs of relative intolerance to plasmoquine and plasmoquine-compound are slight cyanosis, dyspepsia, colic, and splenic pain.

SPLENIC ANÆMIA AND PORTAL THROMBOSIS.

By J. CONWAY DAVIES, M.B. Camb., M.R.C.P. Lond.,

PHYSICIAN TO THE SEAMEN'S HOSPITAL, GREENWICH; DEMONSTRATOR OF PATHOLOGY, ST. BARTHOLOMEW'S HOSPITAL.

The relation between splenic anæmia, Banti's disease, and portal thrombosis has been the subject of much controversy in medical literature. The current orthodox view applies the term "splenic anæmia" to a condition of primary splenomegalic anæmia of unknown origin, without enlargement of lymph nodes or cirrhosis of the liver and having a striking tendency to gastro-intestinal hæmorrhage; the expression "Banti's disease" is confined to cases in the above group which terminate in atrophic hepatic cirrhosis with ascites. Therefore cases of splenic anæmia which progress without showing any tendency to cirrhosis, or which develop a late hæmolytic jaundice—again without cirrhosis—as described by Banti himself,[1] would be excluded from this group. On the other hand, cases of splenic anæmia exhibiting later the signs of Banti's syndrome would be regarded after the event as early cases of Banti's disease. The latter, it is held, is a terminus towards which certain cases of splenic anæmia progress. They do not all do so, and therefore the terms can only be synonymous in certain cases, and then only retrospectively. Splenomegalic anæmia associated with syphilis, malaria, tuberculosis, or kala-azar should also, on this view, be grouped separately. According to this classification it will be seen that any case exhibiting Banti's *syndrome*, attributable to a hitherto recognised cause, ceases to be one of Banti's *disease;* this applies also to splenic *anæmia*. Both are essentially expectant groups awaiting nomination. This is the view taken by Leon-Kindberg, amongst others, in his admirably clear and discriminating article on the sclerotic splenomegalies.[2]

Differing Interpretations.

Many writers, however, chiefly French and American, disagree with this conception, and wish to classify the conditions under the general headings of (1) hepatic congestion or cirrhosis, (2) syphilis, and (3) malaria. Gilbert and Lereboullet,[3] in 1904, pointed out that a condition indistinguishable from Banti's disease can be produced by portal congestion of hepatic origin. The spleen, in their view, is the satellite of the liver, and splenomegaly of this type is merely an episode of portal hypertension. Persistence of the umbilical vein, so that excessive amounts of blood are carried to the portal sinus, has also been described as a cause. Oettinger and Fiessinger,[4] and Warthin,[5] consider that Banti's disease as such is an illusion, and describe a group of splenomegalic anæmias associated with portal thrombosis. Warthin is particularly out-spoken, and says: "Until it has been shown that the splenic anæmia of Banti's complex can exist without any evidence of obstruction in the portal or splenic veins, then my contention must hold that the complex is no disease-entity. Until this is done, splenic anæmia and Banti's disease must be regarded as coördinated symptom-complexes and not individual disease-entities." Elsewhere he says that an infective thrombophlebitis of the portal or splenic veins is the essential feature of all these cases, no matter under *what head reported—splenic or portal thrombosis*, splenic anæmia or Banti's disease. The importance of this view is further emphasised by the fact that of the six cases diagnosed clinically as either splenic anæmia or Banti's disease in the post-mortem register at St. Bartholomew's Hospital since 1920, portal thrombosis was present in every one. The facts, then, are not in question. What seems doubtful is the interpretation to be placed upon them, whether such thrombosis is primary or secondary, and the exact discrimination of the causal sequences at work. Relation in point of time is notoriously difficult to establish by post-mortem methods, and it is difficult to see how this question can be settled other than by an analysis of events occurring within the course of the disease itself. Two cases, occurring recently at St. Bartholomew's Hospital, seem to go some way towards meeting Warthin's challenge and supplying a solution to this problem.

Two Cases Related.

CASE 1. *Fatal Termination.*—A woman of 50 was admitted to hospital complaining of breathlessness, palpitation, epigastric pain after food, and pain in the left side of the chest, all of one year's duration. She was pale and sallow. The spleen was palpable, and both it and the liver were described as being "three fingers-breadth below the costal margin." Ascites was absent. There had been no hæmatemesis. The Wassermann and sigma reactions were negative, and the fragility of the red cells was within normal limits. Van den Bergh's test was not done, but there was no obvious jaundice. A blood count showed: Hæmoglobin, 35 per cent.; red cells, 2,540,000; white cells, 3800 (polymorphs, 2508; lymphocytes, 1216); colour-index, 0·7. No nucleated red cells or megaloblasts were seen.

The patient had never had malaria or jaundice, and there were no enlarged lymph nodes. A diagnosis of splenic anæmia was made, and three blood transfusions were given, which raised the hæmoglobin to 40 per cent. and the red blood cells to 4,900,000. Splenectomy was then performed. The patient progressed uneventfully until the fourteenth day after operation, when she suddenly felt faint and her temperature dropped from 99° to 95° F.; pulse-rate, 100; respirations, 20. The abdomen was distended, but no pain, tenderness, rigidity, or shifting dullness was noticed. The patient passed two stools containing bright-red blood. Early the next morning the pulse-rate suddenly rose to 150; temperature, 95°; respirations, 20. A blood count at this time showed: Red cells, 6,890,000; hæmoglobin, 85 per cent.; white cells, 63,400. (Six days after operation a leucocyte count showed only 6900.) The striking rise in the number of red cells and in the hæmoglobin content was evidently due to sudden concentration of the blood, associated with shock. The patient was considered too ill for operation, but a further transfusion was done, one hour after which the temperature rose to 102°. The patient died the following morning with a temperature of 107°.

Post-mortem Examination.—The peritoneal cavity contained much clear yellowish fluid. The lower three feet of the ileum were congested and œdematous. The ligatures on the splenic pedicle were intact and there was no evidence of suppuration. A film made from the tissues of the pedicle and stained by Gram's method showed no organisms.

capsule was thickened. There was no evidence naked-eye to suggest a chronic enlargement, the fibrous trabeculæ and vascular sheaths appearing normal. Nor was there any secondary condition such as an infarct which would have given rise to the rupture. Unfortunately no microscopical examination was made.

The interest of the case lies in its being opposed to the generally accepted opinion that great enlargement of the spleen does not usually occur in a primary attack of induced malaria. Dr. Philip Manson-Bahr informs me that in naturally acquired malaria the mortality from ruptured spleen is only about one in every hundred thousand infections, and I believe that there have only been four similar cases recorded after induction of malaria. The case would be more easily explicable had there been a history of previous malaria, pointing to chronic enlargement of the spleen. Personally, I feel that, when treating cases of general paralysis with malaria, a careful watch should be kept for undue enlargement of the spleen, especially if the patient has previously had malaria.

My thanks are due to Dr. Manson-Bahr and the Ministry of Pensions for their information; also to the medical superintendent of this hospital for allowing me to publish the case.

Sheffield.

Dr. T. Chetwood's report is this year limited to a concise statement of the progress of medical inspection and treatment. Shortage of staff may account for the brevity of his survey, for he says that an additional school medical officer is urgently required, and it is also clear that additions to the school nursing service are desirable.

Sheffield differs from most other English towns in separating the offices of school medical officer and medical officer of health, but the two departments are in daily and friendly consultation. In the existing open-air school there is accommodation only for 290 day scholars, but plans have already been approved for the establishment of a new school at Bents Green, with room for 50 residential pupils and 100 day scholars. Since Sheffield contains nearly 2000 delicate children, this additional school is obviously required. Valuable work is being done for delicate and convalescent children at a home at Fairthorn Green, supported by the generosity of the Sheffield teachers. A new central clinic has been opened at Leopold-street, which is also the administrative centre of the school medical service. Increased clinic accommodation is needed. Dr. Chetwood offers his thanks to many practitioners for willing coöperation and help in the effort to secure for school-children prompt treatment of their ailments, and the implication is that Sheffield practitioners are not reluctant to take advantage of such facilities as X ray treatment for ringworm afforded by the clinics.

The clinics received for treatment only seven children from the welfare centre, and there is still no nursery school in the city, but it is hoped that one will be opened during the current year. Mr. G. Wilkinson, whose resignation from the post of aural surgeon is much regretted, evidently had the confidence of the parents, for out of 232 cases of tonsils and adenoids recommended for operation, there were only 18 whose parents refused treatment. The ophthalmic surgeons dealt with 1179 new cases during the year, and the dental clinic with 18,000. 128 extra evening clinics were held after school hours for children suffering from toothache. This service is much appreciated locally, but most local authorities throughout the country do not favour large number of casuals, and possibly, when extra dental surgeons are appointed in Sheffield, the routine work will be so extended that casual sufferers will be almost eliminated. Dr. E. F. Skinner, the dermatologist, reports that severe cases of ringworm seem to be getting fewer every year. Among those who are afflicted X ray treatment is less often required; very small patches are dealt with, cheaply and efficiently, by shaving and parasiticide ointment, while 27 selected cases have been treated by the thallium acetate method with good results. Orthopædic treatment is given at the Edgar Allen Institute, and there are three special schools for physical defectives, and a residential sanatorium school for surgical tuberculosis. The school arrangements will be much improved when the education authority has appointed the proposed special orthopædic surgeon. The report of the superintendent of physical training, Mr. H. Cole, forms an interesting appendix, and his observations on the importance of postural training to health and efficiency are convincing.

Wigan.

Wigan has not in the past been a very healthy place for children to live in, and school medicine and hygiene are therefore of particular importance. Unfortunately the county borough still lacks many of the valuable agencies to be found elsewhere. For example, no open-air school exists, though there are large numbers of delicate children in Wigan. The initial cost of a residential open-air school would be considerable; Dr. H. Whitehead asks at present only for an open-air day school, and this at least should be established forthwith. Fifteen per cent. of the children attending school in Wigan are verminous. This figure, which is much too high, is nevertheless an improvement on former records. There are no school baths and the accommodation at the Corporation baths is quite inadequate. The congestion may soon be somewhat relieved by the establishment of Corporation baths at Pemberton. Physical drill is taken by the teachers with the advice of the assistant school medical officer, in the absence of any organiser of physical training. A number of girls have spinal curvatures, for which special exercises are necessary. For children with severe deformities a P.D. school is urgently needed. Following operative treatment for tonsils and adenoids, the children are taken home by ambulance, accompanied by a school nurse. This arrangement is certainly preferable to a journey home by public conveyance, but not comparable to the organisation now established by more progressive authorities, whereby children are retained in hospital for at least one night following the operation. In two directions the county borough has made some advance: (1) a definite scheme has been put into operation which will eventually ensure proper care and attention for orthopædic cases—the central clinic is already in working order; (2) in July, artificial sunlight treatment began at the Infirmary, and the results up to date have been very good. It is hoped that a light centre will be provided at an early date by the local authority in order that more cases may be treated.

Dr. Robert Fielle Library
Medical College

it must be remembered that here shock was probably the predominant factor.

Summary.

The relationships between splenic anæmia, Banti's disease, and portal thrombosis are mentioned. The classical view of Banti, and later of Leon-Kindberg, is summarised, and contrasted with that of Warthin. Two cases of anæmia with splenomegaly associated with portal thrombosis are described in detail. Reasons are given for believing them to be examples of primary splenomegalic anæmia (which therefore exists) rather than of thrombotic splenomegaly. For this reason it is suggested that they may meet Warthin's challenge, quoted in the body of the paper. Rosenthal's work on the platelet content of the blood in Banti's disease is mentioned, and an attempt made to relate this with the tendency to thrombosis.

I have to thank Prof. G. E. Gask, Mr. R. M. Vick, and Dr. George Graham for their kindness in allowing me to refer to cases under their charge.

Clinical and Laboratory Notes.

A CASE OF CERVICAL RIB.

By George A. Dunlop, M.B. St. And.,
D.T.M. & H. Liverp.,
MEDICAL OFFICER TO THE EUROPEAN HOSPITAL, KUALA LUMPUR, FEDERATED MALAY STATES.

The discovery of cervical rib by X rays is not uncommon, but the symptoms of this case were interesting.

The patient, an assistant school-master, is a healthy man of 24, who has twice fractured his left clavicle. I first saw him in his bungalow in October, 1927, when he looked rather pale and complained of a feeling of compression over the left side of the chest and of severe pain in the left supraclavicular region, radiating down the left arm. He felt "giddy" and "faint," and had "palpitation." The pulse-rate was 140 but regular, the apex-beat was visible in the fifth interspace just outside the nipple line. The heart sounds were well heard at all areas, regular and closed. There was no swelling or œdema of the arms or legs, and no bony deformity of the clavicle; nothing abnormal could be palpated at the root of the neck and there were no signs or symptoms of disease of the nervous system.

He stated that he had had a number of these attacks since August, 1926, the first attack occurring in a rickshaw, when he had "giddiness in the head, general numbness down the left arm and side, and pain in the chest." This was diagnosed as pseudo-angina. A second attack, in October, 1926, was similar, but he noticed "a feeling of tightness in the left arm and a swollen appearance of the veins." During a third attack, in November, 1926, while in a motor-car, there was "numbness" and a feeling of cold in both arms and extreme cardiac pain. In December, 1926, he had a fourth attack in Hong-Kong during a dance, when, after the first dance, he had a violent palpitation and similar sensations in the arm and chest on the left side only. During 1927 he had a series of similar attacks up to October, when I saw him. He also had attacks of palpitation in bed at night after he had been lying down for some time, and he recognised prodromal symptoms of sleepiness and general weariness before an attack.

About ten days after I first saw him, the head-master of his school telephoned me to come urgently as the patient had "fainted" while teaching and was unconscious. When I arrived he appeared to have just regained consciousness. His face was bluish, his respirations quick, and his pulse-rate 167. He was very confused mentally and was groaning. There was no swelling of either arm, and he said that the compression and pain in the chest was suffocating him. He was assisted to his feet but was too "giddy" to stand alone; he felt better after being made to walk about. He had developed a marked neurosis about his condition and was glad to come into hospital for investigation.

Physical examination did not reveal anything, but X ray examination of the upper thorax and cervical region showed bilateral cervical rib. The clavicles were normal in outline. He was shown the X ray films, the condition was explained to him, and he was discharged. During the next five months the neurotic symptoms cleared up, but he had occasional attacks of pain, palpitation, and a feeling of constriction of the chest. I advised him to walk about at the onset of an attack, and this relieves him. As he was proceeding to England on leave he was advised to seek surgical advice at home.

Dr. R. Dowden, principal medical officer, F.M.S., kindly gave me permission to communicate this case.

NORMAL BIRTH OF A CHILD WEIGHING SIXTEEN POUNDS.

By F. R. Parakh, M.D. Manch., M.R.C.S. Eng.,
CHIEF MEDICAL OFFICER, DR. PARAKH HOSPITAL, BOMBAY.

A Parsee woman was admitted to the Dr. Parakh Hospital on Jan. 13th, 1927, with strong pains and in full labour. The woman was well built, of average weight and height. She was 28 years old, and a primipara, with normal pelvic measurements. The abdomen was enormously enlarged, and twins, hydramnios or triplets were suspected, but after a careful examination these were eliminated and a monster or a giant was diagnosed. There were no fœtal heart sounds audible, and as the head was fairly low into the pelvic cavity, and the soft parts were dilating and bulging well, no interference was indicated. After a labour of 11 hours she was delivered of a well-formed healthy stillborn child weighing 16 pounds. The child showed no signs of any monstrosity or any other deformities, and looked a child of three months of age. The length of the fœtus was 59 cm., and the testicles very large. There was a plentiful growth of hair on the head, the bones of which were fairly hard. The father of the child is a small-made man of 30 years of age. Two children by his first wife weighed 9 and 10 pounds each. All the members of his family and his present wife's family are of ordinary size and weight.

The puerperium has been normal throughout, and the perineum, which was badly ruptured, has healed well and firmly.

A CASE OF
RUPTURE OF THE SPLEEN AFTER ARTIFICIAL INDUCTION OF MALARIA.

By Noel G. Harris, M.B. Lond.,
ASSISTANT MEDICAL OFFICER, SPRINGFIELD MENTAL HOSPITAL, TOOTING.

The following case is, I think, worth recording:—

A man, aged 30, was admitted to Springfield Mental Hospital suffering from general paralysis of the insane. The disease was in an early stage, the first symptoms having been noticed only three to four months before admission. Physically he was sound, except for the fact that he suffered from chronic dysentery, having contracted both the amœbic and bacillary forms during the late war. There was no history of any malarial infection.

On Dec. 6th he was inoculated with benign tertian malaria. He had ten good rises of temperature lasting over a period of 12 days. On the morning following the tenth rise he jumped out of bed suddenly. A few seconds after getting back he collapsed, and was dead in an hour. At autopsy the abdomen was found to be full of blood from a ruptured spleen. The spleen was only semi-solid, and the vessels appeared to have just torn away, no defined rent being visible. The capsule was thickened. There was no evidence naked-eye to suggest a chronic enlargement, the fibrous trabeculæ and vascular sheaths appearing normal. Nor was there any secondary condition such as an infarct which would have given rise to the rupture. Unfortunately no microscopical examination was made.

The interest of the case lies in its being opposed to the generally accepted opinion that great enlargement of the spleen does not usually occur in a primary attack of induced malaria. Dr. Philip Manson-Bahr informs me that in naturally acquired malaria the mortality from ruptured spleen is only about one in every hundred thousand infections, and I believe that there have only been four similar cases recorded after induction of malaria. The case would be more easily explicable had there been a history of previous malaria, pointing to chronic enlargement of the spleen. Personally, I feel that, when treating cases of general paralysis with malaria, a careful watch should be kept for undue enlargement of the spleen, especially if the patient has previously had malaria.

My thanks are due to Dr. Manson-Bahr and the Ministry of Pensions for their information; also to the medical superintendent of this hospital for allowing me to publish the case.

* Excluding uncleanliness and dental defects.

Sheffield.

Dr. T. Chetwood's report is this year limited to a concise statement of the progress of medical inspection and treatment. Shortage of staff may account for the brevity of his survey, for he says that an additional school medical officer is urgently required, and it is also clear that additions to the school nursing service are desirable.

Sheffield differs from most other English towns in separating the offices of school medical officer and medical officer of health, but the two departments are in daily and friendly consultation. In the existing open-air school there is accommodation only for 290 day scholars, but plans have already been approved for the establishment of a new school at Bents Green, with room for 50 residential pupils and 100 day scholars. Since Sheffield contains nearly 2000 delicate children, this additional school is obviously required. Valuable work is being done for delicate and convalescent children at a home at Fairthorn Green, supported by the generosity of the Sheffield teachers. A new central clinic has been opened at Leopold-street, which is also the administrative centre of the school medical service. Increased clinic accommodation is needed. Dr. Chetwood offers his thanks to many practitioners for willing coöperation and help in the effort to secure for school-children prompt treatment of their ailments, and the implication is that Sheffield practitioners are not reluctant to take advantage of such facilities as X ray treatment for ringworm afforded by the clinics.

Dr. Robert Fiel

The clinics received for treatment only seven children from the welfare centre, and there is still no nursery school in the city, but it is hoped that one will be opened during the current year. Mr. G. Wilkinson, whose resignation from the post of aural surgeon is much regretted, evidently had the confidence of the parents, for out of 232 cases of tonsils and adenoids recommended for operation, there were only 18 whose parents refused treatment. The ophthalmic surgeons dealt with 1179 new cases during the year, and the dental clinic with 18,000. 128 extra evening clinics were held after school hours for children suffering from toothache. This service is much appreciated locally, but most local authorities throughout the country do not favour large number of casuals, and possibly, when extra dental surgeons are appointed in Sheffield, the routine work will be so extended that casual sufferers will be almost eliminated. Dr. E. F. Skinner, the dermatologist, reports that severe cases of ringworm seem to be getting fewer every year. Among those who are afflicted X ray treatment is less often required; very small patches are dealt with, cheaply and efficiently, by shaving and parasiticide ointment, while 27 selected cases have been treated by the thallium acetate method with good results. Orthopædic treatment is given at the Edgar Allen Institute, and there are three special schools for physical defectives, and a residential sanatorium school for surgical tuberculosis. The school arrangements will be much improved when the education authority has appointed the proposed special orthopædic surgeon. The report of the superintendent of physical training, Mr. H. Cole, forms an interesting appendix, and his observations on the importance of postural training to health and efficiency are convincing.

Wigan.

Wigan has not in the past been a very healthy place for children to live in, and school medicine and hygiene are therefore of particular importance. Unfortunately the county borough still lacks many of the valuable agencies to be found elsewhere. F example, no open-air school exists, though there a large numbers of delicate children in Wigan. Tl initial cost of a residential open-air school would l considerable; Dr. H. Whitehead asks at presen only for an open-air day school, and this at leas should be established forthwith. Fifteen per cent. of the children attending school in Wigan are verminous. This figure, which is much too high, is nevertheless an improvement on former records. There are no school baths and the accommodation at the Corporation baths is quite inadequate. The congestion may soon be somewhat relieved by the establishment of Corporation baths at Pemberton. Physical drill is taken by the teachers with the advice of the assistant school medical officer, in the absence of any organiser of physical training. A number of girls have spinal curvatures, for which special exercises are necessary. For children with severe deformities a P.D. school is urgently needed. Following operative treatment for tonsils and adenoids, the children are taken home by ambulance, accompanied by a school nurse. This arrangement is certainly preferable to a journey home by public conveyance, but not comparable to the organisation now established by more progressive authorities, whereby children are retained in hospital for at least one night following the operation. In two directions the county borough has made some advance: (1) a definite scheme has been put into operation which will eventually ensure proper care and attention for orthopædic cases—the central clinic is already in working order; (2) in July, artificial sunlight treatment began at the Infirmary, and the results up to date have been very good. It is hoped that a light centre will be provided at an early date by the local authority in order that more cases may be treated.

Cambridge.

The percentage of children requiring treatment (7 per cent.) is remarkably low in Cambridge compared with the rest of the country, and the fact that it is higher in 1927 than in the previous seven years is probably due to more stringent marking. On the other hand, the tuberculosis figures for Cambridge are high—38 cases were notified for pulmonary tuberculosis—that is nearly 2 per cent. of those seen at routine inspection, the usual figure for England and Wales being about ½ per cent. The open-air school about to be opened may do much to combat this high incidence. The proposed school will not be quite of the usual type, since it is to accommodate 120 physically defective and also 30 mentally defective children. Previously there were no special schools, and the exact type of child taken into the class for backward children is not specified. Dr. A. J. Laird gives a table showing the steady decline of cases of ringworm in the borough over a period of 14 years.

Cambridge is well known for pioneer dental work, and Mr. W. Baird Grandison can use for comparison tables dating from 1908. Three sets of figures are given to show how much improvement has been effected during this period. The percentage of sound permanent teeth has risen from 12·5 per cent. in 1909 to 63 per cent. in 1927. The proportion of children with sound dentitions, temporary as well as permanent, is now 39·2 per cent. against 2·6 per cent. in 1909. The percentage of unsavable permanent teeth is said to have decreased from 30·6 per cent. in 1909 to 1 per cent. in 1927. These figures are set out to prove the value of a deliberate attempt to preserve the permanent dentition by sound preventive and constructive principles. Mr. Grandison acknowledges the coöperation of other workers, especially the teachers. A scheme of dental education was applied to 150 older girls; the course of lectures was followed by an examination, the results of which were so good that the lectures are to be repeated to double the number of children. Mr. Grandison makes a special plea that if an 11 o'clock meal is held to be desirable, the food consumed should be selected so as to eliminate injury to the teeth.

MENTAL HOSPITAL REPORTS.

The *Hertfordshire County Mental Hospital* at *St. Albans* had 918 patients on its books at the end of last year. The recovery-rate for the year was 22·1 per cent. and the death-rate 5·18 per cent. Thirty-two post-mortem examinations were held. There is serious overcrowding, so that proper classification and adequate treatment on modern lines is impossible. The general health was good; there were four cases of dysentery, one of diphtheria, and one of erysipelas. Five patients were notified as suffering from tuberculosis. The dental surgeon treated 158 cases. Patients were allowed out on leave on 296 occasions. The ward on each side is run on the open-door system, and a number of patients have full parole outside the grounds. Others are free to walk about the estate and a few have been allowed to go into St. Albans for football matches. There has been no abuse of these privileges. Improvements have been made in the dietary. A pathologist has been appointed, and his work has already been of great value in treatment. A sistor-tutor has also been appointed, and seven nurses and one attendant obtained certificates during the year. Possession has now been obtained of a site at Hixberry which is to be used for mental defectives.

The *Essex and Colchester Mental Hospitals* are two in number. At *Brentwood* there is overcrowding on the female side and urgent need for expansion, with 1770 patients on the books. Of the 185 patients discharged during the year, 136 were sent out on preliminary trial. The recovery-rate was 26·27 per cent., a very fair figure considering the large proportion of patients who are hopeless on admission. The death-rate was 8·11 per cent., and the principal causes of death were cardio-vascular degeneration and general paralysis. Eight cases of the latter disease were treated by induced malaria; two were discharged, and two others greatly improved. The consulting surgeon has performed a number of operations, with excellent results. Full use is made of the verandahs on the admission and infirmary wards, and the 21 cases of tuberculosis are nursed on them. Nine wards are administered on the open-door principle, and liberal parole is granted. A nurses' home is badly needed, and plans for one have now been passed. A consulting engineer has been appointed to report on the question of electric light and power. Weaving and handicraft work have gone steadily forward, and about 50 women are employed on it. The visiting dentist has seen a large number of patients, and artificial dentures are being supplied to many of them. 119 nurses are now certificated. The Visiting Commissioners urge the appointment of a fifth assistant and a pathologist.

At *Severalls* there were 1730 patients under treatment at the end of the year. The death-rate was 7·52 per cent. and the recovery-rate 23·2 per cent. The general health was good except for a few cases of typhoid. Search is being made for carriers. A useful annexe has been opened for acute cases and the home for night nurses is nearly ready. An infirmary ward and a verandah are being built. The handicraft instructress has done good work and both patients and nurses have benefited from gymnastic classes. There are now 113 certificated nurses, but far too many of the women are untrained and inexperienced.

Of the two *Kent County Mental Hospitals*, that at *Barming Heath* housed 1853 patients at the end of the year. The new Nurses' Home has added 157 beds to the hospital accommodation as well as realising a long-cherished ideal concerning the better training and education of the staff. Since 1911 it has been compulsory for nurses to obtain a certificate, and every effort is made to attract the well-educated girl. The recovery-rate of 36·1 per cent. was above the average; the high death-rate of 8·7 per cent. was caused by a severe outbreak of influenza in the spring. Pneumonia accounted for a quarter of the deaths, and general paralysis for one-tenth. Post-mortem examinations were made in 94·4 per cent. of cases. The hospital has been free from dysentery and enteric for two years. The new cinema is much appreciated by the patients. The Visiting Commissioners advise the installation of X and violet rays and the provision of clinical rooms. Much occupational work is carried out in the wards, as well as on the farm and in the shops and laundry. In each large "chronic" ward a room is set aside for difficult patients, and they are encouraged to occupy themselves with some simple handicraft. On the male side 68·5 per cent. are usefully employed, and the shops are becoming overcrowded.

At *Chartham Downs* there were 1275 patients, and it is foreseen that the hospital will be over-full in a few years' time. The new clinical laboratory and the X ray plant are proving valuable additions, but at present there is no operating theatre and no specialists attend regularly. Twenty-four per cent. of the patients admitted were regarded as hopeless cases. The death-rate was 8 per cent. and the recovery-rate 29 per cent. Twenty patients are suffering from tuberculosis, but half of them had the disease before admission. Verandah accommodation is much needed. One clinical room has been arranged and others are to be provided. Twenty-four patients were allowed out on trial, and parole is granted beyond the estate to 46 patients and within it to 88; only nine of the privileged are women. One female and two male wards are conducted on the open-door system. Thirty-four men and 22 women nurses are certificated or registered.

Institutions for Private Patients.

There were 173 patients at *James Murray's Royal Asylum, Perth,* on March 31st last. Forty-two of the 66 new patients admitted during the year came on a voluntary basis. The recovery-rate among voluntary boarders was 39 per cent.; among the certified 30 per cent. The medical superintendent ascribes the difference in the figures partly to the feeling of spontaneous coöperation and the absence of compulsion and restraint. He discusses the problem of the voluntary patient in an interesting essay. The bodily health on admission was seriously impaired in most cases. The death-rate was 8·6 per cent.; autopsy was performed after 5 of the 14 deaths. The general health was good and there were no epidemics. The chief structural improvement of the year was the installation of a new central heating plant in the autumn. In each hospital ward an airy annexe has been provided for elderly infirm patients. Half the attendants, but only 18 per cent. of the nurses are certificated. The seaside home at Elie provides for some convalescent women patients. A few patients work in the gardens.

The report of *The Retreat, York*, is, as usual, beautifully illustrated; one photograph shows a group of articles made by patients, and is a testimonial to the occupation centre, which is already demanding more room for expansion. There were 199 patients on the books at the end of the year; 66 out of the 104 patients admitted came voluntarily. The recovery-rate was 27 per cent. and the death-rate 5·8 per cent. There was no serious epidemic disease, although influenza raged in the neighbourhood. The prophylactic campaign against it forms the subject of an interesting special report; the principal measure was a daily throat spray and gargle for all. General paralysis is being treated by induced malaria and the medical superintendent feels that this therapeutic measure is undoubtedly efficacious in most cases. A house at Goathland was rented for the summer and new accommodation, including 13 acres of ground, has been secured at Garrow Hill. The out-patient clinic at York County Hospital is running well. Parole beyond the grounds is granted to 21 patients, and within the grounds to 53. Forty-four of the patients are usefully employed. Fifty nursing staff are certificated.

Barnwood House Hospital, near *Gloucester*, had an average of 142 patients in residence during 1927, and the number of certified patients admitted during the year was greater than the number of voluntary boarders—contrary to expectation. The recovery-rate was 36 per cent. and the death-rate 7 per cent. The general health was good. One case of general paralysis was treated by induced malaria but showed no improvement. Several patients were treated by protein shock, but the results were not encouraging. Visiting specialists have been appointed and a laryngologist is to be added to their number. The wireless installations are much appreciated by the patients, and classes in handicrafts are held during the winter months. Five new bedrooms have been added on the male side, three of them with verandahs. Negotiations are in progress for installing electric light, and a new solarium has been opened. Full parole is allowed to 17 patients and limited parole to another 20. About half the nurses are certificated. three more having obtained their M.P.A. certificate during the year, while three others passed the General Nursing Council's final examination.

The eighteenth report of the *Scottish Western Asylums Research Institute* is somewhat unhappy reading. for it is doubtful whether the work can be carried on unless further funds are obtainable. Of its value there is no doubt, and a special meeting of the committee declared that it would be nothing short of a disaster if the scheme were abandoned. There has never been enough money to provide for an adequate staff, and at least £2500 would be needed annually to run the institute as it ought to be run. We sincerely hope that some solution of the problem may be found. The routine work of the year has been on the usual lines, except that the number of investigations for typhoid diminished considerably. In all, 1256 specimens were examined, chiefly for blood tests. Research has been carried out into the treatment of general paralysis and the chemistry of the cerebro-spinal fluid. A brief summary is given of the comparative results of treating general paralysis by various methods. Classes for medical officers have been held from time to time.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED AUGUST 25TH, 1928.*

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 141 (last week 114); scarlet fever, 1419; diphtheria, 816; enteric fever, 153; pneumonia, 514; puerperal fever, 48; puerperal pyrexia, 88; cerebro-spinal fever, 6; acute poliomyelitis, 15; encephalitis lethargica, 22; continued fever, 1; dysentery, 5; ophthalmia neonatorum, 129. No case of cholera, plague, or typhus fever was notified during the week.

The following counties each notified three or more cases of enteric fever:—London, 30; Essex, 37 (of which Colchester 31); Kent, 4; Lancaster, 11; Middlesex, 5; Norfolk, 3; Northumberland, 3 (Newcastle-on-Tyne); Southampton, 4; Suffolk East, 3; Surrey, 14; Sussex East, 4; Yorks West Riding, 5; Monmouth, 3. The total of 153 includes 46 cases of paratyphoid fever, of which 16 were notified in London and 11 in Surrey.

The cases of small-pox were notified from the following 18 counties:—London, 1; Derby, 14; Durham, 24; Essex, 1 (East Ham); Gloucester, 2 (Bristol); Lancaster, 7; Northampton, 10 (Northampton); Northumberland, 4; Nottingham, 3; Soke of Peterborough, 1; Stafford, 10 (Walsall); Warwick, 6 (Coventry); Yorks, East Riding, 4 (Hull); North Riding, 1 (Middlesbrough); West Riding, 30 (Goole 8, Pontefract 9); City of York, 1; Glamorgan, 9; Monmouth, 13.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on August 28th–29th was as follows:—Small-pox under treatment, 12; scarlet fever, 1495; diphtheria, 1499; enteric fever, 122; measles, 137; whooping-cough, 255; puerperal fever, 13 (plus 6 babies); encephalitis lethargica, 71; polio-myelitis, 2; "other diseases," 18. At St. Margaret's Hospital there were 18 babies (plus 8 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 5 (0) from enteric fever, 10 (0) from measles, 1 (1) from scarlet fever, 30 (5) from whooping-cough, 20 (1) from diphtheria, 89 (28) from diarrhœa and enteritis under two years, and 18 (4) from influenza. The figures in parentheses are those for London itself.

The fatal cases of enteric fever outside London were reported from Southampton, Coventry, Tynemouth, Newport, and Cardiff. Of the 10 fatal cases of measles 4 were reported from Liverpool, and in the same week 5 from Belfast. Of the 25 fatal cases of whooping-cough outside London 4 were reported from Birmingham and 2 each from Manchester, Preston, Bradford, Doncaster, Middlesbrough, and Sunderland, while Glasgow reported 5 that week. Of deaths from diarrhœa Liverpool reported 9, Hull 5, and Nottingham 4, while Glasgow and Dublin reported 6 each.

The number of stillbirths registered during the week was 244 in the great towns (corresponding to a rate of 37 per 1000 births), including 49 in London.

EXTENSION OF ST. BARTHOLOMEW'S HOSPITAL.—The annual report of the treasurer, Lord Stanmore, records the expenditure of over £60,000 upon the purchase of contiguous sites and premises which may eventually be needed for extensions. The new surgical ward block and operating theatres are in course of construction at a cost of £177,000, of which £85,000 has been received or promised. On recreation rooms for the nursing staff £13,000 is being spent. The income of the hospital last year was £194,948, of which £36,000 was derived from receipts on account of patients; the expenditure was £196,000, an increase of £14,000 over the preceding year. On the average in-patients stayed 21 days and cost £15 8s. 2d. each. The new out-patients numbered 75,000 and cost 13s. 6d. each. The nursing staff numbers 330.

At *Severalls* there were 1730 patients under treatment at the end of the year. The death-rate was 7·52 per cent. and the recovery-rate 23·2 per cent. The general health was good except for a few cases of typhoid. Search is being made for carriers. A useful annexe has been opened for acute cases and the home for night nurses is nearly ready. An infirmary ward and a verandah are being built. The handicraft instructress has done good work and both patients and nurses have benefited from gymnastic classes. There are now 113 certificated nurses, but far too many of the women are untrained and inexperienced.

Of the two *Kent County Mental Hospitals*, that at *Barming Heath* housed 1853 patients at the end of the year. The new Nurses' Home has added 157 beds to the hospital accommodation as well as realising a long-cherished ideal concerning the better training and education of the staff. Since 1911 it has been compulsory for nurses to obtain a certificate, and every effort is made to attract the well-educated girl. The recovery-rate of 36·1 per cent. was above the average; the high death-rate of 8·7 per cent. was caused by a severe outbreak of influenza in the spring. Pneumonia accounted for a quarter of the deaths, and general paralysis for one-tenth. Post-mortem examinations were made in 94·4 per cent. of cases. The hospital has been free from dysentery and enteric for two years. The new cinema is much appreciated by the patients. The Visiting Commissioners advise the installation of X and violet rays and the provision of clinical rooms. Much occupational work is carried out in the wards, as well as on the farm and in the shops and laundry. In each large "chronic" ward a room is set aside for difficult patients, and they are encouraged to occupy themselves with some simple handicraft. On the male side 68·5 per cent. are usefully employed, and the shops are becoming overcrowded.

At *Chartham Downs* there were 1275 patients, and it is foreseen that the hospital will be over-full in a few years' time. The new clinical laboratory and the X ray plant are proving valuable additions, but at present there is no operating theatre and no specialists attend regularly. Twenty-four per cent. of the patients admitted were regarded as hopeless cases. The death-rate was 8 per cent. and the recovery-rate 29 per cent. Twenty patients are suffering from tuberculosis, but half of them had the disease before admission. Verandah accommodation is much needed. One clinical room has been arranged and others are to be provided. Twenty-four patients were allowed out on trial, and parole is granted beyond the estate to 46 patients and within it to 88; only nine of the privileged are women. One female and two male wards are conducted on the open-door system. Thirty-four men and 22 women nurses are certificated or registered.

Institutions for Private Patients.

There were 173 patients at *James Murray's Royal Asylum, Perth*, on March 31st last. Forty-two of the 66 new patients admitted during the year came a part of their names, is to return to the pathological outlook of a century ago. Other omissions are the absence of reference to the treatment of epilepsy by a ketogenic diet, to encephalitis periaxialis diffusa, and post-vaccinal encephalitis, while progressive lenticular degeneration receives an inadequate 25 lines in a chapter on topical diagnosis. Those who recall the constant care of the late Sir William Osler that each successive edition of his own text-book should contain the most recent additions to medical knowledge will regret that his name should be associated with a book which fails so signally in this respect.

Pathology of the Nervous System.

Nouveau Traité de Médecine. Fasc. XVIII. Pathologie du système nerveux; sémiologie générale. By Various Authors. Paris: Masson et Cie. 1928. Pp. 812. Fr.85.

The present volume of the elaborate Treatise of Medicine appearing under the editorship of Prof. G. H. Roger, Prof. F. Widal, and Prof. P. J. Teissier contains a number of articles on the general symptomatology of the nervous system, from the pen of a series of distinguished French and foreign neurologists. Three of the authors—Prof. Karl Petren, Madame Dejerine, Dr. Charles Foix—have not lived to see their contributions in print. Taken as a whole, the volume adheres to the accepted doctrines of the French school of neurology, and in some respects, we consider, is not so up to date as it might be. The article on apraxia (Dr. J. Lévy-Valensi) repeats the rather artificial distinctions of Liepmann, based on the no less artificial generalisations of Wernicke. That on the aphasias, by the late Charles Foix, opens with the fear that to understand aphasia completely passes our ordinary comprehension and powers, and that in spite of its progress neurology will never attain the desired end. It may be so, but at least with the help of psychology some advance on the present situation can be expected; yet the article in question follows the clinico-pathological method too slavishly to be of outstanding value. The sections on the pathology of sleep are regrettably brief and frankly insufficient; as far as we have observed the word narcolepsy is not mentioned. Whether the psychopathologist of to-day will be impressed with the chapters on "Les Grands Syndromes Psychiatriques" may be doubted; they take little cognisance of the developments of modern psychopathology on the basis of psychological analysis, and, being almost entirely descriptive, are unsatisfactory from the viewpoint of ætiology and pathogenesis.

Such criticisms, it may willingly be conceded, do ot detract materially from the many excellences of ie book; the long articles on disorders of motility, sensibility, and in the domain of the reflexes, are a high standard. The chapter on the cerebro-inal fluid, by Prof. J. A. Sicard, is, as might be -pected, admirable.

The Extra-Ocular Muscles.

A Clinical Study of Normal and Abnormal Ocular Motility. By Luther C. Peter, A.M., M.D., Sc.D., Professor of Ophthalmology of the Medical Department of Temple University, &c. London: Henry Kimpton. With 98 engravings and 5 coloured plates. 1928. Pp. 294. 18*s*.

After giving a full account of the anatomy and physiology of the external eye muscles and of binocular vision, Prof. Peter devotes fully one-quarter of this book to heterophoria, a subject which American oculists have made peculiarly their own. Elsewhere the importance of any considerable want of balance between the vertically moving muscles is well recognised, but it is generally thought that lateral errors require treatment comparatively rarely. By far the commonest lateral error is exophoria, of which Dr. Peter says: "There are few patients who will not experience discomfort with more than two diopters (prism-diopters) for distance and more than three diopters at the near-point." The treatment he advocates consists mainly in prism training by means of rectagonal prisms held before the eyes base out. The training is continued at home with increasingly strong prisms until the patient is able to overcome the displacement produced by a prism of 70 diopters base out, a faculty which can only be attained after much practice. In esophoria, on the other hand, the author's experience is that prism training is disappointing." Nor is much good likely to come of ordering prisms, base out, for constant wear. When the patient is hyperopic, the main reliance must be placed on the correction of the refraction to as complete a degree as the patient will tolerate. Cyclophoria is usually connected with oblique astigmatism, and the accurate correction of this by glasses will in most cases abolish it. The rest of the book deals with concomitant squint, paralytic squint, and nystagmus. For training the fusion faculty the Worth amblyoscope is used either as a preliminary to operation or when possible without it. The author disagrees with those who wait until the child is 12 years old and operate under a local anæsthetic. He advocates early operation under a general anæsthetic when necessary.

There is little or nothing in the work about the details of surgical technique, but in other respects this book gives a good account of the causation and treatment of squint and its allied conditions.

The Early Diagnosis of the Acute Abdomen.

Fifth edition. By Zachary Cope, B.A., M.D., M.S., F.R.C.S., Surgeon to St. Mary's Hospital and to the Bolingbroke Hospital. London: Humphrey Milford, Oxford University Press. 1928. Pp. 244. 10*s*. 6*d*.

The successful treatment of acute abdominal disease depends more than anything else upon early diagnosis. Mr. Cope's book places in the hands of the busy practitioner the means to acquire easily such knowledge as will enable him to distinguish abdominal complaints demanding surgical remedi Five editions within seven years can only mean th the author has supplied a real need. The descriptio of diseases and methods are vivid, terse, and simple emphasis is laid upon essentials which stand ou clearly in the mental picture aroused in the reader' mind. Minor revisions in each edition have adde to the value of a book which is likely to remain as popular as it always has been.

A Manual of Physics.

Third edition, enlarged. By Hugh C. H. Candy, B.A., B.Sc., F.I.C., Lecturer on Chemistry at the London Hospital Medical College; late Arnott Professor of Natural Philosophy in Queen's College, London. London, Toronto, Melbourne and Sydney: Cassell and Company, Ltd. 1928. Pp. 487. 7*s*. 6*d*.

The author's Manual of Physics first appeared in 1911 and has been used by a large number of medical students since then. In its third edition it bec rather bigger volume and well covers the required for any pre-medical examination in subject. The author, in view of the introducti the subject of the kinetic theory of gases int syllabus of the Conjoint Board, has given account of this theory. Most medical students find this theory difficult to grasp, and we trust examiners will not really expect candidates to mastered its details.

The subject matter in the book is clearly sented and the illustrations are well selected. colour plate of spectra as the frontispiece shou prove a valuable map of reference to the medic student in his later studies.

Reviews and Notices of Books.

PHYSICAL DIAGNOSIS.

By CHARLES PHILLIPS EMERSON, A.B., M.D., Professor of Medicine, Indiana University School of Medicine. London: J. B. Lippincott Company. 1928. Pp. 553. 35*s.*

IT has always been difficult for authors to define the scope of the term which Prof. Emerson has chosen as the title of this volume. It is continually dinned into our ears that our fathers before us made their diagnoses without the adventitious aids which we now possess, but those who sing the previous glories of a golden age of medicine forget that the assistance of such aids has always been sought when available; at one period horoscopes were all the rage and the position of the planets more important than that of the fragments of a broken limb; the stethoscope was once regarded as a deplorable innovation, likely to destroy all the finesse of diagnosis. The stethoscope, the ophthalmoscope, and even the sphygmanometer have now been generally accepted as clinical aids; there still remain those who regard a microscope or a test-tube with suspicion.

Prof. Emerson is not in this group, but in his preface he does make a valiant effort to separate "physical" diagnosis from the other sort, whatever that may be. The effort has been made before and will be made many times again, but the result can never be quite satisfactory. The diagnostician will make use of such methods as he considers likely to assist him to his goal. These may comprise the exercise of palpation, the use of a thunder-box, the examination of a blood film, or the casting of a horoscope. Any of them may be supposed to constitute aids to diagnosis; but the art remains obstinately indivisible, and efforts to split it by definition are never satisfactory, since assistance which is scorned to-day may be recognised to-morrow as indispensable. Yet Prof. Emerson has produced a book both valuable and important, larger than most works of its kind, and packed with sound and interesting information. It is doubtful if "Ellis's S-shaped curve of dulness" ever afforded much information not available by the use of an exploring needle, and even Grocco's triangle is usually identified after the diagnosis has been established. But the author is an instructive guide, with a keen historical sense, and an ardent desire to impart information as to early diagnostic technique. It is good for a medical man of this generation to understand the steps by which the methods he uses daily at the bedside were developed, and to contemplate the difficulties which faced his forebears, though it may lead him to be thankful that he has no need to rely solely on his own powers of observation, and can call in help not available to them.

The illustrations are excellent, those in the section on the skin almost constitute an atlas of diseases of the integument, and the diagrams are clear and instructive. The book deserves a wide popularity among students and medical practitioners alike.

A TEXT-BOOK OF GYNÆCOLOGY.

By JAMES YOUNG, D.S.O., M.D., F.R.C.S.(E.), Physician, Royal Maternity Hospital; Assistant Gynæcologist, Royal Infirmary, Edinburgh. London: A. and C. Black. 1928. Pp. 338. 15*s.*

THE second edition of this text-book has been completely revised and alterations made to bring it into line with recent discovery. The section on the ovary and the relation of its cyclic changes to menstruation has been rewritten. The exposition of this part of the subject is now thoroughly up to date and is the best with which we are acquainted in any of the smaller text-books, as might be expected from an author whose own contributions to the physiology of menstruation have been so noteworthy. A brief section on endometrioma has been added, though a clearer account of the work of J. A. Sampson would probably have added to its value. Perhaps the author will consider whether, in a future edition, the chapter on "endometritis" should not be considerably modified so as to bring it into line with the most recent views. Chronic metritis is described as synonymous with "fibrosis uteri," and although if this change were present it would be adequate to explain the chief symptom from which the patient suffers, it does not represent the true pathology in the majority of cases. Myomectomy and hysterectomy are the only alternatives recommended for fibroids that have undergone necrobiosis during pregnancy, whereas experience shows that with expectant treatment most of these cases settle down and go on to term. The final short chapter on minor gynæcological procedures is a most useful one, for it gives a concise account of such procedures as vaginal douching, application of tampons, upon which the student is apt to have rather hazy ideas. This book can be thoroughly recommended to the practitioner and to the student preparing for his final examinations. It gives clearly what he wants to know, with the minimum of unnecessary detail.

MODERN MEDICINE, ITS THEORY AND PRACTICE.

Edited by Sir WM. OSLER, M.D., F.R.S., THOMAS MCCRAE, M.D., and ELMER H. FUNK. Vol. VI. Diseases of the Nervous System—Diseases and Abnormalities of the Mind. Third edition. London: Henry Kimpton. 1928. Pp. 964. £12 12*s.* per set.

SOME unevenness is to be expected in a work containing contributions by a number of authors, but it is exceptional to find in a text-book of the standing of Osler and McCrae's Modern Medicine such grave inadequacies and inaccuracies as are present in its sixth volume, that on diseases of the nervous system, of which the third edition has just been published. Some of the articles in this, at once be it said, are unexceptionable. It would be an impertinence to praise Dr. Harvey Cushing's contributions on "Cerebral Tumour" and "Hydrocephalus"; the editors may be congratulated on having induced Dr. Cushing to put his unique experience within easy reach of the general practitioner and the medical student. The articles by Dr. Gordon Holmes, Sir Farquhar Buzzard, and Dr. C. P. Symonds leave nothing to be desired. But, at the other extreme, we cannot but condemn an article on subacute combined degeneration of the spinal cord in which the statement is made that "the blood changes so commonly found in these cases are more often of the nature of a secondary anæmia than of the pernicious variety," in which gastric achylia receives no mention, and nothing is said concerning treatment by the administration of acids or a liver diet? The section on intracranial aneurysms is an abstract of an article on this subject by Beadles, published in 1907. It contains no reference to more recent work, no mention of the congenital or embolic origin of such aneurysms, and no adequate account of the clinical picture which follows leakage of blood from the aneurysmal sac. The writer who deals with trigeminal neuralgia has clearly no personal experience of treating these cases by alcoholic injection of the Gasserian ganglion, or so at least it is to be hoped, for he states that after the first injection two or three more are given within a week to complete the treatment, and that following the injection the pain is relieved in "three or four hours." No description of the technique of these injections is given. There is unconscious humour in the mis-statement that tennis elbow is an occupation neurosis, and in the quaint juxtaposition in one chapter of astasia-abasia and adiposis dolorosa. The inclusion in one chapter, under the title Scleroses of the Brain, of disseminated sclerosis, pseudo-sclerosis, and tuberous sclerosis, three conditions which have nothing in common but

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 8, 1928.

SCIENCE AND CRAFTSMANSHIP.

In reflecting on the miserable conditions under which our primitive ancestors must have survived William James has remarked somewhere that it is characteristic of man that he prefers life on any terms to no life at all. It is equally characteristic that he makes every effort to improve his circumstances, and if by "craftsmanship" we mean the skill which is exercised in the production of whatever is wanted for human welfare, then craftsmanship represents in a summary way man's effort to live. Such is the meaning which Sir William Bragg puts on the word in his presidential address delivered before the ninety-eighth meeting of the British Association for the Advancement of Science, which was opened at Glasgow on Wednesday, Sept. 5th. Prof. Bragg has charmed many audiences at the Royal Institution with his explanations of and commentaries on the intimate relation between modern scientific knowledge and the empirical practice of old artificers, and the burden of his present discourse is that scientific training and scientific method provide the craftsmanship of modern industry. There is a cult which exalts the beautiful and efficient implement made long ago by hand, singly and painfully, to a level which is wholly denied to the products of the machine tools and factories of to-day—a cult which often misleads itself by thinking that the average excellence of past production is fairly represented by the examples of old work which owing to their exceptional quality have survived for us to see and use.

With such a point of view the President of the British Association has very little sympathy; he sees that the mass conditions of to-day demand for success just that same combination of imagination, intelligence, and manipulative skill which was needed when man was groping his way through the early stages of the development of what Samuel Butler so aptly calls detachable limbs. Conditions have changed because what is knowable has outgrown the capacity of one human mind to know, and specialisation has come in with, as always, some tendency to disintegration. The intelligence and imagination of modern production are now largely derived from those who pursue natural knowledge, and progress in invention depends on the progress of science and the degree to which use is made of its discoveries in the practical world. Leonardo or Réaumur are impossible to-day, but there is no reason why science and technology should not achieve equal triumphs if they can coöperate with such free friendliness as takes no count of status or credit, if only the common good is achieved. Empiricism is not the prerogative of technology, nor coherent knowledge of natural science. The wave theory of light is good because, in some relations, it works; the electrical theory is also good because it also, in other relations, works. And no one so far has had the wit to see how the two theories may be reconciled. That such a state of affairs should prevail in the branch of natural knowledge which has made the most notable progress in the last 50 years testifies alike to the common humanity of science and to the field which it offers for intellectual adventure. In its applications to industry the opportunities for adventure are no less. "Thou shalt love the Lord thy God with all thy heart and with all thy soul and with all thy strength" means to the student of science that he is to put all he is into his work, knowing that every attempt to understand the world he lives in is worth while. And if he writes up, "Sirs, ye are brethren" as well, he will help his fellows all the better.

◆

THE LATE RESULTS OF BREAST SURGERY.

Now that operation as the method of choice in treating cancer of the breast is being seriously challenged by the supporters of radium therapy, Dr. Janet Lane-Claypon's survey[1] of the late results of various kinds of operation for growths at different stages is opportune. She has here freed the literature of breast surgery from the reproach, exposed by her previous analysis (No. 33 of the same series of grey books), that most of the statistics published are based on a follow-up after operation of only three years, which period she found to be the average duration of life in untreated cases. Surgeons will be gratified, if hardly surprised, to learn that on the whole the impressions derived from short periods of observation are confirmed; the lasting success of the Halsted technique or one of its modifications depends almost entirely on the stage of disease at which it is performed. The basis adopted by Dr. Lane-Claypon for calculating results is that of the net survival rate—that is, the proportion of survivors to those operated upon, after deducting entirely from the sample those not traced and also those certified as having died from causes other than cancer. Early cases, where the primary growth was undoubtedly malignant but microscopical examination showed no invasion of cancer glands (Group IP.) show the remarkably high survival-rate, ten years after operation, of 73·3 per cent. This rate includes *partial* operations, and rises to 77·2 if only those cases submitted to radical operation are included. In many other respects — such as the mean lowered fertility in the history, delay in seeking treatment, and the good functional results after removal of the pectoral muscles—the commonly accepted teaching is also confirmed. It is profitable, however, to examine this exhaustive study in order to ascertain in what respects the conclusions reached differ from those generally held. The lessons that the clinician may learn through the massed results from eight important county boroughs are noteworthy.

Broadly speaking, it seems that the clinical criteria of malignancy of a primary growth are reliable and need no revision. At least this is the deduction to be drawn from the direct evidence afforded by 364 cases where the diagnosis was not confirmed by a pathological report on the primary growth. The results following operation on these cases have been considered separately and have been if anything slightly worse than those of the confirmed cases. Indirect evidence, on which Dr. Lane-Claypon lays considerable stress in a closely written argument (Chapter 13), is less flattering to the clinician. Among the total number of cases in the survey there were 380 in which the malignancy of the primary growth was established histologically, though neither pathologist nor clinician could find any trace of invasion of the axillary glands; 370 of these were classified

---

[1] Reports on Medical Subjects, No. 51. Report on the Late Results of Operation for Cancer of the Breast, being an Analysis of 2006 Cases occurring in the Practice of the General Hospitals of Eight County Boroughs of England and Wales during the period 1910–1921. London, 1928, Ministry of Health, H.M. Stationery Office. Pp. 143. 3s.

A WEST INDIAN PEPPER-POT.

By T. R. ST.-JOHNSTON. With coloured illustrations by EVA WILKIN. London: Philip Allan and Co. 1928. Pp. 209. 10*s.* 6*d.*

THE Colonial Secretary introduces Colonel St.-Johnston's new book to the public, pointing out that slowly, but steadily, after long years of seclusion and stagnation, the West Indies are returning into the Imperial picture. Mr. Amery, therefore, holds that anything which tells us of the life of the general community in the West Indies is to-day worthy of attention. Colonel St.-Johnston, as the Administrator of St. Kitts-Nevis, is able to write from first-hand experience. And this experience he uses with skill and humour in 13 "Quashie" stories, "Quashie" being a sort of generic slang term for the West Indian peasant, as "Taffy" is for a Welshman, or "Pat" for an Irishman. Some of the stories are sensational, some are mystical, and some are both, and all help to set before us, as they are, an agricultural people in districts where agriculture reigns supreme, and where the Christy Minstrel type is non-existent. The illustrations are bold examples of modern colour-printing, and convey well the spirit and the messages of the stories.

MEDICAL VIGNETTES.

By T. F. DEWAR, C.B., M.D., D.Sc. Glasgow: Alex Macdougall. 1928. Pp. 73.

DR. DEWAR has republished a series of sketches first issued in the *Caledonian Medical Journal* and, in one instance, in *Chambers's Journal.* They are all well written, and many of the incidents form the right material from which to construct an episodal note or story. If this may be said especially of those which tell of occurrences during the war, the other vignettes have for the most part a message which was worth delivering—some medical lesson, perhaps of large significance, illustrated by a small every-day happening.

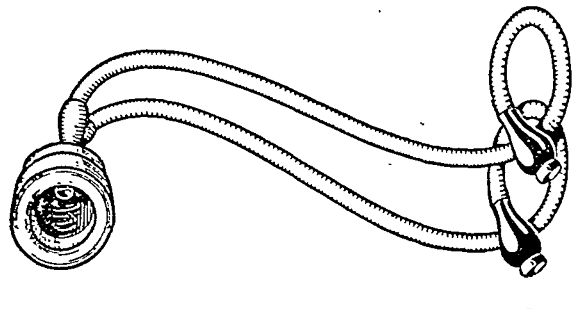
JOURNALS.

ANNALES DE MÉDECINE.—The June number is devoted to neurology under the direction of Prof. Guillain. The first article is a lecture given at the Salpêtrière by Dr. A. F. Hurst on Subacute Combined Degeneration of the Spinal Cord and its Relation to Pernicious Anæmia. Even though at the onset of the spinal symptoms no anæmia may be present, nevertheless the red blood cells show the increase in their average size which is characteristic of pernicious anæmia, and gastric achlorhydria is always present. Achlorhydria is the most important ætiological factor, since, in the absence of free HCl in the stomach, streptococci gain entrance to the bowel, and hence their toxins gain access to the blood and nervous system. Subacute combined degeneration is usually a consequence of a constitutional achlorhydria, but has also resulted from that of gastric carcinoma and of chronic alcoholic gastritis. Liver treatment, though it cures the anæmia, has, by itself, no influence on the progress of the spinal disease.—In the next article Guillain, Alajouanine, Bertrand, and Garcin describe a case of acute myelitis with optic neuritis. One of its peculiarities was the occurrence of a focus of degeneration in the sub-thalamic region, and this manifested itself clinically by frequent tonic crises resembling tetany, affecting the limbs of the opposite side to the lesion. In the eight months of its duration the illness showed several remissions and exacerbations; the first attack caused spastic symptoms and severe pains; the second, a month later, gave rise to the tonic fits; the third, three months later, left the patient blind; and the fourth, a few weeks afterwards, produced a state of flaccid paralysis and led up to the fatal termination. Detailed examination of the nervous system after death showed extensive foci of acute necrosis in the spinal cord, a focus in the subthalamic region, and another in the optic chiasma. The ætiological relationships of the disease are discussed.—Guillain and Thevenard, in a subsequent article, on the subject of Extracortical Jacksonian Epilepsy, describe four cases with typical Jacksonian attacks in which no lesion of the cerebral cortex at the site indicated by the attacks was found at operation or post-mortem. They associate these cases with those described by Spiller as subcortical epilepsy.—Guillain and Garcin contribute an important article dealing with the syndrome of paralysis of all the cranial nerves of one side; this is always due to sarcoma of the base of the skull and yet there are no signs of increased intracranial pressure nor of invasion of the brain by the growth. Three personally observed cases and one from the literature are given. The lesser syndromes resulting from injuries of groups of cranial nerves at their various foramina of exit from the skull are also briefly discussed.—Guillain and Alajouanine, in the next article, draw attention to the occasional occurrence of somnolence as a symptom of desseminated sclerosis; it always occurs in an acute phase of the disease, and may give rise to difficulty in the differential diagnosis from encephalitis lethargica.—In the last article Bertrand and Hadzigeorgiou describe their technique for using infra-red rays in the microscopic study of the nervous system; photographs are taken on specially sensitised plates and must be developed in complete darkness. The effect of the long wave-length of the infra-red region is that there is little dispersion by the particles of the tissue and the power of penetration is consequently very great; refraction is practically avoided by cutting out all waves less than approximately 700 λ. Neuroglial elements and the intracellular structure of ganglion cells are remarkably well revealed by this method of examination.

New Inventions.

AN IMPROVED STETHOSCOPE.

WE have contrived and been using for some time an instrument which combines the handiness of the pocket phonendoscope with the clear transmission of the wooden stick stethoscope. As is shown in the illustration, the ear pieces are separate and made to twist well into the ears where they remain firmly in place. The chest piece is of light composition, very durable, and causes no such pull on the ears as does the usual heavy phonendoscope. The lumen of the transmitting tube is constant throughout, and by tapering at the joints between the tube and the chest and ear pieces all dead space for "backwash" is eliminated. The chest piece is protected by a rubber cap to ensure comfort for the patient and added clearness for the transmission. The essential distinctiveness of the instrument is its exceptional conduction and handiness for carrying about. It has the additional advantage of selling at a moderate price.



The stethoscope is made by Messrs. R. Sumner and Co., Ltd., 40, Hanover-street, Liverpool.

J. KILPATRICK REID, M.B., Ch.B. Liverp.
W. OWEN MORRIS, M.B., Ch.B. Edin.

In a statistical study of the efficacy of artificial pneumothorax (A.P.) treatment, E. RIST and F. HIRSCHBERG[1] have endeavoured to ascertain the percentage of cures in a series of cases treated at the Laënnec Hospital by comparing the after-history of patients so treated with that of others who did not submit to a similar course. The authors point out that the ideal method would have been to select a series of patients suffering from the same type of disease, to treat half the cases with A.P., and to deny this treatment to the remainder. Humane considerations made this impossible. It was, however, possible to divide a series of patients into two classes, those willing to receive A.P. treatment and those unwilling or unable to do so. The classes were not strictly comparable. Many of those who refused the treatment were probably persons of low intelligence or lacking in determination. for whom the prognosis is usually unfavourable. In others the presence of adhesions which rendered treatment impossible may have indicated some difference in the type of disease. In the main, however, a fair comparison can be made between the two groups.

The patients selected by the investigators for the study were suffering from unilateral disease, tubercle bacilli were constantly present in the expectoration, and in each at least half a lobe was shown by radiogram to be affected. 759 in number, they included all cases of this type treated between 1912 and 1926. The controls were 463 patients who did not receive A.P. treatment, either because adhesions prevented collapse of the lung or because such treatment was refused. At the end of the period under review 52 per cent. of the treated patients were " clinically healed," free from symptoms, no longer expectorating tubercle bacilli, and able to lead a more or less normal life; 32 per cent. were dead, and the remainder either unbenefited or worse. Approximately 54 per cent. of the controls had died. If the number of patients exhibiting signs of progressive disease be added to the deaths, the advantage of the treated cases is still more apparent, as the percentage for the former is 44 while for the latter it is 82. It is noteworthy that while many of the clinically healed group were able to work, and all had ceased to expectorate tubercle bacilli, none of those who had refused treatment was fit for employment, and most in this group were still infectious. As this first study included patients who had only recently commenced treatment, the ultimate result of which could not be known, a further investigation was carried out on a group of cases first seen between July 1st, 1919, and July 1st, 1921. A period of seven years is thus available for review. The figures obtained again demonstrate the great value of collapse therapy. The percentage of the controls who were dead by the eighth year is 90, thus being more than twice as high as the figure for the treated cases. At this time 35·8 per cent. of the treated cases were classed as healed. None of the untreated cases had recovered and none was capable of work. Among the treated cases nearly 50 per cent. of the deaths occurred in the first two years following induction. After this period the mortality-rate fell, and no deaths were recorded after the fifth year had passed.

Drs. RIST and HIRSCHBERG consider that the word " cure " should not be allowed until three years have passed during which there has been complete freedom from symptoms and an absence of tubercle bacilli from the sputum. At this stage the question of abandoning the refills may be considered. After the fifth year the danger of relapse is small, and in many cases it is desirable to maintain pulmonary collapse till the completion of five years after induction. The female mortality among both the treated and the untreated cases greatly exceeded that of the males. Thus in the first year of treatment a female mortality of 26·8 per cent. was contrasted with a male mortality of 6·3 per cent. They attribute this special susceptibility of women to an inferior power of resistance, the result of the legal and economic inferiority of women which is still maintained in France by legal enactments and social institutions. The ages of the patients are not given, but from the type of cases selected for treatment it seems possible that the majority belonged to the early adult group. A high female mortality-rate is characteristic of this group in countries where women enjoy equal legal and social advantages with men. Unfortunately, nature cares nothing for sexual equality, and it is probable that physiological rather than social disabilities account for the more disastrous effect of tuberculosis among women in the earlier years of adult life.

Annotations.

"Ne quid nimis."

THE VITAL RECORD OF ENGLAND IN 1927.

WE gave in our last issue (p. 459) some of the outstanding figures of general and specific death-rates in England and Wales for 1927, as set out in Part I. (Medical Tables) of the Registrar-General's Review for that year. While awaiting the Text of this Review, which may be many months in coming, it is possible to make some comparisons of 1927 with the experience of previous years. The lowering of the birth-rate and of the rate of infant mortality have already been noted. As is well known, the lowered birth-rate is producing an altered distribution of the population according to age which ere long must lead (*ceteris paribus*) to a stationary or to an increasing crude death-rate at all ages, and it is not surprising, therefore, to find that this rate, which at all ages averages 15·4 in 1901–10 and 12·2 in 1921–25, has only declined to 11·6 in 1926 and 12·3 in 1927. This is the case, notwithstanding the fact that in successive periods of life, right up to 75, the death-rate per 100, living at each age was lower in 1927 than in 1906–10. The Review enables each medical officer of health to ascertain his official position in regard to infant mortality as compared with that in other sanitary districts. We have once more to draw attention to the contrast in respect of death-rate in infants under 4 weeks of age in different parts of the country. In London during 1927 the death-rate during these four weeks was 24·4 per 1000 births, but it was 34·5 in the aggregate of all county boroughs. A study of detailed causes of death, as stated in the tables of the Review, gives some imperfect idea of the extent to which this mortality was preventable in character. The excessive mortality occurred chiefly in the North of England and in Wales; nor in these more rugged regions was it confined to the large centres of the population, but characterised also their rural areas. Table XIII. in the Review makes a more detailed comparison possible. Thus, comparing county-boroughs with each other, the following extremes are noteworthy. At ages under 4 weeks the death-rate in Blackpool, Newcastle, and Sheffield was 40, in South Shields it was 42, in Dudley, Swansea, and Huddersfield 44, in Gateshead 46, in Oldham and in Preston 47, and in Burnley 49, while in Bath, out of every 1000 born alive, the number lost under 4 weeks only numbered 20, in Bootle 25, in Brighton and Croydon 26, and in Eastbourne only 17. The possibilities of preventive medicine for this early period of infancy are far from exhausted.

Table VI., comparing the incidence during a long series of years of the death-rate from the chief infectious and general diseases, is always of great interest. It is noteworthy that the death-rate from total tuberculosis for two years in succession has been well below 1 per 1000 of population, and there is no indication that the limits of decline—if they exist—are being approached. Encephalitis lethargica unfortunately maintains its place in the list of causes of death; and it is not without interest to compare its magnitude with that of enteric fever which no longer in a table according to the operation performed, nine being discarded because the exact technique used was not recorded, and one for no stated reason. The five operating methods used were: 1 (244 cases), radical operation; 2 (45 cases), two operations—that is, removal of tumour or breast for pathological report, followed by radical operation at a later date; 3 (28 cases), removal of the breast, together with such of the axillary contents as could be taken without removing the pectorals; 4 (18 cases), amputation of breast only; 5 (35 cases), removal of tumour only. Dr. Lane-Claypon gives her reasons for considering that where methods 2, 4, and 5 were chosen—that is, in 98 cases—there must have been an original error in clinical diagnosis. In none of them is there a note of either a preliminary incision or a frozen section, and in several instances the first operation was performed in the out-patient department or by the patient's own doctor. From these and other considerations she assumes that the practitioners were reasonably satisfied as to the innocence of the growth. In one of the 45 cases where method 2 was used, duct papilloma had in fact been recorded, in another chronic mastitis, while 11, diagnosed as suffering from cysts, had in fact cysts, with small foci of cancer cells in the wall or in an intracystic papilloma. Incidentally, these cases provide instructive examples of the different microscopical appearance to be found in different parts of the same breast, to which Sir Lenthal Cheatle has drawn attention, and support his contention that a pathological report confined to the obvious tumour may be highly misleading. Statistically, the method of two operations gives results nearly as good as does radical operation at one sitting, but since a second operation is sometimes refused and much distress of mind often occasioned, it is recommended that in all cases tumours should be removed under such conditions that the surgeon can proceed at once to the larger operation if he thinks it desirable. Leaving for the moment consideration of method 3, we note that pathological reports on the 53 cases in which methods 4 and 5 were used indicate that the growth was very early. In 20 of them the clinical diagnosis was definitely that of an innocent condition, and it may be assumed that no surgeon would do such a very limited operation in the face of a suspicion of cancer. The data supplied in this report does not show the converse side of the picture—how many persons have had a radical operation for a benign growth. This may be relatively unimportant to those chiefly concerned with the public health, but the practitioner considering drastic operation for a doubtful tumour might pertinently ask the question. An educated patient who has been persuaded to have breast and pectoral muscles removed may await the pathologist's report with keen apprehension, but her relief when she hears that her tumour was a benign growth may well react on her faith in her medical adviser, especially if hers is one of the rare cases where the functional results are indifferent. It is possible, too, that when women are trained to report any swelling of the breast to their doctors immediately they notice it, the difficulty of clinical diagnosis will be greatly enhanced since the chief criteria of malignancy with which every student is familiar may not be apparent in really early cases. This is a bogy that need not yet cause alarm, for, unfortunately, the doctor rarely sees the disease at its inception, and the malignant nature of a primary growth is probably diagnosed more successfully in the breast than in any other situation.

---

[1] Paris Médical, 1928, i., 17.

The clinical estimation of the invasion of axillary glands is, apparently, far less satisfactory, and it is obvious that at an early stage of invasion these glands are not palpable. In Chapter 6 of her report Dr. Lane-Claypon shows that while positive findings are for the most part confirmed by histological examination, palpation is quite unreliable as a method of assessing the condition of these glands. Of the 169 cases in which examination at the bedside gave negative results, 90—or 53 per cent.—were incorrect. The import of this grave error is best seen in regard to the selection of operation. The third method in Dr. Lane-Claypon's list consists of removal of the breast together with such of the axillary contents as can be taken without removing the pectorals, and has evidently been chosen by the surgeon in the mistaken hope of saving from the radical operation those patients in whom the axillary glands are deemed to be normal. The fate of patients operated on by this method is, as Dr. Lane-Claypon puts it, surprising and very deplorable, being much worse than that of those in whom either breast or tumour only was removed. The survival-rate after method 3 in the group of cases showing no clinical evidence of invaded axillary glands is lower at all periods after operation even than the rate of the advanced group where the glands were definitely palpable. There is, moreover, reason to believe that the cases operated on by method 3, far from being advanced, were considered to be so doubtfully malignant as to be suitable for a conservative operation. The conclusion reached is that the terrible results are due to the rapid spread of the growth following incision into axillary tissue which contained undetected cancer cells, and that this operation should never be performed. Evidence that clinical palpation of the axillary glands is not reliable has another bearing not mentioned in the report. Some surgeons of the younger school are inclined to despair of the possibility of eradicating the disease if the axillary glands are already palpable, and are inclined to remove the breast only as a palliative measure. We call their attention to the fact that positive results of axillary palpation, though more accurate than negative ones, are too pessimistic in 17 per cent. of cases, and that the survival-rate after ten years, even of the group where glands are easily palpable, is by no means negligible if radical operation is performed.

◆

COLLAPSE-THERAPY IN PULMONARY TUBERCLE.

Nearly half a century has elapsed since the first tentative experiments in collapse therapy were made, but it is only in the last 25 years that the method has been generally employed. In that period the treatment of pulmonary tuberculosis by artificial pneumothorax has saved more lives than all the other methods of treatment added together. By its means those who would formerly have been regarded as incurable have regained health, and the dying have been restored to life. Time, which has seen the rising and setting of innumerable "cures," has only established more firmly the value of pneumothorax. Unhappily, only a minority of the afflicted can benefit by this method of treatment. Those suffering from bilateral disease may obtain a measure of relief from artificial pneumothorax, but in their case only temporary benefit can, as a rule, be expected, while probably more than half of the unilateral cases are unsuitable on account of adhesions which bind the lung to the chest wall and prevent efficient collapse. The greatest triumphs of collapse therapy have been obtained in the case of patients in whom the disease is limited to one lung and in whom the pleura is free. If these conditions are present, complete and lasting cure may be anticipated in a proportion of cases availability of suitable transport, the means of rapid loading and dispatch, the adequacy of roads free from a crowding exodus of other citizens, and the facilities for light and water will materially affect decisions on this important point. I believe, and others share the view, that each medical officer of health should in consultation with the local profession and the hospital authorities have ready and prepared a series of schemes suitable for various contingencies such as prevalent wind, extent of attack, and numbers of persons affected. These schemes should be known to all concerned so that the broadcasting of a code word will immediately set in operation an orderly sequence of events." This implies that the time has come for all ambulance workers to be trained in anti-gas drill, all drivers of emergency transport to be similarly instructed, and all doctors and nurses to know what is expected of them, and it is hard to say that it is more unreasonable to prepare for air attacks which may never come than to have fire drills in buildings where fires are not likely to occur. When we are told that these things can go forward without unduly alarming the civil population in the same way as measures are taken quietly to deal with possible outbreaks of infectious disease, we do not agree. while certainly it will be hard to raise enthusiasm for measures which may never be needed. But such precautions would offer no provocation to other nations, a criticism which can be levelled against offensive preparations. They would show that having realised a possible and serious danger we are taking the apposite measures.

TISSUE IMMUNITY.

By republishing in book form various contributions to medical journals and conferences which he has made since 1898, Alexandre Besredka has summarised 30 years of work of research on immunity from the preventive and curative side of vaccine therapy. We use this term in its widest sense. Some of the earlier chapters of the book awaken memories of "battles long ago"—Metchnikoff and phagocytosis, the diversity of the streptococcal species, antistreptococcal serum and others. But perhaps the most interesting of all the numerous subjects which the author treats in his clear and lucid style are the later ones which deal with his now well-known theories with regard to clinical immunisation by the cutaneous, buccal, and intestinal portals of entry. Prof. Besredka's method of immunisation by the sensitisation of the gastro-intestinal tract with bile previous to the ingestion of vaccine or anti-serum is now well known. In France, where prophylactic typhoid vaccine is extensively administered in this way, the method may be said to have passed the experimental stage. A considerable amount of statistical evidence of its efficacy is now available. The method has obvious advantages to make it attractive to the clinician, but the rôle of the bile in gastro-intestinal bacterial infections is only dimly understood at present and there is need for a good deal more experimentation, especially combined team-work of physiologist and bacteriologist, before complete reliance can be placed on the method as a satisfactory alternative to the now well-established subcutaneous inoculation. Laboratory animals, unfortunately, are not entirely suitable for the work and the actual steps of this tissue immunisation, if true immunisation it be, have not yet been worked out, and precisely how far the humoral phenomena of immunity, precipitins, agglutinins, and the like are affected by these methods cannot yet be estimated.

We have dealt at some length on two previous occasions[1] with Prof. Besredka's theories on tissue immunity in relation to the skin and the gastro-intestinal tract. Briefly, he considers that the body defends itself primarily by a local reaction in the tissue through which the micro-organism gains access to the body, and he has elaborated his thesis with numerous experiments with *B. anthracis* and other organisms. Much yet remains to be done before a conclusive opinion can be expressed. No one can look at a histological section of the skin in a case of leprosy without being impressed with the local powers of phagocytosis. Similarly the extensive work of A. S. Griffiths[2] over a long period of years has shown that in lupus there is a frequent modification of the pathogenic properties of the tubercle bacillus which are probably the result of adaptation of the bacilli to the resistant action of the skin. Other examples might be quoted, notably a long series of investigations by A. K. Krause[3] on guinea-pigs with tubercle bacilli. But the histological side of the picture, the questions of absorption and lymphatic drainage, local antibody production, and so on, have not yet been exhaustively explored.

SECOND INFECTION IN SYPHILIS.

Athough a second infection of syphilis in man had occasionally been reported before the introduction of salvarsan, it was only after the use of the arsphenamins had become general that examples became at all frequent. The diagnosis of a second infection is by no means free from pitfalls. The *chancre redux* which appears at the site of the original primary lesion many years later, and may be followed by cutaneous manifestations simulating the secondary stage, is really a gummatous lesion. C. R. L. Halley and H. Wasserman[4] have recently published observations on collected reports of 676 cases of second infection. The majority failed to satisfy the criteria which these authors considered necessary to establish both the first and the second infection. To the 229 examples which were found to be acceptable as true cases of second infection, the authors have added eight cases under their own observation. On analysis 97 per cent. of these cases were found to have received treatment with modern remedies early in the course of the first infection. No example of second infection could be found in cases whose first infection remained untreated until the tertiary stage; only one instance of a congenital syphilitic acquiring a second infection was noted. The rarity of second infection in women (only 3·3 per cent. of the total) is in keeping with the general experience that the majority of women come under treatment at a later stage of infection than men. Halley and Wasserman point out that the number of second infections diminish as the interval between the onset of infection and the commencement of treatment increases. Similar observations have been made in the experimental syphilis of rabbits. Recent researches on immunity in syphilis have shown that reinfection in man does not constitute certain proof of the complete cure of the original infection. The occurrence of superinfection following inoculation with material containing spirochætes in the very early stages of human syphilis and in experimental syphilis in rabbits is also well known. G. Mestchersky and S. Bogdanoff,[5] who have recently reported the effects of experimental inoculation in various stages of human syphilis, achieved results which led them to conclude that superinfection is possible at all stages of syphilis. But the lesions in their successful cases were those of a modified infection; no characteristic primary lesions were produced, nor was there any evidence of generalisation of the infection. Their experiments, like those of Finger and Landsteiner,[6] in which the inoculation with spirochætes of cases in the tertiary stage resulted in lesions of tertiary type, indicate that the tissues are refractory to second infection but that immunity is not absolute. It is of interest to recall that experimental inoculation of rabbits already infected with syphilis is successful in a much higher ago than 1896–1900 was responsible for a death-rate of 176 per million persons living. Compare this with the rates for the year 1921 when separate returns for encephalitis lethargica became available, and for the six subsequent years—

[6] Quoted by A. M. Chesny, Immunity in Syphilis, London, 1927, p. 22.

Enteric fever	16	12	12	13	10	9	9
Encephalitis lethargica	19	9	13	36	34	32	28
Diabetes	90	99	92	87	88	89	95

We have added a column dealing with diabetes, on which a recent report of the Registrar-General contained a valuable study in detail.

A note may be made, in conclusion, on the tables of cases of infectious diseases notified to medical officers of health during 1927 in each sanitary area. It would be interesting to ascertain how many or, rather, how few, medical officers see these tables tucked away in the last pages of a volume for which the non-official purchaser must pay 15*s*. Their public health value is great in reviewing the experience of each year and in comparing this experience with that of other areas: They are valuable finger-posts, indicating where further investigation is needed from an administrative standpoint; and their value as implements of epidemiological research rises year by year. We take this opportunity of emphasising the importance of these tables to every medical officer of health in the country.

THE USE OF WELCHII ANTITOXIN IN ACUTE OBSTRUCTION AND GENERAL PERITONITIS.

THE actual cause of the toxæmia in cases of acute intestinal obstruction and general peritonitis remains obscure, and attempts are continually being made to elucidate it. Gatch, Trusler, and Ayres[1] consider that the toxæmia following obstruction is due to the absorption by a damaged mucous membrane of toxins which would not be absorbed by the normal mucous membrane. Further strangulation ensures the development of an ideal culture medium for the rapid proliferation of pathogenic bacteria, and the gases resulting from putrefaction cause increased pressure within the lumen and so increase absorption. Dragstedt[2] and his collaborators have shown that experimentally closed loops of duodenum or jejunum prove rapidly fatal unless drained from the outside, and further, that if closed loops of intestine are first washed with ether or an astringent wash the obstruction is not fatal to the aninal. All these observers agree that death is caused in cases of strangulated bowel by conditions which increase the absorption of toxins, the actual nature of which toxins being still undetermined. Working in the Clinical Surgical Unit of St. Thomas's Hospital, B. W. Williams[3] attempted to demonstrate the presence of a true bacterial toxin of intestinal origin and to indicate its nature and the conditions of its development. Struck by the clinical similarity between the toxæmia in acute obstruction and general peritonitis, and the toxæmia of gas gangrene, he was led to investigate the development of *B. welchii* in the two first conditions. He showed that there is evidence of immense proliferation of *B. welchii* in the contents of the small intestine of patients with acute obstruction and peritonitis with stasis, and also of the presence of the exotoxin of the organism; the clinical aspects of patients, the occurrence of intravascular hæmolysis, and the microscopical changes in the heart and liver of fatal cases suggest that absorption of toxin has taken place. The truth of his hypothesis appeared to be confirmed by the results of a therapeutic test of *B. welchii* antitoxin at St. Thomas's Hospital in cases of acute obstruction and general peritonitis. A comparison of cases so treated with a control series showed definite lowering of the mortality and alleviation of the symptoms and clinical signs of toxæmia, even allowing for the difficulty of prognosis before treatment and therefore of assessing its results. Following the publication of Williams's paper, Bower and Clark[4] have used *B. welchii* antitoxin at the Samaritan Hospital, Philadelphia, in 25 cases. Eleven of these suffered from acute diffuse suppurative peritonitis, nine had acute intestinal obstruction, and five were cases of acute suppurative cholecystitis, in which the process had extended to the peritoneum or pancreas. In the first and second of these groups the authors were able to substantiate the claims made by Williams. The patients treated with antitoxin were less restless, consciousness was less acute, the pulse-rate was diminished, the temperature was reduced, distension became less, and the intestines were evacuated earlier. Two cases in the third group also appeared to derive benefit from the antitoxin. The small number of cases treated and the wide variation possible in the type of case chosen for treatment by different observers make percentage mortality figures useless for comparison with those from another institution. The fact that workers under quite different conditions have obtained confirmatory results suggests that Williams's hypothesis should be followed up and given further trial, for if surgical treatment of intestinal obstruction can be supplemented by a trustworthy method of combating toxæmia, its high mortality should be considerably reduced.

MEDICAL PROBLEMS IN AERIAL WARFARE.

THE Kellogg Treaty recognises that war is not inevitable, while responsible statesmen must explore every avenue to prevent its occurrence. Almost simultaneously with its signature the aerial manœuvres round London have reminded us that, though the contingency of war may appear remote, there is a weapon forged which can strike with swiftness and effect into the heart of a nation—a weapon, moreover, that can be immediately mobilised from the rapidly increasing supply of commercial aircraft. We are reminded by a correspondent of the medical problems that might arise in future conflicts in the air. "At the outbreak of the last war," he writes, "we had a breathing space, for which the late Lord Haldane was largely responsible, in which to gather our full fighting strength, but in the future, with a rapid declaration of war and perhaps an equally rapid decision, we shall stand or fall by our degree of preparedness at the actual moment of the commencement of hostilities. Though, with the majority of our countrymen, medical men hope and truly believe in better things, we should be false to a trust if we failed to point out certain aspects of the question. While the care of the sick and wounded in our home towns will be largely in the hands of the men on the spot, none can say exactly where a blow may be delivered. The attack may quite as easily fall on some small country town as a large city; the object of bombardment from the air, comprising high explosive, incendiary and gas bombs, may be intentional or unintentional at any particular spot. The actual concentration of gas is immaterial; it may disable by killing or by sickness, but whichever it is it must be dealt with energetically and at once." These things are sadly true. The hospitals are almost without exception situated near the bull's eye—for the target will always be the large city, and they may for this very reason become useless. The victimisation of the small centre will be accidental, and the real problem will be to evacuate the hospital patients as well as other casualties into some gas-free zone, and a clear idea is therefore desirable as to the best procedure.

Ought this to be a matter of immediate attention on the ground that if organisation is not arranged while it is not needed, when it is needed the preparation will be too late? Our correspondent writes further: "We shall discover the necessity for doctors and nurses to understand all the details of anti-gas precautions, but far larger matters are at issue. The siting of temporary hospitals on high ground to windward at the shortest possible distance from the town is a matter which needs thought. Conditions such as the few papers have had a more far-reaching effect than the one in question. Literally hundreds of thousands of eyes have been saved from permanent blindness by von Graefe's work. He died suddenly in 1870 while the Franco-Prussian War was in progress.

LADY OSLER.

THE death of Grace Osler, widow of the famous Regius Professor at Oxford, has evoked expressions of regret from a remarkably wide circle. The number of guests, medical and literary, to whom Sir William dispensed at Norham-gardens an unending hospitality would be surprising if it were known, and Lady Osler, as his wife, was responsible for their entertainment. The house was nearly always full, for every doctor who visited England from America or Canada, and most of those who came to our shores from the continent, considered it a duty and privilege to "look up Osler and his wife." Grace Revere, Lady Osler, born 74 years ago at Boston, was the great-granddaughter of Paul Revere, the hero of the famous ride. As a young woman she married Dr. S. W. Gross, a professor of the Jefferson Medical College, Philadelphia, and the son of Samuel Gross, the famous American surgeon. She was left a young widow in 1888, and four years later married William Osler, who, having come south from Canada, was earning his famous reputation as a scientist and physician at Baltimore. For 13 years Lady Osler was her husband's helpmate at Baltimore; then, in 1905, came the appointment to the Oxford chair, and from the moment that Osler and his wife arrived in the old University city it was seen how admirably they were fitted for what they made into a joint effort. A well-known Oxford professor writes of her: "She was an instant success and their home became a centre of attraction, drawing all sorts and conditions of men from every quarter of the globe, the most gifted and famous mingling with the youngest undergraduates arriving to present letters of introduction. Her house was also converted into a veritable home for many of the Rhodes scholars, and not a few of these will remember with affection and respect the care she bestowed upon them, her valuable influence and her practical help—things which greatly assisted in promoting the success of Cecil Rhodes's scheme." The outbreak of war found Lady Osler in America, but she returned immediately and threw herself whole-heartedly into all the activities connected with the succour and treatment of the wounded, while, through her influence in America, she was from the beginning able to obtain great sums of money to carry on various schemes. As is well known her only son was killed at St. Julien, but stricken as she was, she only bestirred herself to help with more intimate and perfect sympathy those who could not help themselves. She was an ideal companion to her husband. Tireless in promoting the interest which he had at heart, it was felt, therefore, by everyone that her appointment at Sir William Osler's death as Trustee of the Ewelme Charity was thoroughly fitting; the mastership of Ewelme in connexion with the Chair of Physics had been a mediæval appointment which had made a special appeal to Sir William Osler.

THE DEVELOPMENT OF OBSTETRICS AND GYNÆCOLOGY.

THE three subjects chosen for the discussions at Cardiff, reported on p. 521, indicate how greatly the responsibilities of the gynæcologist have increased since the days when etiquette restricted his operative activities to the perineum. The diagnosis and treatment of sterility, the differentiation of acute conditions in the pelvis by laparotomy if other methods fail, and the actual technique of radium therapy all come within his accepted sphere. An important result of the development of gynæcology has been the clear demonstration that too large a proportion of the commoner diseases of women, notably salpingitis and prolapse, are often traceable to unsuspected infections of venereal disease, or to unscientific midwifery, both of which causes may have long-delayed effects. Venereal disease is now being resolutely attacked, but the practical teaching of obstetrics, as we have recently pointed out, still needs even closer attention than has been given to it by most of the licensing bodies. Dr. George Peachey reminds us in his letter (p. 530) that in the first part of the eighteenth century a licence for the practice of midwifery had to be obtained from the Bishop of London, but that in 1783 the College of Physicians took cognisance of practitioners of that art and instituted for a short term of years only a distinct order of licentiates in midwifery. It is not to be doubted that interest in obstetrics will be stimulated by the reinstitution of a special diploma such as that now granted by the Society of Apothecaries of London. A historical review[1] of the achievements of the nineteenth century in the field of gynæcology and obstetrics, recently published in Vienna, is opportune in view of the efforts now being made to secure for obstetricians and gynæcologists a status appropriate to the range of their specialty. Dr. Fischer's survey, undertaken with the patience and thoroughness that marks the whole of the vast text-book of which it is a part, covers every department of the subject, section by section, and refers to every book and paper worth reading that appeared during last century. The bibliography alone fills no less than 41 pages of small type. Nearly all the vast network of scientific investigation which has culminated in the institution of chairs of gynæcology and obstetrics of every university, with laboratories in which anatomy and physiology of the normal and pathological reproductive organs are constantly being studied, has grown up since 1800. The results of the works of Lister, Koch, and Semmelweis, and the discovery of the nature of micro-organisms, have in no other department of medicine been of more vital import for prophylaxis, diagnosis, and therapy. The discovery of the application of general and local anæsthesia in conjunction with aseptic technique, and the later discoveries in serology and radiology, have been as useful to the gynæcologist as to the general surgeon.

Dr. Fischer's synopsis is not light reading, but the reader intent on tracing the evolution of any aspect of midwifery or gynæcology through the age most critical for its growth, will find it an admirable guide. He will notice the gap between 1899, when the survey ends and the present day, the more for the guidance he has had through the preceding century. This century has been of even more interest than the last and has witnessed a progress twice as rapid as that which Dr. Fischer chronicles. It is to be hoped that this volume may be supplemented by an account of the development of obstetrics and gynæcology in the first quarter of this century.

EDUCATION AGAINST TUBERCULOSIS

THE National Association for the Prevention of Tuberculosis has been successful in its appeal for £100,000, and thanks to the funds thus provided extensive propaganda throughout the country is now being undertaken. The report of the Association for the year 1927 which has just been issued gives some details of the educational work which is in progress under the guidance of the medical commissioner, Dr. William Brand, and three assistant medical commissioners who were appointed last year. They have all been actively engaged in different parts of the country, where they have aroused interest and percentage of cases when a heterologous strain of spirochæte is employed than with a homologous strain. The refractory state towards a second infection in rabbits, which develops in time, is more marked towards the homologous strain than a heterologous strain. Second infection in cases of neuro-syphilis would, if frequent, add support to the existence of dermotropic and neurotropic strains of spirochæte; but Halley and Wasserman were unable to find any tenable reports of such reinfection. The increasing number of reported cases of second infection in man, and their preponderance among those who received treatment with organic arsenical compounds in the early stage of the disease, support the claim made for these remedies of producing complete sterilisation in early syphilis.

BLOOD FORMATION.

USING the bones of fœtal and young guinea-pigs and rabbits, Prof. Witherington Stump, of the Department of Anatomy of the University of Sydney, has recently reinvestigated the problem of blood formation, so far as it takes place in the red marrow. Prof. Stump found this type of material particularly well suited for investigation, and expresses surprise that previous workers have so seldom used it. The results, which appear in a recent number of the *Medical Journal of Australia* (1927, ii., 702), contribute few new facts but constitute a valuable commentary on the present state of our knowledge of blood formation. Prof. Stump finds himself most closely in agreement with the views of Dantschakoff and Maximow on the genesis of the various cells produced in the red marrow; he is a convinced and thoroughgoing monophytist, believing that all the peculiar cells of the red marrow, even to the megakaryocytes, are produced from a common stem cell. This cell he believes to develop by direct maturation of certain of the indifferent mesenchyme cells; the remaining mesenchyme cells finally produce the reticular system in which the differentiated stem cells then come to lie. These stem cells occurred abundantly in the tissues used by the author; they are described as possessing a large deeply staining nucleus, with abundant chromatin and a strongly basophile cytoplasm. From this cell the author was able to trace the development of red cells, granulocytes of all three orders, and megakaryocytes—the monocytes apparently did not come within the purview of the study. The article contains some valuable hints as to technique for those wishing to follow a similar line of investigation, for Prof. Stump is one of those rare individuals possessing a simplifying mind. He keeps his descriptive terms within strict limits, and has a hard word for the "unwieldly terminology (of hæmatology) which has passed beyond the limits of scientific application." It is, however, possible to be too simple, and it is to be hoped that Prof. Stump will in due course publish more detailed descriptions of his researches.

SINGULTUS EPIDEMICUS.

THE occurrence of epidemics of hiccough associated with influenza has been reported now and then; an interesting account of six cases during the epidemic of 1926–27 in Czechoslovakia is given by Dr. B. Kuklová,[1] the first woman to hold a chair of medicine in that country. The accompanying influenza epidemic lasted from Nov. 1926 to March 1927, affecting mainly persons between 20 and 30 years of age. Hiccough occurred in four women and two men, all between 18 and 28 years of age, with the exception of an old man of 65. The onset varied: in three cases the hiccough was the first and only sympton, in two cases it set in with a raised temperature and catarrhal symptoms, and in one it was associated with an exacerbation of an already existing digestive disorder. The hiccough in every case was extremely resistant to treatment. Sleep was always disturbed and the sugar in the cerebro-spinal fluid was increased. There were present also myoclonic contractions which affected both halves of the diaphragm, the muscles of the upper part of the chest, the throat, the external eye muscles, and eventually those of the extremities. In two cases the respiratory rhythm was disturbed after the hiccough had passed off, or between the attacks, and in one case compression of the eyeballs produced apnœa. The first attack of hiccough lasted from one hour to 14 days, most frequently being three to four days in duration. In four of the patients subsequent attacks developed some weeks later. The shortest duration of the illness was seven days and the longest 110 days. In four of the patients there was a well-marked hysterical element. In the chronic cases galvanism of the phrenic nerve was employed with success in treatment. Attempts to transmit the disease to rabbits and guinea-pigs failed, although the presence of an infective agent in the nasal and nasopharygeal mucus of the other influenza patients had been proved by experiment. These cases of hiccough raise interesting points for study; there is a close parallelism between many of the associated nervous symptoms and those occurring in or following epidemic encephalitis.

ALBRECHT VON GRAEFE.

FEW in surgery, and none in ophthalmic surgery, have better deserved than Albrecht von Graefe the familiar apostrophe "E tenebris tantis tam clarum extollere lumen qui potuisti." In his short life of 42 years he revolutionised much of ophthalmology. His glaucoma operation has stood the test of time, while his cataract knife is used daily throughout the world. In this country his name is always coupled reverently with those of Bowman, George Critchett, and Donders. The four were great friends; Bowman and Critchett were mainly responsible for placing the science of ophthalmology on a sure basis in this country and von Graefe did a like service for it in Germany. This is von Graefe's centenary year. He was born in Berlin a hundred years ago; he was the youngest son of Charles von Graefe, a well-known surgeon of his day in Germany. His father died while he was yet in childhood, and he was largely dependent for his upbringing on his mother's care. After the usual course of study at Berlin he spent some time in the chief foreign clinics, notably under Arlt at Prague and in Vienna. To Arlt is said to belong the credit for having first turned von Graefe's attention to ophthalmology. He also visited the British Isles and spent some time in London, Edinburgh, and Dublin. Ample private means sometimes have a soporific effect upon a young professional man, but they had no paralysing effect upon von Graefe, who built a hospital of his own and rapidly acquired a tremendous reputation not only in Germany but throughout Europe. He was lucky in starting on his ophthalmological career at a propitious time; in 1851 von Helmholtz gave to the world his epoch-making discovery of the ophthalmoscope. Von Graefe was quick to see the enormous advantages that would accrue to those who made themselves familiar with the new instrument. He is credited with having announced in an address that "Helmholtz has opened a new world." This appreciation of the ophthalmoscope on the part of von Graefe is in marked contradistinction to that accorded by Wharton Jones, a few years earlier, when shown a similar model of an ophthalmoscope by Charles Babbage. Not content with an enormous practice, von Graefe founded, in 1854, the *Archiv für Ophthalmologie* and ran it single-handed for the first year. In 1855 he was joined by Arlt and Donders in the editorship. From that date until his death hardly a number of this journal appeared without containing a communication by von Graefe, and in 1857 he gave his famous work on iridectomy in "Glaucoma, and on the glaucomatous process" to the world in its columns. It can safely be said that few papers have had a more far-reaching effect than the one in question. Literally hundreds of thousands of eyes have been saved from permanent blindness by von Graefe's work. He died suddenly in 1870 while the Franco-Prussian War was in progress.

LADY OSLER.

THE death of Grace Osler, widow of the famous Regius Professor at Oxford, has evoked expressions of regret from a remarkably wide circle. The number of guests, medical and literary, to whom Sir William dispensed at Norham-gardens an unending hospitality would be surprising if it were known, and Lady Osler, as his wife, was responsible for their entertainment. The house was nearly always full, for every doctor who visited England from America or Canada, and most of those who came to our shores from the continent, considered it a duty and privilege to "look up Osler and his wife." Grace Revere, Lady Osler, born 74 years ago at Boston, was the great-granddaughter of Paul Revere, the hero of the famous ride. As a young woman she married Dr. S. W. Gross, a professor of the Jefferson Medical College, Philadelphia, and the son of Samuel Gross, the famous American surgeon. She was left a young widow in 1888, and four years later married William Osler, who, having come south from Canada, was earning his famous reputation as a scientist and physician at Baltimore. For 13 years Lady Osler was her husband's helpmate at Baltimore; then, in 1905, came the appointment to the Oxford chair, and from the moment that Osler and his wife arrived in the old University city it was seen how admirably they were fitted for what they made into a joint effort. A well-known Oxford professor writes of her: "She was an instant success and their home became a centre of attraction, drawing all sorts and conditions of men from every quarter of the globe, the most gifted and famous mingling with the youngest undergraduates arriving to present letters of introduction. Her house was also converted into a veritable home for many of the Rhodes scholars, and not a few of these will remember with affection and respect the care she bestowed upon them, her valuable influence and her practical help—things which greatly assisted in promoting the success of Cecil Rhodes's scheme." The outbreak of war found Lady Osler in America, but she returned immediately and threw herself whole-heartedly into all the activities connected with the succour and treatment of the wounded, while, through her influence in America, she was from the beginning able to obtain great sums of money to carry on various schemes. As is well known her only son was killed at St. Julien, but stricken as she was, she only bestirred herself to help with more intimate and perfect sympathy those who could not help themselves. She was an ideal companion to her husband. Tireless in promoting the interest which he had at heart, it was felt, therefore, by everyone that her appointment at Sir William Osler's death as Trustee of the Ewelme Charity was thoroughly fitting; the mastership of Ewelme in connexion with the Chair of Physics had been a mediæval appointment which had made a special appeal to Sir William Osler.

THE DEVELOPMENT OF OBSTETRICS AND GYNÆCOLOGY.

THE three subjects chosen for the discussions at Cardiff, reported on p. 521, indicate how greatly the responsibilities of the gynæcologist have increased since the days when etiquette restricted his operative activities to the perineum. The diagnosis and treatment of sterility, the differentiation of acute conditions in the pelvis by laparotomy if other methods fail, and the actual technique of radium therapy all come within his accepted sphere. An important result of the development of gynæcology has been the clear demonstration that too large a proportion of the commoner diseases of women, notably salpingitis and prolapse, are often traceable to unsuspected infections of venereal disease, or to unscientific midwifery, both of which causes may have long-delayed effects. Venereal disease is now being resolutely attacked, but the practical teaching of obstetrics, as we have recently pointed out, still needs even closer attention than has been given to it by most of the licensing bodies. Dr. George Peachey reminds us in his letter (p. 530) that in the first part of the eighteenth century a licence for the practice of midwifery had to be obtained from the Bishop of London, but that in 1783 the College of Physicians took cognisance of practitioners of that art and instituted for a short term of years only a distinct order of licentiates in midwifery. It is not to be doubted that interest in obstetrics will be stimulated by the reinstitution of a special diploma such as that now granted by the Society of Apothecaries of London. A historical review [1] of the achievements of the nineteenth century in the field of gynæcology and obstetrics, recently published in Vienna, is opportune in view of the efforts now being made to secure for obstetricians and gynæcologists a status appropriate to the range of their specialty. Dr. Fischer's survey, undertaken with the patience and thoroughness that marks the whole of the vast text-book of which it is a part, covers every department of the subject, section by section, and refers to every book and paper worth reading that appeared during last century. The bibliography alone fills no less than 41 pages of small type. Nearly all the vast network of scientific investigation which has culminated in the institution of chairs of gynæcology and obstetrics of every university, with laboratories in which anatomy and physiology of the normal and pathological reproductive organs are constantly being studied, has grown up since 1800. The results of the works of Lister, Koch, and Semmelweis, and the discovery of the nature of micro-organisms, have in no other department of medicine, been of more vital import for prophylaxis, diagnosis, and therapy. The discovery of the application of general and local anæsthesia in conjunction with aseptic technique, and the later discoveries in serology and radiology, have been as useful to the gynæcologist as to the general surgeon.

Dr. Fischer's synopsis is not light reading, but the reader intent on tracing the evolution of any aspect of midwifery or gynæcology through the age most critical for its growth, will find it an admirable guide. He will notice the gap between 1899, when the survey ends and the present day, the more for the guidance he has had through the preceding century. This century has been of even more interest than the last and has witnessed a progress twice as rapid as that which Dr. Fischer chronicles. It is to be hoped that this volume may be supplemented by an account of the development of obstetrics and gynæcology in the first quarter of this century.

EDUCATION AGAINST TUBERCULOSIS

THE National Association for the Prevention of Tuberculosis has been successful in its appeal for £100,000, and thanks to the funds thus provided extensive propaganda throughout the country is now being undertaken. The report of the Association for the year 1927 which has just been issued gives some details of the educational work which is in progress under the guidance of the medical commissioner, Dr. William Brand, and three assistant medical commissioners who were appointed last year. They have all been actively engaged in different parts of the country, where they have aroused interest and enthusiasm. Each lecturer is accompanied by a caravan fitted with exhibits consisting of models, photographs, pictorial posters, and literature; a cinema projector with lantern attachment is carried along with films and lantern slides. Already a considerable part of the country has been covered, and everywhere the closest coöperation with local health authorities and voluntary organisations has been secured. The particular objects of these educational campaigns may be described as two-fold. There is, first, the prevention of infection by attention to general hygenic principles, and special precautions in the event of the disease being present in a member of the family; secondly, there is the education of the public to know what to do when afflicted by tuberculosis, including the life to be led after sanatorium treatment. The films used by the lecturers illustrate these two main objects. "The Invisible Enemy," deals with the prevention of the disease, showing by means of a story, of a mother and her dying son, what must be done to avoid the disease. "The Story of John M'Neil," features the eradication of tuberculosis in a family on the Edinburgh system. "A Day in a Sanatorium" and "Burrow Hill Colony," paint sanatorium life and its extension in the colony idea. The Association aims at letting the public know that early treatment of the disease is essential, and its educational work is partly concerned with the "warnings" of the disease and the facilities for treatment. It is also directing some of its energies to educate the "fool" who, it has been said, can never be cured of tuberculosis—unless, that is, he is first cured of his folly. The dangers of milk and the social problem of tuberculosis are also dealt with, so that a very wide field is covered. With the impetus given by the success of the recent appeal, the Association should be able to carry out its ambitious programme of educating the whole community.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

II.—REPORTS ON SWABS FROM THE THROAT AND NASAL PASSAGES.

By J. E. McCartney, M.D., Ch.B., D.Sc.,
DIRECTOR OF RESEARCH AND PATHOLOGICAL SERVICES, METROPOLITAN ASYLUMS BOARD.

(1) Cases Suspected of Diphtheria.

It is the habit of many practitioners, when there is any acute inflammatory condition of the throat, to take a swab of the throat and send it to the laboratory for a report. Often there is no information furnished regarding the patient, and when such information is sent it is often meagre and of little or no assistance. The clinician frequently waits for the laboratory report before instituting treatment, and his whole conduct of the case is usually guided by the pathologist's findings in the material sent. Many practitioners regard the laboratory report as infallible, and in so doing are content to assume that the responsibility of diagnosing the case must rest with the pathologist. This attitude is misleading and dangerous. The pathologist can assist the clinician by giving certain information, which must be considered in relation to the condition of the patient. The practitioner himself must assess the value and significance of the pathologist's report with regard to each individual patient. Half a dozen identical reports may be issued from a laboratory, but the interpretation of them may be absolutely different in each case. It is the object of this article to try and indicate what significance should be attached to various laboratory findings in respect of these swabs according to the clinical condition of the patient.

Klebs-Löffler Bacillus (K.L.B.).

The great majority of throat swabs are sent to the laboratory in order to ascertain whether the diphtheria bacillus is present or not, and great care should be exercised by the practitioner in taking the swab that material is obtained direct from the lesion.

Laboratory Technique.—The technique usually employed is to inoculate a tube of Löffler's serum, which is then incubated at 37° C. for 18 to 24 hours. In addition, two direct films are made from the swab, and one is stained and examined for the diphtheria bacillus, while the other is stained with dilute carbol-fuchsin or methyl-violet to determine if the organisms of Vincent's angina are present. In a proportion of cases positive results may be obtained immediately by an examination of direct films, but cultures must also be made as a routine.

After incubation, films are made from the culture and stained with the particular diphtheria stain in use in the laboratory, which may be Löffler's methylene blue; Neisser's stain (either the original method or a modification); Pugh's acetic acid—toluidine blue; or Albert's method, which is a modification of Pugh's stain. The particular stain used depends entirely on the choice of the individual bacteriologist, and should have no influence on the accuracy of the report.

The stained films are examined microscopically, and the characteristic beaded appearance of the diphtheria bacillus makes its recognition easy in definitely positive cases. A number of bacilli of the "diphtheroid" group resemble the diphtheria bacillus more or less closely, but a competent bacteriologist can usually discriminate between them with confidence.

The Significance of Positive Reports.

The report as to the presence of diphtheria bacilli is made from the microscopic examination of the culture. When the swab is taken from a case of acute inflammation of the throat or nasopharynx, and the clinical disease is suggestive of diphtheria, the presence of diphtheria bacilli in the cultures—i.e., positive report—is sufficient evidence that the disease is diphtheria, and that the bacilli are virulent. In carriers, however, or in persons not showing clinical symptoms of diphtheria, fermentation and virulence tests must be carried out to establish the full identity of the organism.

The report may be variously drafted:—

(1) "Diphtheria bacilli present."
(2) "Diphtheria bacilli positive."
(3) "Diphtheria bacilli +" (or ++, or +++).
(4) "Diphtheria bacilli positive (scanty)."
(5) "Bacilli morphologically indistinguishable from diphtheria bacilli are present. A virulence test is being done, and the report will be forwarded in 5–8 days' time."

In any report the terms "K.L.B." and "diphtheria bacilli" are synonymous. The reports (1), (2), and (3) explain themselves.

(4) This report indicates that only a very few diphtheria bacilli can be recognised even after culture, and must be interpreted solely in the light of the clinical condition. If the case is one of acute inflammation of the throat, but clinically *not* diphtheria, a report such as this would be almost equivalent to a negative finding. The case should be watched and a further swab sent immediately. On the other hand, if the swab is from a convalescent, it indicates that the diphtheria bacilli have almost disappeared and that the case may soon be considered fit for discharge.

(5) Where no indication is given to the bacteriologist as to the clinical condition and site of the disease; where the material is from some other part of the body, such as the ear, eye, or in a wound; or where the case is that of a suspected carrier or even a chronic carrier, the mere presence of diphtheria-like

organisms does not mean that these bacilli are virulent—i.e., capable of causing the disease—or even true non-virulent diphtheria bacilli, since certain diphtheroids may simulate microscopically the Klebs-Löffler bacillus. Under the conditions above mentioned it is impossible to determine virulence purely from microscopical examination, and a virulence test is absolutely necessary. As indicated in the report quoted above, a virulence test is frequently done without further notice by the laboratory, and the conduct of the case will be determined by the result of this test. On the other hand, it must be remembered that some bacteriologists, realising that the diagnosis of the presence of virulent diphtheria bacilli cannot be made solely from microscopical examination, issue the positive report always in the cautious manner of "bacilli morphologically indistinguishable from diphtheria bacilli are present." If a virulence test is not suggested by the bacteriologist, this form of report may be regarded as positive.

To sum up, any acute condition of the throat in which a positive report is received must be regarded as diphtheria and treated as such until evidence is obtained to the contrary. In doubtful cases it is advisable to have the organisms isolated if possible and a virulence test performed.

The Significance of Negative Reports.

A negative result means that no diphtheria bacilli can be recognised microscopically in the culture. When the swab has been taken from a person who has not active or clinical diphtheria, such as a carrier, it is important that the culture tube showing a negative result should be incubated for a further 24 hours. It would appear that in many of these cases the bacilli are in a state of "lag," and do not commence to grow as quickly as organisms from acute cases. The percentage of positive results from carriers may be as much as 50 per cent. higher when the cultures are re-examined after a further 24 hours' incubation.

If the case is one of acute inflammation, and from the clinical appearance the presumption is that it is *not* one of diphtheria, then a negative report is of value and will confirm this opinion. If, on the other hand, the symptoms are those of diphtheria, then the diagnosis of diphtheria must still be maintained, and specific treatment continued in spite of a negative report. A further swab should be submitted to the laboratory.

If a convalescent diphtheria case is ready for discharge, one negative report does not mean that the patient is free from infection. Three consecutive negative reports are required, and the swabs should be taken carefully, and not immediately after meals or after local treatment such as antiseptic gargles. With carriers even three negative reports are not sufficient to declare the case as free from infection. If virulent diphtheria bacilli have been present six consecutive negative reports at twice-weekly intervals will be necessary.

If the case, when first seen by the practitioner, is recovering from an illness thought to be diphtheria, a negative swab report must be considered in conjunction with a Schick test. Broadly speaking, a positive Schick test and a negative swab indicates that the case is not diphtheria, while a negative Schick test and a negative swab in a young person suggests that the disease is likely to be diphtheria.

It must be remembered that in diphtheria a throat swab alone is not sufficient, particularly in convalescents and suspected carriers, and a *nasal swab should always be taken as well*, while in certain cases a swab from the ear should also be secured. The report on the nasal swab should be considered in the same manner as that on the throat swab.

Remarks.

In considering laboratory reports the clinical aspect of the case must be taken into consideration. The responsibility rests with the clinician, who must not rely implicitly on the bacteriological diagnosis; in any case where there is a reasonable suspicion of diphtheria it is his duty to administer antitoxin at once, and to continue to do so even in spite of a negative laboratory report. *The practice of withholding antitoxin until the report on the swab has been obtained cannot be too strongly condemned.*

The mortality of diphtheria increases with the delay in administering antitoxin, and the wait of 18 to 24 hours which must elapse before the bacteriological report can be given may in some cases determine the fatal issue. If antitoxin has been given, and the case turns out not to be diphtheria, no harm has been done, but if the patient is really suffering from the disease the prompt administration of antitoxin increases tremendously the chance of recovery. As an aid to the clinical diagnosis the laboratory report is invaluable, but it must never be considered a substitute.

The foregoing remarks apply particularly to the first few days of the acute stage of the disease. It must be remembered that diphtheria bacilli rapidly disappear from the throat during convalescence. At the end of the fourth week only one-third of the patients harbour bacilli, while only one-fifth show a positive swab by the end of the sixth week. These facts must be borne in mind when assessing the significance of a laboratory report. A report showing "scanty diphtheria bacilli" will have a different significance depending on whether the case is an acute tonsillar inflammatory condition not clinically diphtheria, or a convalescent patient almost ready for discharge.

Carriers.

Although in 80 per cent. of cases the diphtheria bacilli have disappeared by the sixth week, in some instances they may still persist for a long time, and if they are present after 12 weeks from the onset of the disease (8·73 per cent. of cases), the patient is arbitrarily termed a "carrier." It is essential tha the virulence of diphtheria-like organisms in such cases should be tested, since only virulent organisms are capable of spreading the disease; if the bacilli are non-virulent the patient can be released from quarantine. When diphtheria-like organisms are found in the throats of those not suffering from the clinical disease, as in healthy contact cases, or suspected carriers, the morphological appearance alone is not diagnostic.

Virulence Test.

The diphtheria bacillus must first be isolated in pure culture by plating on special media, and fermentation tests are then carried out. Production of acid should occur in glucose but not in saccharose. A guinea-pig is then inoculated intracutaneously with a small amount of the culture. Usually a week must elapse before a report on the virulence test can be received. As far as is known, non-virulent diphtheria bacilli are not capable of giving rise to the clinical symptoms of diphtheria.

Other Organisms in Association with Diphtheria.—Some reports mention the other organisms that are found in the cultures, in addition to diphtheria bacilli, and reference is made sometimes to the presence of hæmolytic streptococci. In most cases of diphtheria hæmolytic streptococci are present, often in large numbers, and as long as there is nothing out of the ordinary in the clinical aspects of the case the mere presence of these organisms has no special significance. On the other hand, it must be recognised that severe adenitis may be caused by streptococci, and that they accentuate the severity of the throat lesions.

The presence of Hofmann's bacillus has no pathological significance. It is often found in large numbers in the throats of convalescent diphtheria patients, particularly when the Klebs-Löffler bacilli have disappeared. It is non-virulent to laboratory animals.

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING AT CARDIFF.

(*Continued from p. 469.*)

SECTION OF MEDICINE.

Dr. A. FERGUS HEWAT (Edinburgh), Vice-President of the Section, took the chair at a discussion on the

PREVENTION AND TREATMENT OF DIPHTHERIA.

Dr. J. D. ROLLESTON (M.A.B.) considered prevention under two headings: (1) general measures, including isolation, disinfection, and treatment of the carrier; and (2) specific immunisation. Although it was doubtful whether isolation of diphtheria patients in special hospitals had had much effect in reducing its incidence, it was generally agreed that diphtheria required such treatment more than any other disease admitted to fever hospitals. There was a growing tendency among medical officers of health, medical superintendents of fever hospitals, and other sanitary authorities to discredit the value of terminal disinfection after diphtheria, and to regard the living carrier as responsible for the spread of the disease. The period of isolation of a patient should be determined by clinical considerations. In the absence of any discharges from the nose or ear or acute inflammatory condition of the throat, a patient who had had a mild attack might be set at liberty at the end of a month. In cases of any degree of severity the patient should be detained at least six weeks, as during that time some form of paralysis was most likely to develop. No uniformly successful method had yet been discovered for dealing with the carrier. The most efficacious measures were tonsillectomy and treatment of sinus infections, but they were not always practicable nor invariably successful. The practice of insisting on one or two negative faucial and nasal cultures before discharging a patient was merely illusory, as owing to the frequent occurrence of intermittency in the carrier state a false sense of security might arise from obtaining such cultures. As the return case rate was no higher in those hospitals which had abandoned the practice of swabbing patients before discharge than in those in which it was still observed, Dr. Rolleston had discontinued the practice at his own hospital since his appointment as medical superintendent two and a half years ago, without finding that this discontinuance had been followed by an increase in the return case rate. Specific immunisation against diphtheria was either passive, by injection of small doses of antitoxin, or active, by injection of toxin-antitoxin or similar preparations. The immunity conferred by passive immunisation, though immediate, was only of short duration, and the injection of antitoxin also predisposed the individual to an unusually severe reaction when a therapeutic dose was needed in the course of the next few years. Dr. Rolleston said that in hospitals and in families where the children could be kept under close observation after exposure to infection he did not think it necessary to carry out passive immunisation, though he was aware that in some clinics, especially on the continent, it was the practice to administer prophylactic doses of antitoxin with or without a preliminary Schick test, on the occurrence of a single case of diphtheria in a children's ward.

In carrying out active immunisation, which conferred a more durable and possibly permanent immunity, it had recently become the practice, especially in public health work in dealing with children under 6 years of age, to dispense with the preliminary Schick test, as the great majority of them were susceptible to diphtheria. In adults, on the other hand, who were more likely to react severely, a preliminary Schick test was necessary. In a large number of fever hospitals it was now the rule to carry out active immunisation of the nursing staff on joining. Since the introduction of active immunisation of newcomers the incidence of diphtheria among the nurses at the Western Hospital (Metropolitan Asylums Board), though it had never been very high, had shown a slight fall. Attacks of diphtheria occasionally did occur in nurses whose Schick reactions were negative either spontaneously or as the result of immunisation. This was probably due to nurses being exposed to massive doses of virulent infection, whereas other negative Schick persons who were exposed to only slight and occasional infections escaped. In addition to protecting nurses, active immunisation was indicated in schools, creches, orphanages, and other collections of children. Although no fatal accidents following active immunisation had occurred in this country, as they had in the United States, Austria, China, and Russia, the local reaction and constitutional disturbance were often severe. Owing, therefore, to the occasional failure to protect, and the possibility of severe reactions, Dr. Rolleston had been unwilling to make active immunisation against diphtheria compulsory, like vaccination against small-pox, especially as diphtheria antitoxin was an infallible remedy within the first 24 hours, whereas in small-pox no treatment, however early it was employed, invariably modified the course of the disease.

Dr. Rolleston discussed the treatment of diphtheria, in order of importance, under the headings of serum therapy, general measures, and local treatment. Like most of his colleagues in the Metropolitan Asylums Board hospitals he was, he said, in favour of comparatively large doses of antitoxin—viz., 4000–8000 units for mild faucial or nasal cases, 12,000–16,000 units for moderate attacks, and 24,000 units, repeated, if necessary, for severe attacks. He preferred intramuscular injection into the vastus externus to any other method, as it ensured a much more rapid absorption of antitoxin than the subcutaneous method, and was much safer and pleasanter for the patient than intravenous injection, which was followed in a large proportion of cases by rigors or shock. While fully convinced of the importance of early administration of antitoxin, having never seen a death from diphtheria nor severe paralysis when antitoxin had been given on the first day of the disease, he could not too strongly denounce the doctrine that antitoxin was of no value after the fifth day of disease. As he had maintained many years previously,[1] clinical rather than chronological considerations should be the guide in the treatment of diphtheria, the presence of membrane in the throat, nose, or elsewhere being an indication for sero-therapy. The chief advance in recent times in the treatment of diphtheria had been the use of a refined or concentrated serum, whereby the incidence of rashes and other unpleasant sequelæ had been reduced to a minimum. The only manifestation of serum sickness now seen was urticaria, the frequency of which, however, had been reduced from 60 to 30 per cent. of the cases injected. The most important principle in the general treatment of diphtheria was the enforcement of rest for a period proportionate to the severity of the initial angina. It was doubtful if any drug had power to modify favourably the course of the disease, though adrenalin appeared to be of value in forestalling or combating the suprarenal insufficiency which played an important part in the syndrome known as cardiac paralysis. Alcohol, which for long had been regarded as indispensable in diphtheria, so far from being of any value in the disease, was liable to increase the myocardial degeneration initiated by the diphtherial poison. In 1927, when no alcohol at all was used in the treatment of diphtheria at the Western Hospital, the case mortality (3·01 per cent.) was lower than in any of the other M.A.B. hospitals.[2] Since the introduction of antitoxin local applications to the throat had occupied a very secondary position in treatment. In a series of 3000 cases Dr. Rolleston had employed local treatment in only 364 (12·13 per cent.). Most of these patients were older children or adults, who welcomed any form of local treatment which younger children as a rule resisted. From comparative observations it had been found that the average period for the throat to become clean after injection of antitoxin was practically the same whether local treatment had been employed or not.

[2] See THE LANCET, 1928, i., 820.

Discussion.

Dr. GRAHAM FORBES (London) gave a summary of diphtheria preventive work in Great Britain up to June, 1928: (*a*) of 44,131 persons tested in council schools and welfare centres, 72 per cent. had proved positive and 40,512 had been immunised; (*b*) of 36,329 persons tested in residential schools, 13,625 had proved positive and 9155 had been immunised; (*c*) of 10,511 members of hospital staffs, 3598 (34 per cent.) had been found positive and 4184 had been immunised. In this total of 91,036 persons of all ages, of whom 53,841 had been immunised, no known serious harmful effect—still less a fatality—had resulted, though a total of at least 300,000 injections had been given.

Dr. E. W. GOODALL (late M.A.B.) marvelled that after so many years there should still be a divergence of opinion on such important questions as the method of administration and the dosage of antitoxin. There could be no question that the serum was brought into immediate contact with the toxin in the blood by intravenous injection, yet when the remedy was first introduced most remarkable results were obtained by the subcutaneous method. The dosage of the early days would be considered insignificant by most modern clinicians. As the result of trial of intravenous injections, and large doses up to 200,000 units, he had come to the conclusion, after a very large experience, that intravenous injection should be reserved for the more severe cases, intramuscular for the moderately severe, and subcutaneous for the benign. He considered that about 30,000 units was the limit of dosage beyond which it was unnecessary to go. As regards serum treatment, every case should be treated on its clinical merits, irrespective of the duration of the illness. It was folly to wait for the result of a bacteriological examination before administering serum. Prolonged rest in the recumbent position was essential if the patient was to be secured from the risk of heart failure during convalescence. He had long been of the opinion that cardiac stimulants were useless in the acute stage.

Dr. JOHN MCGARRITY (Cardiff) said that with the late Dr. Claude Ker he had carried out the Schick test in over 3000 individuals of all ages, including patients, nurses, and medical students during the latter part of 1922, and during 1923 and 1924 in the City Hospital of Edinburgh. At Dr. Ker's suggestion he had immunised with toxin-antitoxin over 300 Schick-positive children in that institution, practically all under 10 years of age. This group showed so little local or constitutional reaction that Dr. Ker advised the public health authorities of Edinburgh that similar measures could safely be employed among the school-children of that city. The work had been begun in 1923, and over 6000 children had now been immunised without any ill-effects. In those days toxin-antitoxin was used, and while few, if any, of the children under 10 years of age were upset in the least by the inoculations, many of the nursing staff, 132 of whom were immunised, suffered severely, both locally and constitutionally, especially those who showed pseudo-reactions when Schick tested. Since the use of toxoid-antitoxin had become general, it was unusual to encounter any reactions at all, even among adults. During the last three years none of the nurses in the Cardiff Isolation Hospital had complained of anything worse than a sore arm and slight headache. In the Cardiff schools some hundreds of children had been tested and immunised since the work began in 1926 without any ill-effects. In Cardiff no child who had given a negative Schick reaction when tested in the schools had up to date developed diphtheria; nor during the last three years had any of the nurses or maids at the Isolation Hospital with a negative reaction contracted the disease. The treatment of diphtheria depended very largely on the early clinical diagnosis and the early administration of a suitable dose of diphtheria antitoxin, although the after-care was very important. Dr. McGarrity's practice was to give an intramuscular injection in doses of from 3000–4000 units for mild cases, 6000–8000 units for moderate cases, and from 10,000–20,000 units for severe cases. He seldom found it necessary to give more than 60,000 units of antitoxin to the most severe cases, but he invariably gave the first dose in severe cases intravenously and the rest intramuscularly. He had found caffeine-sodio-salicylate or camphor the best drugs to use in threatening heart failure, given hypodermically in from gr. ½ to grs. 1 or 2, every two or four hours. He was also in favour of alcohol in small doses. In the treatment of laryngeal diphtheria he preferred intubation to tracheotomy, but did not recommend it for use in general practice. He recommended spoon-feeding rather than feeding by nasal tube in either case.

Dr. CYRIL LEWIS (Cardiff) presided when Prof. T. GILLMAN MOORHEAD (Dublin) opened a discussion on

ACUTE NEPHRITIS.

A study of the reports of the Irish Free State for the last five years showed, he said, that one death in every 231 registered to be due to acute nephritis. In England and Wales over the same period, one death in every 334 was found to be caused by acute nephritis. Owing to the comparative infrequency of the disease, the study of groups of cases was not possible until the Great War period. Prof. Moorhead desired to emphasise at the outset three points in prophylaxis—the common-sense removal of all septic foci, with especial attention to the throat and nasal sinuses; Osman's alkali treatment, which he received with hope but with caution, for Peters had found no significant difference in the onset of [illegible] those treated with and without [illegible] in a series of 8000 cases analysed for the period 1910–22. The third point—the value of scarlatinal antitoxin was still sub judice—but reports up to date were "fairly satisfactory."

The repeated attempts at classification had resulted in a lack of recognising the unity which underlies the varying pathological manifestations of the acute condition. The term nephrosis was not necessary, as he regarded it merely as a variety of acute nephritis identical with the condition called toxæmic kidney by English writers. Rather than have a classification it was wiser to have in mind "the kidney composed of four elements—glomerular, tubular, interstitial, and vascular—and that each element may be involved in a varying degree according to the cause of the inflammation, its severity and its duration, and provided we remember that the functional changes are likely to vary also with the degree of involvement of each of these structures and the severity of that involvement, we will do better as clinicians to recognise one form of acute nephritis only." That staphylococcal toxins are more likely to produce parenchymatous lesions and resultant œdema, and streptococcal toxins glomerular lesions, is not a view that has been convincingly proved, and hæmorrhagic and œdematous cases are by no means invariably clear cut. The value of blood-pressure estimations was stressed, for a rise occurs in all primary acute attacks, and a fall accompanied by a diminution in size of the heart are favourable signs. The only cases that are open to any doubt in diagnosis are cases of anuria with palpable swelling of one or both kidneys and delayed appearance of œdema.

The character of the protein in the urine desires further and closer study; attention was drawn to the work of Kellaway, Davies, and Williams, who suggest that much of the protein present consists of kidney substance in cases of severely damaged kidneys. The estimation of the quantity of protein passed per diem is of value in acute nephritis, but the Esbach's albumino-

ANNUAL MEETING AT CARDIFF.

(Continued from p. 469.)

SECTION OF MEDICINE.

Dr. A. FERGUS HEWAT (Edinburgh), Vice-President of the Section, took the chair at a discussion on the

PREVENTION AND TREATMENT OF DIPHTHERIA.

Dr. J. D. ROLLESTON (M.A.B.) considered prevention under two headings: (1) general measures, including isolation, disinfection, and treatment of the carrier; and (2) specific immunisation. Although it was doubtful whether isolation of diphtheria patients in special hospitals had had much effect in reducing its incidence, it was generally agreed that diphtheria required such treatment more than any other disease admitted to fever hospitals. There was a growing tendency among medical officers of health, medical superintendents of fever hospitals, and other sanitary authorities to discredit the value of terminal disinfection after diphtheria, and to regard the living carrier as responsible for the spread of the disease. The period of isolation of a patient should be determined by clinical considerations. In the absence of any discharges from the nose or ear or acute inflammatory condition of the throat, a patient who had had a mild attack might be set at liberty at the end of a month. In cases of any degree of severity the patient should be detained at least six weeks, as during that time some form of paralysis was most likely to develop. No uniformly successful method had yet been discovered for dealing with the carrier. The most efficacious measures were tonsillectomy and treatment of sinus infections, but they were not always practicable nor invariably successful. The practice of insisting on one or two negative faucial and nasal cultures before discharging a patient was merely illusory, as owing to the frequent occurrence of intermittency in the carrier state a false sense of security might arise from obtaining such cultures. As the return case rate was no higher in those hospitals which had abandoned the practice of swabbing patients before discharge than in those in which it was still observed, Dr. Rolleston had discontinued the practice at his own hospital since his appointment as medical superintendent two and a half years ago, without finding that this discontinuance had been followed by an increase in the return case rate. Specific immunisation against diphtheria was either passive, by injection of small doses of antitoxin, or active, by injection of toxin-antitoxin or similar preparations. The immunity conferred by passive immunisation, though immediate, was only of short duration, and the injection of antitoxin also predisposed the individual to an unusually severe reaction when a therapeutic dose was needed in the course of the next few years. Dr. Rolleston said that in hospitals and in families where the children could be kept under close observation after exposure to infection he did not think it necessary to carry out passive immunisation, though he was aware that in some clinics, especially on the continent, it was the practice to administer prophylactic doses of antitoxin with or without a preliminary Schick test, on the occurrence of a single case of diphtheria in a children's ward.

In carrying out active immunisation, which conferred a more durable and possibly permanent immunity, it had recently become the practice, especially in public health work in dealing with children under 6 years of age, to dispense with the preliminary Schick test, as the great majority of them were susceptible to diphtheria. In adults, on the other hand, who were more likely to react severely, a preliminary Schick test was necessary. In a large number of fever hospitals it was now the rule to carry out active immunisation of the nursing staff on joining. Since the introduction of active immunisation of newcomers the incidence of diphtheria among the nurses at the Western Hospital (Metropolitan Asylums Board), though it had never been very high, had shown a slight fall. Attacks of diphtheria occasionally did occur in nurses whose Schick reactions were negative either spontaneously or as the result of immunisation. This was probably due to nurses being exposed to massive doses of virulent infection, whereas other negative Schick persons who were exposed to only slight and occasional infections escaped. In addition to protecting nurses, active immunisation was indicated in schools, creches, orphanages, and other collections of children. Although no fatal accidents following active immunisation had occurred in this country, as they had in the United States, Austria, China, and Russia, the local reaction and constitutional disturbance were often severe. Owing, therefore, to the occasional failure to protect, and the possibility of severe reactions, Dr. Rolleston had been unwilling to make active immunisation against diphtheria compulsory, like vaccination against small-pox, especially as diphtheria antitoxin was an infallible remedy within the first 24 hours, whereas in small-pox no treatment, however early it was employed, invariably modified the course of the disease.

Dr. Rolleston discussed the treatment of diphtheria, in order of importance, under the headings of serum therapy, general measures, and local treatment. Like most of his colleagues in the Metropolitan Asylums Board hospitals he was, he said, in favour of comparatively large doses of antitoxin—viz., 4000–8000 units for mild faucial or nasal cases, 12,000–16,000 units for moderate attacks, and 24,000 units, repeated, if necessary, for severe attacks. He preferred intramuscular injection into the vastus externus to any other method, as it ensured a much more rapid absorption of antitoxin than the subcutaneous method, and was much safer and pleasanter for the patient than intravenous injection, which was followed in a large proportion of cases by rigors or shock. While fully convinced of the importance of early administration of antitoxin, having never seen a death from diphtheria nor severe paralysis when antitoxin had been given on the first day of the disease, he could not too strongly denounce the doctrine that antitoxin was of no value after the fifth day of disease. As he had maintained many years previously,[1] clinical rather than chronological considerations should be the guide in the treatment of diphtheria, the presence of membrane in the throat, nose, or elsewhere being an indication for sero-therapy. The chief advance in recent times in the treatment of diphtheria had been the use of a refined or concentrated serum, whereby the incidence of rashes and other unpleasant sequelæ had been reduced to a minimum. The only manifestation of serum sickness now seen was urticaria, the frequency of which, however, had been reduced from 60 to 30 per cent. of the cases injected. The most important principle in the general treatment of diphtheria was the enforcement of rest for a period proportionate to the severity of the initial angina. It was doubtful if any drug had power to modify favourably the course of the disease, though adrenalin appeared to be of value in forestalling or combating the suprarenal insufficiency which played an important part in the syndrome known as cardiac paralysis. Alcohol, which for long had been regarded as indispensable in diphtheria, so far from being of any value in the disease, was liable to increase the myocardial degeneration initiated by the diphtherial poison. In 1927, when no alcohol at all was used in the treatment of diphtheria at the Western Hospital, the case mortality (3·01 per cent.) was lower than in any of the other M.A.B. hospitals.[2] Since the introduction of antitoxin local applications to the throat had occupied a very secondary position in treatment. In a series of 3000 cases Dr. Rolleston had employed local treatment in only 364 (12·13 per cent.). Most of these lying factor in cases of resistant œdema. The chemistry of the urine should not be neglected—much knowledge can be gained by the simple urinary observation on the progress of nephritis cases by repeated examinations.

---

[1] THE LANCET, 1907, i., 1112.

[2] See THE LANCET, 1928, i., 820.

Dr. R. L. **Mackenzie Wallis** (London) dwelt on the means of distinguishing a toxic and an inflammatory condition of the kidneys. He has found that in toxic kidneys the main diagnostic features are a low blood-urea, a raised diastase content of the urine, and the presence of a relative excess of globulin in the urine. Dr. Wallis finds that the administration of HCl orally is very helpful in reducing the blood-urea in cases of acute nephritis.

Dr. A. F. S. **Sladden** (Swansea) wished to stress that all laboratory tests in all pathological states were only auxiliary and secondary to clinical observation. He had found the estimation of ammonia in the urine to be valuable in estimating the progress—as it was diminished in acute nephritis, and when conditions improved the excretion of NH_3 increased.

Dr. J. **Wilkie Scott** (Nottingham) remarked that rise of blood pressure seemed now to be generally regarded as an important factor in the attacks of convulsions and unconsciousness. He had found great benefit from venesection both in uræmic attacks and in eclampsia when the pressure was high. In acute suppression of urine of more than 36 hours' duration the advisability of capsulotomy should be considered.

SECTION OF SURGERY.

Pancreatitis.

Mr. J. W. **Geary Grant** (Cardiff) opened the discussion. The term "pancreatitis" had been deliberately chosen in order to include the many varieties of this rather rare disease. His own remarks were based on personal experience of six cases seen in the last two years. He proposed to limit himself to acute necrosis of the pancreas. This term was preferred because it did not beg the question of a primary inflammatory origin and did not postulate hæmorrhage as a necessary part of the picture. The pancreas possessed two ducts which varied in their relative size and might, or might not, anastomose. The main duct of Wirsung joined the bile-duct about 4 mm. from the duodenal opening, the distance varying from zero to 11 mm. The text-books described four types, shown by Brocq to be four stages, of acute pancreatitis: œdematous, hæmorrhagic, gangrenous, and suppurative. Some of the suppurative cases were probably examples of primary infection, others were secondary infections following on necrosis of the gland. In studying papers and case reports on acute pancreatitis striking differences were found in types of disease and mortality in different clinics and also wide divergence of views on ætiology and treatment. Pancreatic necrosis depended on the setting free of the secretion and its activation in the ducts of the gland. For this it was necessary that the pancreas should be in the phase of secretion and that the proferments should be activated by some agent. The importance of the first condition was shown by Brocq's experiments, in which bile, injected up the duct of Wirsung, failed to produce pancreatitis unless the dog had previously had a full meal. Clinically sudden onset of the disease often followed a heavy meal. Activation of the proferments could be brought about by normal bile or, better, bile deprived of its mucus or concentrated, by succus entericus if it gained access to the gland through a patent duct of Santorini, and probably by products of cytolysis of gland cells and leucocytes, calcium salts, and bacteria. It was therefore probable that acute necrosis could occur in more than one way. At present three main theories were held concerning it: 1. Vascular, due to embolism or thrombosis of pancreatic vessels. Experimental evidence gave no support to this view. 2. Infective. This theory, strongly supported by Deaver and Maugeret, and lately by Graham and others, held that infection spread by way of the lymphatics from the gall-bladder to the head of the pancreas. Against this theory it might be said that in the vast majority of instances the hæmorrhagic fluid in the general abdominal cavity and in the lesser sac was sterile. Experimental infection of liver and gall-bladder with staphylococci did not produce pancreatic necrosis. Infections of the gall-bladder were common; if they were the cause acute necrosis should be more frequent than it was. Gastric and duodenal ulcers were not followed by pancreatitis, although infection might be conveyed to the pancreas in these conditions. 3. Theory that necrosis caused by regurgitation of bile up the pancreatic ducts. Brocq and Binet found that when the duct of Wirsung in the dog was divided and left open in the peritoneal cavity, fat necrosis did not ensue, but if the secretion was allowed to mix with bile hæmorrhage and steato-necrosis followed. The activating agent in the bile was the glycocholate of soda. The probable mechanism by which bile regurgitated into the pancreatic duct was the impaction of a small calculus in the bile papilla and several such cases had been reported. For the bile to reach the pancreas the stone must block the papilla without blocking the duct of Wirsung. This could only occur in a certain number of people where the length of the ampulla was at least twice the diameter of its opening into the duodenum, but as acute pancreatitis was comparatively a rare disease the theory would not be invalidated on that account. Spasm of the sphincter of Oddie might cause regurgitation of bile if it embraced the common duct distal to the junction of the duct of Wirsung. Another way in which secretion in pancreatic ducts could be activated was by the forcing of duodenal contents with succus entericus into the valveless duct of Santorini during violent vomiting. A rare cause of pancreatitis was the entry of an ascaris into the duct of Wirsung. A few cases had followed various abdominal operations and were due to injury to the pancreas or ducts.

Diagnosis might be very difficult especially in the "formes frustes" of the disease. The speaker felt that the teaching that acute conditions of the gall-bladder should be allowed to settle down before operation was entirely wrong, for pancreatic disease was often present. If there was any suspicion of the pancreas being involved it should be inspected at operation. With regard to treatment abdominal drainage in the region of the pancreas, incision of the gland, gauze tamponage and drainage, or either treatment with drainage of the biliary tract had all given good results. Under no conditions should the gall-bladder be removed. The administration of aspirin and hexamine might do good.

Mr. **Digby Chamberlain** (Leeds) confined his remarks to acute pancreatitis. At Leeds they had had experience of 21 cases in the last ten years. The condition was probably not as uncommon as was thought for many cases settled down without operation. They all knew of cases of gall-bladder disease which had settled down, and later when they were operated on a swollen pancreas was found with fat necrosis. He was unable to differentiate between the cases which should be operated on and those which should not. In all of his cases except one he had found an infected gall-bladder with stones. Bile taken at operation in four cases had contained a hæmolytic streptococcus. The cyanosis, which was so often present, was not the result of septicæmia as had been suggested because no methæmoglobin was found in the blood. It was due to impaired action of the diaphragm and was found in other conditions besides pancreatitis. The diastatic index in the urine was important in diagnosis. For treatment he advised immediate operation with drainage of the gall-bladder as well as of the pancreas. The ideal was to drain posteriorly, resecting the eleventh rib in the mid-axillary line, but generally the patient could not stand the extra ten minutes involved in this procedure. He protected the abdominal wall from the action of gastric juice by painting with rubber meter is quite unreliable—the readings of which vary widely with the temperature. Dr. Moorhead thought that the progress of the case and the immediate prognosis may be better determined by blood-urea estimation than by any other laboratory examination. Discussing the question of chlorides and their absence from the urine, he regarded it the result of a locking-up of chlorides in the body due to tissue demand rather than to renal failure. A slight acidosis, due to diminution of the sod. carbonate content of the blood, is also present—an observation which had been foreshadowed long ago by clinicians who knew that it was more difficult to make the urine alkaline in acute nephritis than in health.

An increase of phosphates in the blood is associated with the development of toxic symptoms, and the return of the phosphates to a normal level is of favourable significance. This is the basis of von Noorden's special recommendation, that large quantities of calcium be given to all cases of nephritis taking milk as their stable diet, for the phosphoric acid content of milk is high.

Changes also occur in the cerebro-spinal fluid in acute nephritis—it is under increased pressure—an increase of urea and an increased protein content. Writers have also remarked on the high chloride content of the cerebro-spinal fluid in nephritis, and that a high chloride value is invariably found in uræmia. Regarding *prognosis*, by far the largest number of cases pursue a favourable course. In the experience of Dr. Moorhead, those cases which present the greatest increase of blood pressure recover most rapidly. He refers to the observation of de Wesselow, that 70 per cent. of the war nephritis have recovered completely, and also the work of Hume and Nattrass, who showed a recovery in 77 per cent. in war cases, but only 45 per cent. recovery in acute cases in the period 1922–25. In judging these cases following an acute attack, functional tests are most valuable, but he cannot agree with some writers who have stated that provided these tests are normal, a persistent albuminuria can be discarded, for, in his opinion and experience, they remain poor in health and are liable to intercurrent infections.

Speaking on treatment, Dr. Moorhead thought that the rigid rests in bed treatment had been overdone; provided there is no hæmaturia, cases with albumin in the urine and œdema often improved when they are allowed to get up. For the few days of the acute condition, when there is frequently anorexia, small quantities of milk and water, to which a little calcium carbonate has been added, satisfies. Later, carbohydrates can be increased, followed by a gradual increase in the protein intake; but restriction in protein intake is recommended for some time, even when there is almost complete recovery. No drug treatment is required apart from the giving of mild diaphoretics and purgatives. The kidney should not be stimulated. Ammonium chloride, so warmly recommended by the Mayo Clinic, has not proved successful, and novasurol should most certainly be used with great caution in renal œdema. "When coma develops, either subsequent to or independent of epileptiform convulsions, and when all ordinary measures, such as hot packs, the use of pilocarpine in small doses, and purging, fail to produce rapid improvement, venesection should be performed." Dr. Moorhead also advocated lumbar puncture in acute nephritis, complicated with nervous phenomena; he has always found it to be beneficial and that it has never resulted in any harmful effects. He has not obtained any satisfaction in the use of Fischer's solution, and the injection of plain sodium chloride and of sodium citrate solutions can be justified only as diluents of retained toxins. Morphia—the sheet-anchor for the allied condition, eclampsia—should be used in the treatment of convulsions; although having been under suspicion for long it is both safe and satisfactory.

Dr. H. LETHEBY TIDY (London) dealt with

Acute Hæmorrhagic Nephritis

the form of nephritis of which the outstanding and frequently the only characteristic of which is renal hæmorrhage. It is the condition described by Hale-White in 1911 as essential renal hæmaturia. All hospital records show that it is a common disease—in fact, that it is commoner than "acute parenchymatous nephritis." Cases may attend in an out-patient department once or twice and then, owing to the absence of any symptoms, disappear permanently. It is most common in children and young adults, and a throat infection is present in 75 per cent. of the cases. There is either a frank tonsillitis or a marked adenitis. Predisposing infections are not so commonly found in adults, and that is why such cases are investigated surgically. Renal hæmorrhage is frequently sudden, and a large amount of blood may be passed in the urine. Bacteriological examinations are nearly always negative—but sometimes the same organism is isolated from the urine and from the pus from an abscess in the neck. The classical symptoms of acute nephritis are absent. Œdema is usually entirely absent; when present, it is only a slight puffiness of the eyelids or more often a pallor of the face with a puffiness of the forehead. The hæmaturia disappears rapidly in the majority of cases—in some, especially in children, in whom it has remained for three to four weeks, it quickly disappears after tonsillectomy. The large majority of the cases recover completely, but a small number, about 5 per cent., remain with definite evidence of renal deficiency after the lapse of some years. These are the cases in whom the initial attack caused anxiety by general signs of ill-health, persistence of albumin and hæmaturia, and defective urea, concentration tests. This small group advances to chronic interstitial nephritis, eventually dying of uræmia. The pathogenesis of acute hæmorrhagic nephritis is uncertain, but, in general, the group appears to be intermediate between a nephritis and a hæmorrhagic state. The condition may be defined as an acute glomerulitis (Fahr described it as a "diffuse capillaritis of the glomerular loops"). Similar changes are seen in the kidneys in subacute bacterial endocarditis. But, unlike this condition, bacteria are not found in the affected glomeruli, and the urine is practically always sterile in hæmorrhagic nephritis. Again, the hæmorrhage is usually only microscopic in subacute endocarditis. It may be definitely stated that acute hæmorrhagic nephritis is not due to bacterial emboli. The diagnosis is easy in children, but in adults the surgical causes of hæmaturia have to be excluded before such a diagnosis is made.

Discussion.

Dr. HUGH GAINSBOROUGH (London) emphasised the importance of focal infection in acute nephritis, and is in agreement with Gray's explanation of the special sensitivity of the kidney to circulating organisms and toxins being caused by the concentration of the blood in the glomeruli and of the toxins in the tubules. Histological evidence of glomerular damage is too coarse a test, and the glomeruli may be injured in the sense of altered permeability, and yet appear normal when viewed by the microscope. This plus the evidence of experimental nephritis speaks against the arbitrary division of nephritis into glomerular, glomerulo-tubular, or pure tubular forms. We cannot yet explain why an acute nephritis becomes chronic—whether it is because of the severity of the original injury, or because of the continuance of the toxic factors, or as a result of metabolic changes brought about, for example, by the continued albuminuria. The metabolic disturbances in acute nephritis are more easily studied in subacute forms, where the disturbances are less transitory though similar in nature. The hypercholesterolæmia is as yet unexplained—the albuminuria may be important in this relationship.

Dr. A. E. GOW (London) emphasised the varying incidence of nephritis in scarlet fever at various periods. He regarded the classification of the different forms of nephritis to be important, and stressed the essential differences between the focal and the diffuse type of nephritis. He also called attention to the possible presence of syphilis as the possible under-concentration of various substances was not equally lowered; chlorides were least affected and urea was less affected than phosphate or creatinine. In the fall of concentration due to renal failure there was diminished chloride excretion, the concentration of chloride falling below that in blood plasma. Defective excretion of urea was not always recognised unless special tests were used, but it was easy to do this.

Dr. **HUGH H. YOUNG** (Baltimore) spoke of the services rendered by Colonel Fullerton to members of the American Medical Corps during the war. He agreed that much that was in text-books concerning urology should be rewritten. The discovery of reflex diuresis by Prof. Fullerton was very important. Dr. Mayrs's work was new and of great interest. He endorsed the remarks which had been made on the subject of pain. He himself had seen a number of cases in which pain was absent. In one of these, seen with Sir Wm. Osler, a calculus the size and shape of a cigar was found in the ureter.

Mr. **KENNETH WALKER** (London) emphasised the value of the wax-tipped bougie in cases where X rays did not reveal the calculus.

Mr. **SWIFT JOLY** (London) spoke of cases of silent stone in which the only symptom was pyuria. Symptomless pyuria was due to stone. X rays afforded the best means of diagnosis at the present time.

Mr. **J. B. MACALPINE** (Manchester) showed two lantern slides of a stone which, although not visible at first with X rays, was located with a catheterisation pyelogram.

SECTION OF OBSTETRICS AND GYNÆCOLOGY.

THE DIAGNOSIS AND TREATMENT OF STERILITY.

Dr. **ARTHUR E. GILES** (London) opened the discussion from the point of view of the general practitioner. The correct diagnosis, he said, depended upon a thorough and systematic investigation of the anatomical and physiological features affecting the transit of spermatozoa from the vagina to the Fallopian tube, the fertilisation of the ovum, and the transit of the fertilised ovum from ovary to uterus. Sexual maturity was indicated by general appearance and the development of the breasts and pubic hair. The vagina and uterus must be normal, and the tubes and ovaries not obviously abnormal, and there must be a history of regular and normal menstruation. If coitus were accompanied by normal desire and sensation it might be assumed that the ovaries were sufficiently developed and the endocrine function normal. Intercourse might have been impossible through want of virility in the man, but there were several possible reasons why it might be too painful for the woman. These included actual obstruction due to absence of the vagina or imperforate hymen; anatomical tenosis or functional spasm of the vagina (vaginismus); ores, abrasions, or vulvo-vaginitis. In tubo-ovarian nflammation or ovarian prolapse pain might be the sult of deep pressure. The os externum, to receive e spermatozoa, must be duly patent. Complete clusion was rare, but wide dilatation was not essential. Nevertheless conception often took place even when no opening was apparent, and a good aphorism was: "Do not say that a woman cannot become pregnant until you have youself removed her uterus and ovaries, and even then it is wiser to say it is improbable." Marked retroversion and acute anteflexion turned the cervix unduly forward, and during intercourse the external os was virtually shut off from contact with the semen by being pressed against the anterior vaginal wall. Rectification of the position of the cervix was often quickly followed by conception. The vaginal discharge might be strongly acid, and if not adequately neutralised by the cervical secretion might enfeeble or kill the spermatozoa. The only certain way of determining whether live spermatozoa were entering the cervical canal was microscopical examination of its contents two hours after intercourse.

The healthiness of the uterus was indicated by the clarity of the drop of mucus from the external os; a muco-purulent appearance suggested endometritis, which if serious might destroy sperm-cells. Even a mild salpingitis might seal up the tubal opening into the uterus; this could be detected by insufflation. There were no means of telling whether healthy ova were maturing and being received into the tubes, nor adequate knowledge of the conditions governing ectopic pregnancy and failure of an ovum to develop after the stage of nidation. Endometritis might allow impregnation, but forbid healthy placentation.

Treatment.

It was important to recognise the conditions in which sterility was incurable, so that the husband and wife might accept the fact and avoid constant alternation of hope and disappointment. Undersized uterus was not necessarily a bar; its growth was delayed rather than arrested, and the stimulus of marriage might be the best treatment. Thyroid might be given by the mouth, but ovarian substance must be injected, as it was destroyed in the stomach. Pronounced obesity should be reduced by diminishing intake. A rigid hymen should be excised; dilatation under an anæsthetic might remedy vaginal stenosis or vaginismus, and causes of pain should be abolished. If the husband had healthy spermatozoa, but could not introduce them, artificial insemination might be attempted. In dilating an unduly contracted os incisions should be avoided. "Nil nocere" was a good maxim. The remedy for marked anteflexion of the cervix was moderate dilatation with concomitant straightening of the uterus; the patient went to bed for 10 or 12 days with a glass intra-uterine stem pessary in place. Retroversion or retroflexion should be corrected so that the cervix was in a normal position during intercourse. If displacement returned, a Hodge pessary was a possible temporary measure, but it should not be worn for long, and operation was advised for persistent displacement. Noxious discharge was due to adenomatous disease of the vaginal aspect of the cervix or to endometritis, especially of the cervical type; the former should be treated by suitable applications, the latter by curetting, which should be performed thoroughly but gently. In swabbing the uterus afterwards strong reagents should be avoided. Tubal obstruction called for surgery. Endocrine inadequacy might now be detected by the chemical pathologist.

Dr. **SIDNEY FORSDIKE** reported that the semen had been defective in 46 out of 164 men whose wives had complained of sterility.

Insufflation.

Exploration of the uterus by dilatation of the cervical canal should only be undertaken if the tubes were known to be normal. It gave no information in the absence of symptoms and signs, but sometimes succeeded as a therapeutic measure. Inflation of the uterus and tubes, as introduced by Rubin in 1919, had become a diagnostic measure of the first importance, but was counterindicated by any signs of infection in the pelvis. Anæsthesia was only necessary when instruments could not be passed through the os. He used a pressure of up to 300 mm. on conscious patients if they did not complain, for if no air passed at that pressure the tubes were definitely closed. The same pressure was admissible under anæsthetic with the abdomen open so that it was possible to see what was happening, but he did not apply more than 200 mm. when the safeguard of tension pain was absent. Tubes might be temporarily blocked by kinking. It was all-important to decide upon the site of obstruction before undertaking any operation, for plastic operations upon the narrow part of the tube were not justified, but cases of closure of the fimbriated end offered some prospect of success. The most favourable were those in which the fimbriæ could be saved. The ovary should be freed and loosely fixed in the mouth of the new ostium.

dissolved in ether. The speaker believed in the infective theory of pancreatitis, the infection travelling from the gall-bladder via the lymphatic glands of the hilum. The pancreatic duct was guarded by a very efficient valve. The wall between it and the bile-duct became thinned out into a flap which acted as a valve so that regurgitation of bile could not take place. In gastric ulcer the pancreas was protected by fibrous tissue forming on the floor of the ulcer.

Dr. MACKENZIE WALLIS (London) said he had been interested for a number of years in the diagnosis of pancreatitis. In 1920 he had published the results of a long series of investigations on tests for pancreatic function and his conclusions had since been confirmed by others. No individual test was pathognomonic but three—namely, the diastase content of the urine, Loewy's test, and glycosuria if taken together gave a reliable index of pancreatic disease. These tests could be rapidly performed. If time permitted the findings might be confirmed by the finding of excess of undigested fat and muscle-fibres in the stools. The fleeting character of the tests must be borne in mind. They might be positive one day and negative the next. The results were often discarded because this was not recognised. Glycosuria fluctuated exceedingly, but the same was true of the diastase test. The speaker gave examples. In one case the diastase content fell from 200 units to 10, then rose again to 220, and finally remained constant at 10. He regarded these rises as due to recurrent attacks of subacute pancreatitis. The Loewy test was of no value by itself, but useful in conjunction with the others. In chronic pancreatitis the tests were of value, but here complete chemical examination of the stools was indicated. Catarrhal pancreatitis was common in association with jaundice. It also occurred after removal of the gall-bladder; hepatic bile was irritating because it contained no mucus, bile from the gall-bladder was non-irritating. If hepatic bile regurgitated into the pancreatic duct catarrhal pancreatitis followed. Diarrhœa and nausea after removal of the gall-bladder were due to this. Duodenal intubation gave important information especially in chronic interstitial pancreatitis. Cyanosis was due to acidosis set up by fat necrosis. The treatment was to place gauze soaked in horse serum in contact with the tissues. Horse serum had great capacity for absorbing pancreatic ferment.

The President, Prof. A. W. SHEEN (Cardiff) described pancreatitis following parturition and asked whether members had seen similar cases. He commented on the rapid pulse of pancreatitis.

Mr. F. C. PYBUS (Newcastle-on-Tyne) spoke on diagnosis and laid special stress on subscapular pain as a symptom in pancreatitis. Pain under the left subscapular was diagnostic unless ulcer on the lesser curvature of the stomach was present. Rapid pulse and cyanosis were also important. The pancreas should be remembered when dealing with any lesion in the upper abdomen and in anomalous cases of gall-stones, especially if the symptoms were worse than the diagnosis suggested.

Prof. A. H. BURGESS (Manchester) had had 21 cases in the last four years. The mortality was 20 per cent. Contrary to text-book teaching, males preponderated and the mortality amongst them had been much greater—44 per cent. compared to 16 per cent. in females. The disease was commoner than was generally supposed. A swollen pancreas and fat necrosis were often found in operations for gall-stones. There was usually a history of previous attacks and this was true of cases in which no gall-stones had been found.

Prof. A. FULLERTON (Belfast) said that all grades of pancreatitis existed between fulminating and mild cases. In his cases the outstanding feature had been the severity of the pain. Cyanosis was not marked. Even after sloughing of a large piece of the pancreas patients might do well.

Mr. R. ST. L. BROCKMAN (Sheffield) gave an account of a remarkable case of cyanosis in acute pancreatitis. He saw the man one and a half hours after the onset of abdominal symptoms. The patient was the colour of a boiled lobster and the colour had come on since the pain. Soon after the red colour changed to typical cyanosis. The speaker refrained from touching the pancreas at operation. He drained the gall-bladder and, if necessary, put a tube in the pelvis.

Mr. A. W. ADAMS (Bristol) described cases of pancreatitis following pregnancy.

Mr. GRANT replied. He did not agree with Mr. Chamberlain's conclusions, for in many cases both gall-bladder wall and bile were sterile. If the condition was due to hæmolytic streptococci the logical thing would be to remove the gall-bladder, but if this were done the patients died.

DIAGNOSIS OF URETERIC CALCULI.

The discussion was opened by Prof. FULLERTON. He said that contrary to text-book teaching the main constituent of his calculi was calcium oxalate. The symptoms of hæmorrhage and pain were easily accounted for. It was rare for a ureter to be completely blocked by a calculus but reflex anuria might occur. A remarkable phenomenon was reflex polyuria on the affected side. This sign was extremely important in diagnosis. It might be the only sign incriminating the kidney and the speaker described cases to illustrate this. Out of 20 undoubted cases of ureteric calculi with no renal stones diuresis, with diminished specific gravity of the specimen taken by ureteric catheter, was present on the affected side in 70 per cent. The explanation of both anuria and diuresis was afforded by a study of the vasoconstrictor and vasodilator nerves to the kidney. The stimulus of a calculus might cause vasoconstriction and reduction of secretion of urine on that side, or vasodilatation with increased blood flow and diuresis.

Pain was often due to distention of the renal pelvis, and the pain due to passage or arrest of a ureteric calculus could not be distinguished from that due to a renal calculus lodged in the pelvis of the kidney. A precisely similar calculus might give rise merely to discomfort in one patient while in another there might be the severest pain. The site of pain was extremely variable. In one patient it was in the knee, in another it radiated from the lumbar region to the shoulder and head. Pain in the iliac fossa was common and surgeons should be careful not to mistake ureteric calculus for chronic appendicitis. Frequency of micturition was not necessarily present. Hæmaturia might be the first symptom and in rare cases the only symptom of calculus, but might for a time be absent. In taking a specimen for examination it was important not to use a catheter, for any instrument might draw microscopical blood. In the clinical examination of the patient great care must be taken to exclude other abdominal conditions. A stone in the lower end of the urethra could frequently be felt through the rectal or vaginal wall. The speaker then discussed X ray diagnosis, and finally described the cystoscopic appearances. Changes at the ureteric orifice were present in 20 out of 50 cases and sometimes the calculus itself could be seen.

Dr. E. B. C. MAYRS (Belfast) gave the results of analyses of urine obtained by catheterisation of the ureters in 50 cases. Such an analysis seldom failed to distinguish between the normal and the affected kidney. Urines collected from the two kidneys were not always identical in volume and composition, but in normal kidneys the differences were small and were due to irritation from the catheters. Unilateral diuresis of reflex origin could be produced without injury to the kidney. The most important problem was to distinguish reflex diuresis from loss of concentrating power due to insufficiency of kidney epithelium. In diuresis the urine became more like blood plasma for the kidney had less time to produce alterations in the glomerular filtrate. But the strongly to the term "giving the patient the benefit of an exploratory operation." The surgeon might benefit; the patient was very often merely condemned to an added injury. "Open and see" was foolish and might be criminal.

For the gynæcologist the most common abdominal emergencies were hæmorrhage, infection, and thrombosis or strangulation. These required most careful differentiation. The two guiding principles were: (1) to make a meticulous inquiry into the history of the onset—this was often more valuable even than examination, and (2) to pass a catheter and examine the resulting urine. The chief symptom was pain. Pain was not always a liar, as Rochefoucauld had said, but the abdomen should never be opened for pain alone. By far the most important sign, qualitative and quantitative, was the abdominal facies, which never lied. In peritonitis it was anguished and apprehensive: in hæmorrhage it was pallid and waxy, and the muco-cutaneous line of the lip stood out with undue prominence. The ashen face of shock and the cyanotic face of severe toxæmia were also distinctive. It was important to note the patient's attitude. If the lesion were intraperitoneal, she lay on her back with the knees flexed, and any movement was a torture. If she could move readily and turn on her side, there was no grave abdominal lesion.

Hæmorrhage.—The commonest site of this was a ruptured tube, but it might also occur from a ruptured Graafian follicle, or from the rupture of a uterus in labour, or from perforation by a sound or curette. The history was all-important, and in ectopic pregnancy might be lacking altogether. The usual time for rupture from this common cause was between the seventh and twelfth weeks, and the most dangerous situations were the isthmus and cornua. The picture of the cataclsymic case was a rapid pulse, subnormal temperature, and air hunger; the abdomen was frequently tender and sometimes tympanitic. The clot could sometimes be palpated in the pouch of Douglas. The abdomen should be opened, a transfusion given, and the tube removed. A case four or five days old gave the picture of widespread peritonitis and bowel obstruction. In a so-called "chronic" case there was a rapidly growing mass on one side or other of the uterus; decidual casts facilitated diagnosis. A leucocyte count of 20,000 pointed to hæmorrhage rather than inflammation. An exploratory colpotomy did little damage and was useful; if dark blood were found, the abdomen should be opened at once.

Acute Infections.—The distinction between appendicitis and a tubal inflammation was all-important, for, while an infected appendix should be removed at once, it was a surgical disaster to open the abdomen for acute salpingitis. Prof. Chipman detailed the signs and symptoms on which a differential diagnosis should be founded. When in doubt, he said, watch and wait, hour by hour.

Thrombosis or Strangulation.—Patients were frequently aware of the presence of the neoplasm, which was usually an ovarian cyst or a fibromyoma. Pain was severe and colic-like but short in duration. If the condition were severe or examination delayed, the signs of peritonitis, due to infection from the colon, might be superadded.

In suspected bowel obstruction the hernial orifices should be examined. Intussusception was usually confined to the young and adolescent. Iliocæcal tumour led to a discharge of blood from the bowel; left-sided lesions might be palpated, and their symptoms were intermittent colic, altered bowel pattern, constipation, and sometimes vomiting from antiperistalsis. Diverticulitis of the lower colon was a lesion of old age and caused diarrhœa and fever. Stone in the ureter or renal pelvis was a common cause of the surgical violation of the abdomen.

In conclusion, said Prof. Chipman, the function of the good surgeon should be to diminish surgery.

Dr. EVERARD WILLIAMS (London) divided acute pelvic lesions into those accompanied by fever and shock respectively. Of the former, pyosalpinx or salpingitis might be suspected when a bilateral tumour or marked uterine tenderness occurred in a woman of child-bearing age. Operation should be delayed until the inflammatory process had become well established, as it was almost certainly a localising mechanism and not to be interfered with until it had obviously failed in its purpose. Acute pneumococcal peritonitis might simulate salpingitis, and its earliest symptoms might be referred to the pelvis. Signs on the right side alone made it necessary to distinguish between appendicitis and salpingitis. The latter was the last stage in a morbid process, evidence of which was usually to be found in the lower part of the tract. Left-sided symptoms, suggesting a tubal lesion, might be due to diverticulitis. X rays were of considerable aid in differential diagnosis, which was often complicated by œdema and hyperplasia.

The commonest lesion to be accompanied by shock was ectopic pregnancy. Few of the recent diagnostic aids were of much value; the phloridzin test indicated pregnancy only and the "shoulder pain" test gave positive results in other conditions. The diagnosis from torsion of the pedicle of an ovarian cyst was difficult. Other acute abdominal conditions causing shock were acute hæmorrhagic pancreatitis, volvulus of the small intestine during early pregnancy, and acute appendicitis. The importance of the early symptoms was exaggerated. The more urgent the symptoms of internal strangulation, the less likely was the lesion to be a strangulated cyst alone; some other condition was probably present. The two rules to follow were thorough examination of the whole abdomen and pelvis and, if the abdomen were opened, a thorough exploration of all the organs that might be diseased. The practice of removing the appendix through a "button-hole" incision was a bad one, as it allowed for no examination of the other organs.

Discussion.

Mr. L. C. RIVETT said that coliform infections were in his experience rare, and that the genital tract probably had a high degree of resistance to bowel organisms. Colpotomy entailed a great risk of infection of the blood mass. Like his colleagues, Mr. V. Bonney and Mr. A. Bourne, he was in favour of early operation on the tube. To wait until it became chronic lengthened the illness, and tubes were left alone, because of apparent subsidence, for years. They then presented one of the most formidable operations in gynæcology. Surely the tube was causing the peritonitis, not protecting from it? He believed, however, in leaving an acute ovarian cyst for a time.

Prof. J. HENDRY pronounced strongly in favour of leaving tubal infections alone for weeks or even months; this made a much easier and more satisfactory operation and allowed the patient to benefit by her own healing power. A valuable aid in determining the time of operation was the blood sedimentation rate; until this had absolutely returned to normal he did not like to operate. He himself treated ovarian cyst conservatively, giving complete rest and morphia for 24 to 48 hours. The patient was then much better able to tolerate operation. If left too long, however, torsion and multiple adhesions developed and the result to the patient was grave and unnecessary illness. The symptoms might pass as colic for months.

Dr. GRAY WARD (New York) voiced the strong American opinion against operation in acute salpingitis. The appendix could be dispensed with; the loss of the tubes meant sterility. Moreover, to wait gave the patient a better chance of surviving the operation if there had to be one. If it were to become the fashion to wear the tubes and ovaries outside, like the male genitalia, general surgeons would be less ready to operate radically.

Dr. A. GILES agreed with Dr. Williams in condemning the button-hole incision. His experience of tubal infection had been that the operative risk

Another valuable method was X ray examination with lipiodol, which was injected until the patient complained of tension pain.

Small ovarian cysts might prevent ova from ripening by pressure and distortion, and a limited peritonitis might veil off the ovary from the peritoneal cavity. Persistent corpus luteum, which was known to prevent œstrus and pregnancy in cattle, might have the same effect in women. "Incompatibility," or "selective sterility," was the name of the condition in which a presumably normal couple failed to procreate; most cases would not bear critical examination. Dr. Forsdike believed that they were really "combined relative sterility," both partners having low fertilising power.

Sterility in the Male.

Mr. Kenneth Walker's paper dealt with sterility in the husband, which various observers had found in differing degree in more than half the childless marriages they had investigated. Of 57 husbands referred to him by gynæcologists, he had found 25 normal, 18 with azoöspermia, and 14 with impaired fertility. Oligospermia might be due to the condom or to recent coitus; oligozoöspermia should only be diagnosed if indicated by every specimen examined, and oligonecrozoöspermia usually meant an inflammatory focus in the genital tract, probably in the vesicles. Venereal disease was responsible for most male sterility, but a comparatively mild infection of the tubules by other organisms might impair the spermatogenic function of the testicle, which was much more delicate than the internal secretion. Kyrle, who had studied a thousand testicles, stated that a normal testicle was hardly ever seen in a man dead of acute infective disease. Alcohol and similar poisons, endocrine disturbances, heat, diet, and local conditions might be responsible.

Artificial insemination was successful in veterinary but disappointing in medical practice, and the reason was probably that in the former it was always performed after natural coitus. The secretions from the genital passages were probably essential to fertility.

Removal of obstruction or of infections, the improvement of the general health and the administration of gland substance, preferably anterior lobe pituitary extract, were the chief remedial measures. Little or nothing was known of the physiology of reproduction or the function of the secondary glands of sex, and only by combined research could the knowledge be obtained which was indispensable to the scientific treatment of sterility.

Discussion.

Prof. H. Beckwith Whitehouse (Birmingham) stated that pregnancy had occurred in two cases in which he had excised the isthmic end of the tube and inserted the stump into the uterine cavity. Lipiodol prevented the adhesions so common in salpingotomy. He did not think the stress that Mr. Forsdike had laid on saving the fimbriæ was justifiable; as long as the lamina were intact pregnancy was possible. A promising method of artificial insemination was to paint the endometrium with the secretion of the cervical canal just after intercourse.

Prof. R. Vaudescal (Paris) warmly commended lipiodol as safe for the general practitioner. Pregnancy could sometimes be obtained when the tube was destroyed by grafting the ovary into the wall of the womb.

Dr. Margaret Basden (London) remarked on the frequency of blocked tubes. She always used an anæsthetic for insufflation to eliminate tubal spasm. Corpus luteum had corrected amenorrhœa and sterility in obese patients when given in 5-gr. doses three times a day.

Dr. R. C. Buist (Dundee) summed up the treatment of the idle and sterile in the advice, "Live on a shilling a day and earn it." Much vaginismus could be avoided by antemarital education; a wife who was hurt in her first coitus might pass the rest of her life in terror of it and remain childless.

Mr. E. Farquhar Murray (Newcastle-upon-Tyne) said that he had been struck by the frequency—nearly 50 per cent.—of mild vaginal and uterine infections. Tubes sometimes appeared blocked on one test and open on another taken six months later. Of six patients he had opened for blocked tube, five had shown definite signs of miliary tubercle, and he would never hesitate to perform an investigatory operation on a patient with a blocked tube and a tuberculous history.

Dr. F. Edge (Birmingham) recounted the method employed by the late Prof. Taylor, who had penetrated the ovary with a cautery, split it, and stitched it up again, to provide a normal exit for the ovum. It was advisable in all operations for sterility to tell the house surgeon and nurses what was being done, to avoid trouble from the patient later on.

Dr. Mortkane (New Zealand) held that one test for blocked tube was not sufficient.

Dr. Gray Ward (New York) spoke of the good results of X ray stimulation of the ovarian function recently obtained by Dr. Rubin. The method was widely used in America. Not more than three treatments were given, at intervals of a week or a fortnight.

The Chairman hailed insufflation as the most important gynæcological discovery of recent years. Its inventor had enjoined repetition when a negative result was obtained. As an alternative to lipiodol barium powder had been used for photographing the pelvis. No operation should be undertaken without investigation by one of these methods. Dr. Rubin had suggested that insufflation might remedy sterility by displacing a plug of inspissated mucus.

Dr. Giles, Dr. Forsdike, and Mr. Walker replied.

Prof. Vaudescal then read a paper on

MYOMECTOMY DURING PREGNANCY.

This operation, he said, was to be avoided when possible. The indications were (1) diagnosis of a large fibroid before the third month; operation at this time averted later complications; (2) unmistakable signs of necrobiosis; (3) distortion of the uterus likely to cause miscarriage; (4) torsion of the pedicle of the tumour, which caused severe and lasting pain; (5) pressure on neighbouring organs. In operation general anæsthesia was preferable to spinal because it suppressed uterine contraction. The tumour was decapsulated by a single incision over its summit, and all bleeding carefully stopped. When the fibroid was between the layers of the broad ligament, it must be approached by the transligamentous route. No drainage was provided, and one-sixth of a grain of morphine was given every six hours or less during the three days after the operation. Out of eight myomectomies the child had been saved in seven. Out of 21 cases of myoma, however, hysterectomy had been obligatory in 13, and so operative interference should be postponed as long as possible.

Mr. L. C. Rivett (London) recognised only one indication besides necrobiosis—excessive size.

Dr. Giles, Mr. Farquhar Murray, Prof. Whitehouse, and Mr. Tenison Collins also took part in the discussion.

ACUTE CONDITIONS IN THE PELVIS.

Prof. W. W. Chipman (Montreal) quoted Mr. Victor Bonney's saying that the propinquity of the anus to the genital tract was a great defect in human development. He added that, as far as he know, there was at present no remedy, but that this fact, together with venereal disease, explained the liability of the pelvis to acute infections. Moreover, the pelvic cavity was the largest lymphatic space in the body and had a corresponding absorptive power, so that infection was always serious. It was a sort of Valhalla for organisms, providing warmth, moisture, and food. The "emergency abdomen" was always a grave emergency; an abdomen once opened was never the same abdomen, and the decision whether or not to open it was no light one. He objected in inoperable cancer and recommended frequent douching to protect the surrounding skin. Rest in bed was important, but not for too long, as it was far better for the patient's psychic health to be up at her ordinary work.

Prof. J. HENDRY (Glasgow) recalled a suggestion of Dr. Archibald Leitch that many supposedly malignant glands were really enlarged from ordinary septic absorption. This might account for much of the rapid improvement under radium.

Dr. GILES agreed that the importance of the involvement of the higher abdominal glands was much exaggerated. The trouble that mostly occurred after radical operation was low down at the scar. A method that had given good results in the old days was to scrape away as much of the growth as possible with a vigorous curettage, and then to pack the cavity with gauze soaked in a saturated solution of zinc chloride. The vagina was protected by being filled with carbonate of soda. This prolonged life in comfort for perhaps three years, and freed the patient from the constant irritation of septic discharge.

The Chairman, Prof. W. FLETCHER SHAW (Manchester), admitted that he was an ardent operator, but had come to a stage of doubt. Anyone with any humanity who had seen these women in the long-drawn-out convalescent stage would never operate if he thought he could get anything like such good results with radium. The trouble was that the results in England did not approach those of Sweden and America. He doubted, also, whether the policy in this country of leaving radium entirely in the hands of the radiologists had been right, and thought that, if English gynæcologists treated their own patients with radium as their colleagues did abroad, their results would soon be equally good. Those obtained by the Medical Women's Federation had given great promise. Though he did not yet feel justified in saying that he would not operate on every early case, he hoped that in the future every early case would be treated with radium.

Dr. WARD, replying, said that he would not take out a uterus as a precautionary after-measure if the patient was perfectly well; that most glandular enlargement in early cases was non-malignant, and that in America a campaign was on foot to get every woman past 40 to come for systematic examination.

Dr. MURRAY, replying, said that at least half the glandular enlargements were malignant, and suggested that some underwent natural cure. He was opposed to applying radium to the uterus of a young woman unless hysterectomy was the only alternative.

DONATIONS AND BEQUESTS.—Among other bequests Sir George A. Wills, of Bristol, left £1000 each to the Bristol Eye Hospital, the Bristol Royal Hospital for Sick Children and Women, and the Bristol District Nurses' Society, and £250 to the Bristol Eye Infirmary.—Mrs. Elizabeth Frances Acton, Torquay, left £500 each to the Torbay Hospital, the Aberlour Orphanage, Strathspey, and the Hostel for the Dying, Clapham.—Mrs. Christina Elizabeth Feeney, of the Moat, Berkswell, Warwick, left £1000 to the Birmingham Women's Hospital and £500 each to the Birmingham General Hospital, Queen's Hospital, and the Children's Hospital, Birmingham.—Over £7000 will pass to charitable objects under the will of Mrs. Ethel Alexandra Johnson, of Allestree Hall, Derby. The bequests include £1000 to Derbyshire Royal Infirmary, and £500 each to the Derbyshire Hospital for Sick Children, Nightingale Nursing Home, Derby, and Queen Victoria Memorial Home of Rest, Derby.—Mr. Thomas Leigh Parry, Liverpool, besides other bequests, left £1000 to the Royal Infirmary, Liverpool, for the endowment of a bed in memory of his late brothers, and a further £1000 for the endowment of a bed in memory of his sister and himself.—Mr. Andrew MacFarland, of Pembroke, Co. Dublin, left £2000 each to Dr. Barnardo's Homes and to the Magdalen Asylum, Lower Leeson-street, Dublin: £1000 to the Royal Hospital for Incurables, Donnybrook, Dublin, and £500 to St. Dunstan's Hostel for Sailors and Soldiers Blinded in the War.—One thousand guineas is to be handed over for the extension fund of the Huddersfield Infirmary by the villagers of Denby Dale as a result of their great pie-making exertions.—The residuary legatees of Mr. John Cory have allocated the sum of £1000 to the London Lock Hospital.

SCOTLAND.
(FROM OUR OWN CORRESPONDENT.)

A School Experiment.

A SCHEME of research is to be undertaken in the Fifeshire schools with the aim of guiding pupils in the choice of suitable vocations. The experiment differs in two respects from a similar one in the City of London, also organised by the National Institute Industrial Psychology. It is hoped to secure th coöperation of teachers on a more active basis tha in London, particularly in obtaining information o occupational success; and whereas in London al schools were necessarily urban, in Fifeshire two groups of schools have been selected—one rural, the other urban—with the hope of learning by comparison something of the occupational problems of the two types. The examination and study of individual children are to begin between the ages of 11 and 12, and to continue with periodic re-examinations until the termination of school life. Teachers will be asked to supply all the information they can gather of the previous history, health, school record, and home circumstances of the pupils. The medical officer will furnish particulars of the child's physical condition, with an estimate of fitness (or otherwise) for occupations requiring certain degrees of strength, sensory acuteness, and the like; whilst the school records and tests by investigators will indicate mental capacity as well as qualities of temperament and character. Out-of-school activities will come within the scope of the inquiry, and note will be taken of the pupil's hobbies, occupations, ambitions, and opportunities. Some time prior to the pupil leaving school, when the data have been summed up and considered, advice will be given, in consultation with teachers, parents, and child, as to the selection of a suitable vocation. The Carnegie Trustees are assisting the education authority with financial support.

Occupational Therapy.

The report of the General Board of Control sets out how the practice of occupational therapy is being steadily extended in the Scottish mental hospitals. The benefits to the patients have been a matter of frequent comment, and it only required the exhibition of work from all the institutions which recently took place at Bangour to demonstrate into what varied and useful channels it is possible to direct the energies of patients who before the introduction of occupational therapy were apparently unable to do anything of a useful nature, and whose habits were destructive and costly. Many guardians have now set apart a room in which boarded-out patients can sit during the long winter evenings. "These long, dark winter evenings," Dr. H. Ferguson Watson says, "are taken up with such amusements as solving cross-word puzzles, playing games at chess, draughts, dominoes, and carpet bowls, listening to much varied music, lectures, and sermons on the wireless set, and to the gramophone. Some of the patients are accomplished musicians themselves, and entertain their companions with selections on violin, piano, melodeon, concertina, mouth organ, and even a tin whistle. Indeed, some are so expert that their services are in much demand for local gatherings." A proportion of guardians take their patients to the theatre, to concerts, and to lectures, while in all cases where the mental condition will permit the patient is allowed to attend divine service

Observation Mental Wards.

Another subject dealt with by the Board of Control in their report is, as you have noted already, the successful operation of the observation wards established by the parish councils. These have partially served the purposes of the dispensaries and clinics well known in France, Belgium, and the United was much less if the acute phase was allowed to settle down a little. A tube, unlike an appendix, hardly ever perforated. On the other hand, a cyst with twisted pedicle called for immediate operation to prevent necrosis of the tumour, adhesion to the bowel, and peritonitis.

Prof. CHIPMAN, replying, deplored the number of patients who came with retroversion or prolapse that might have been detected and put right at a recent appendix operation if the general surgeon had thought to explore the pelvis as well. He encouraged Mr. Williams to give a fair trial to the operation on the acute tube, but said that his own experience of it had been decidedly unfavourable.

RADIUM THERAPY IN CARCINOMA OF THE CERVIX UTERI.

Dr. GRAY WARD read a paper with this title in which he outlined the results obtained at the Women's Hospital in New York during the past ten years. To assess the value of radium it was necessary to compare its results in operable cases. There were only a few extending back over five years, and his object was to fill this gap. He referred to the recently published statistics of Dr. Janet Lane-Claypon and Dr. Heyman, and compared them with his own. His hospital possessed only 280 mg. of radium salt, which was applied in rubber-sheathed platinum tubes in doses of 2200–4200 mg.-hours, but massive doses had proved elsewhere to give no better results. No high voltages nor X rays were used except to produce lymphatic block, where neighbouring viscera would not be damaged. An essential part of the treatment was close and individual supervision of every patient, and monthly observation for the rest of her life; this, by detecting recrudescence long before the patient was aware of it, was largely responsible for his hospital's results. Thirty per cent. of the patients had had more than one application, and many had had three or more. Subsequent doses were based on the initial reaction. Radium tubes were anchored by sutures at intervals not closer than 2 centimetres, and short needles were preferred to long. A self-retaining catheter was inserted at the same time as the radium. To combat sepsis during the sloughing stage, when toxins were being absorbed, blood transfusion was a valuable adjuvant. 500 c.cm. were given before dosage whenever possible. Daily douches were given to stimulate sloughing.

It was rarely possible to predict the course from the type of cell, as various kinds were usually present in different parts of the same growth.

Results.

The group numbered 134, treated between 1919 and the first five months of 1923, and the figures had been audited by professional statisticians. All cases were of carcinoma originating in the cervix, and none had been treated elsewhere. Of this number 126 had been traced, and 31 were still alive, a percentage of 24·6. Of Classes 1 and 2, where the growth was limited to the cervix, 17 were living out of 32 treated and 30 traced: 56·7 per cent. Heyman's figures had given 18 per cent. of successes from radical operation and 16·3 per cent. from radiological treatment; at his own clinic that author had returned 23·1 per cent., and the successes at the Radiumhemmet had been 22·4 per cent. Against this, however, had to be set a 17·2 per cent. primary mortality with surgery, against less than 2 per cent. with radium. The really vital comparison, of course, was in the "operable" group. Taking Heyman's figures operation had given 35·6 per cent. and radiology 34·9 per cent. At the Women's Hospital Clinic the successes in operable cases had numbered 53·1 per cent.

The stabilisation of therapy was hindered by a lack of standardisation in statistics. Dr. Ward advocated the recognition of two classes only, early and advanced, and that no results of less than five years' standing should be accepted, but approved of the four classes of Dr. Schmidt, of Chicago. Operability and primary mortality rates should, he said, always be given.

Mr. FARQUHAR MURRAY (Newcastle-on-Tyne) delivered a paper on the same subject, describing observations based upon over 200 cases treated with radium since January, 1926, and a series of 130 radical Wertheim operations. His supply of radium had been limited to 100 mg. in hospital and 200 mg. of the salt in private practice. All cases were subjected to a thorough examination under anæsthetic. 100 mg. were applied for 24 hours to the os, or cavity if one existed. The patient then rested for 14 days. Operation was of doubtful value when there were glandular deposits. Operability should be based on the local condition as assessed by the possibilities of a radical operation, and should not take into account the age or general condition of the patient. The term meant that the growth was limited to the cervix or only involved the vagina to a limited extent, and that there was only a slight infiltration into the cellular tissue.

Twenty operable cases had been treated by radium before January of the current year. Two had not been traced, three had improved, three were stationary, and 12 were worse or had died. Mr. Murray did not use radium before operation, as it seemed to make the local condition worse and the operation area more vascular. It should be used if the ulcer were spreading on to the vagina, and there were some infiltration. The results had appeared to be unfavourable to radium, but this was because it had raised the standard of operability. It seemed, however, to increase operative risk. It undoubtedly improved the local condition in inoperable cases. Of 23 inoperable cases treated in 1926 four were alive, but three of these were going downhill. In 1920, however, radium had so improved five cases considered inoperable that the radical operation had been performed; two were alive and well with no evidence of recurrence. In his experience, radium was invaluable and produced results little short of miraculous in certain cases. It was particularly useful in elderly women, in whom the malignant cells were peculiarly susceptible to its action. It had also given very encouraging results in 55 cases of menorrhagia.

In conclusion, radium was practically as certain as hysterectomy, and was especially indicated in disease of the heart, lungs, and kidneys, where long anæsthetics must be avoided, and in all nervous and elderly patients. It was not to be a routine measure for cases complicated by fibroids.

Discussion.

Dr. MABEL RAMSAY (Plymouth) urged the advantages of radium therapy in avoiding operative shock and scar contraction, and in being within the capacity of any surgeon of ordinary ability. The Medical Research Council had given radium to three women's hospitals, and the general feeling was that all cases of cervical cancer should be taken to one of these.

Dr. MARGARET BASDEN (London) testified to the wonderful results in early disease obtained in the hospitals mentioned. She preferred the Wertheim operation, however, in operable cases, especially where glands were involved. She did not approve of radium for non-malignant menorrhagia, fearing its effect on the ovaries, especially of younger women.

Major P. FLEMING GOW (Calcutta) mentioned a diagnostic method he had learned in Vienna. The suspected area was painted with glucose iodine; any malignant tissue, even though not clinically recognisable, remained white. This was because the cancer cells contained no glycogen and therefore could not fix the iodine. In Vienna he had seen several cases cured by operation with an after-effect of chronic cystitis. He asked whether this occurred with radium.

Dr. W. T. HALL (Newcastle-upon-Tyne), speaking to general practitioners far from radium, extolled opium as a palliative for both bleeding and pain

THE MEDICAL REGISTER: UNTRACEABLE PRACTITIONERS IN 1928.

WE are requested by the Registrar of the General Medical Council to publish the following list of medical practitioners who have not replied to his inquiries as to the accuracy of their addresses. Anyone, wherever resident, who finds his or her name included in this list should communicate immediately with the Registrar of the General Medical Council, 44, Hallam-street, Portland-place, London, W. 1, otherwise the name will be omitted from the next issue of the Medical Register. There may be some who have answered while this list is in the press. Those marked "S" should communicate direct with the Registrar of the Scottish Branch Council, 12, Queen-street, Edinburgh.

States. These wards are conducted on hospital lines, and their beneficial effect may be seen from the fact that no fewer than 1240 patients passed through them at Stobhill and Duke-street during one year, and of these 788 returned to their homes without the necessity for certification. In the foreign clinics the advantages are even greater, inasmuch as patients requiring advice do not become "paupers" in the process, while mild cases of nervous and mental breakdown seek skilled advice more freely and receive the special treatment, which, owing to its cost, can be adequately provided only by public authorities. For such patients there is no public provision here beyond the observation wards, the majority being unable to afford the expense of private nursing homes. Early stages of functional nervous and mental disorder are left uncared for or treated in such a desultory manner that in the long run the majority seek admission as voluntary boarders or are certified to asylums. In Scotland the extension of the General Board's powers so as to include all matters relating to mental health should present no great difficulty. This was the course recommended by the Royal Commission last year. If the £115,000 granted annually to improve the care of the lunatic could be allotted at the discretion of the Board to assist all mentally defective persons other than those provided for as mental defectives, no matter what their circumstances or station in life, the objects of the Board would be better furthered.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Professional Secrecy.

THE annual meeting of the Aerzte-vereinsbund was held this year at Danzig, where the most interesting order of the day was professional secrecy, the speakers including medical men and criminologists. Dr. Vollmann, the editor of the Bund's journal, pointed out that professional secrecy is no longer absolute since the laws on workmen's insurance and recently on venereal diseases compel medical men in certain cases to reveal facts concerning their patients. But apart from those exceptions the patient has a right to be protected against indiscretion on the part of his medical attendant as well as of assistants, nurses, and students. Dr. Ebermayer, ex-Public Prosecutor at the High Court of Leipzig, said that the provisions of the criminal law which make a medical man liable to punishment if he violates professional secrecy concern qualified men only. A patient consulting a non-qualified person should be aware that neither can he rely on his professional secrecy nor can he prosecute him should he reveal facts concerning his illness. In the new Criminal Bill shortly to come before Parliament these provisions will be extended to include assistants, nurses, and students. It will also be made illegal for a medical man to confirm a rumour concerning one of his patients. A patient may discharge his medical attendant from the obligation of professional secrecy, but may at any moment revoke this discharge. If a patient has died the good renown of the deceased demands that the medical attendant should observe professional secrecy in the same way as if he were still alive. There are, however, circumstances, legal and social, where these professional rules may be infringed. According to recent legislation taxing authorities are authorised to examine the books kept by medical men. The production of histories of patients written by medical men or in hospitals may be enforced by an order of court and in urgent cases by the police. The principle stands that professional secrecy must be kept as strictly as possible and infringed only when the law obliges. Dr. Hagemann, head of the detective department of the Berlin police, said it often happened that a criminal was injured at the commission of a crime and inquiry was made by the police at hospitals and from medical men for the names of any persons who might have been dressed for injuries about that time. Their inquiries were often, however, fruitless because medical men declined to answer such questions on the plea of professional secrecy. But there are, he said, overruling moral obligations. In the instance of a terrible murder a Berlin medical man, after having scrupulously considered all the circumstances, very reluctantly revealed the name of the criminal dressed by him, so that he could be arrested by the police. He was sure no one would blame the medical man for his action. The meeting ended with the passing of a motion to the effect that the rules of professional secrecy should not be remitted except for reasons of public welfare, that judicial orders to produce books kept by medical men should be prohibited, and that the forthcoming reform of the criminal law should contain provisions to that effect.

The Socialist Party and the Medical Profession.

The number of medical members in the recently elected Reichstag is only four, of whom one is a democrat, one a member of the Bavarian popular party, and two Socialists. Owing to the increased influence of the Socialist Party it is of interest to know their medical programme. It is explained by Prof. A. Grotjahn, who, although not belonging to the Reichstag, is an influential member of the party and occupies the chair of social hygiene at Berlin University. Prof. Grotjahn demands that medical practice should be nationalised by an extension of the existing social insurance system, now limited to certain classes of workers, to every member of the population. Hospitals, dispensaries for infants, for tuberculous and venereal patients would form the nucleus of socialisation. All private institutions, such as sanatoria and convalescent homes, would be taken over. The medical profession would work in these institutions under better conditions than hitherto. They would have the rights of civil servants, their work would be done in common, and thus more economically; they would also enjoy the leisure hitherto denied to them. Pharmacies and factories producing chemical agents and sanitary appliances would be owned by the State. Prof. Grotjahn, who belongs to the moderate wing of the Socialist Party, believes these measures would have to be introduced gradually; for a period the socialised and the capitalistic institutions would exist side by side. It may be pointed out that these principles to some extent have been put into practice by the sick clubs of Berlin, especially those the greater part of which are under Socialist management. They have set up dispensaries for nearly every kind of disease at which appointed medical men are working. They have fitted out those dispensaries with modern apparatus and with laboratories. They have stocked drugs the provision of which is not reserved by law to licensed chemists. When such a drug is prescribed by a medical man the patient is obliged to fetch it not from a pharmacy or a drug store, but from the drug store of the sick club. Prof. Grotjahn's plan aims at extending this system to the whole population.

Statistics of Suicide.

Dr. Prinzing, of Ulm, the well-known medical statistician, has published a report on suicides in Germany and abroad. Of the German States Saxony has the greatest number—namely, 31·9 for each 100,000 of the population during the period 1900 to 1910. This figure increased from year to year, reaching 36·6 in 1925 and 38·1 in 1926. In Prussia the corresponding figures were 21 and 25·4. The lowest numbers were those of Bavaria and of Wurtemberg. The figures of Switzerland were nearly the same as those of Germany. In Austria and in Hungary they were much higher. France had about 20 suicides for every 100,000, Belgium 13–14. The lowest number in Northern Europe were those of the Netherlands with 6 and of Norway with 5 suicides for every 100,000. In Southern Europe the number of suicides was always very small, but in recent years a certain increase has been observed in Italy and in Spain. Immediately after the war suicides were more frequent among women than among men.

Maj. J. D. C. Swan, late R.A.M.C. T.A., to be Temp. Capt., and temporarily relinquishes the rank of Maj.

The undermentioned Capts. to be Majs.: J. C. Preston (Prov.), B. J. Daunt, A. J. Bado (Prov.), and H. M. Alexander (Prov.).

Capt. L. Game, late R.A.M.C., to be Temp. Capt., and temporarily relinquishes the rank of Capt.

Lt. (on prob.) J. C. Gilroy resigns his commn.

Capt. J. V. McNally to be Maj. (Prov.).

The appt. of Lt. G. T. L. Archer is antedated to Jan. 26th, 1927, but not to carry pay and allowances prior to Jan. 26th, 1928.

Temp. Lt. R. Willan relinquishes his commn.

ARMY DENTAL CORPS.

Capt. R. J. Condie to be Maj.

ARMY RESERVE OF OFFICERS.

Lt.-Col. A. L. Scott, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY.

General List.—Lt.-Col. P. J. Gaffikin to be Bt. Col.

Capt. G. M. Brown, having attained the age limit, relinquishes his commn. and retains his rank.

J. B. S. Guy and H. J. Curran to be Lts.

Col. C. I. Ellis, having attained the limit, retires and retains his rank with permission to wear the prescribed uniform.

INDIAN MEDICAL SERVICE.

Lt.-Col. H. Innes retires.

"Audi alteram partem."

THE CLASSIFICATION AND DISPOSAL OF MENTAL PATIENTS.

To the Editor of THE LANCET.

SIR,—In the first leading article in your issue of August 18th you dealt comprehensively with matters debated at Cardiff under the heading of the Early Treatment of the Psychoses and Psychoneuroses, and referred to some of the difficulties with which the subject bristles, reminding us that other powers—Parliament or the public—may cast our deliberations to the winds. It appears to me that controversy, medical and other, hitherto friendly, gathers about one main question: the classification and disposal of patients. Until now, for purposes of disposal, patients, other than the criminal, insane and mental deficients, have been classified as follows:—

1. Certifiable (whether or not actually under certificates).
2. Non-certifiable.
3. Boarders "desirous of voluntarily submitting to treatment" (Lunacy Act, 1890, S. 229), who are individuals permitted to live in Licensed Houses and Registered Hospitals for periods varying from the matter of a few days only to a continuous number of years—e.g., 20 or more. Apparently they have no status; although "submitting to treatment," they are not described as patients, and although living "en pension" they are not treated as "paying guests." The designation of boarder may have been a happy inspiration arising out of the colloquial term "border-line case." It is about this ill-defined class that a considerable amount of abuse has clustered and out of which many of the complaints in connexion with the present system of classification and disposal have arisen.

It is obvious that Classes 1 and 2 above account for the whole community, except the individual in Class 3 who has no status. The general practitioner is well acquainted with the medico-legal distinction between Classes 1 and 2, and no one has any power to consign the non-certifiable section of the community to asylums.

The new classification suggested by the Royal Commission (Report, Part III.—III., IV., V., VI., pp. 157–160) I understand to be as follows:—

The voluntary certifiable patient.
The involuntary ” ”
The voluntary non-certifiable patient.
The involuntary ” ”

This suggested fourfold classification is but a variation of the present one, and, like it, accounts for the whole community, but when it comes to the question of disposal the Commission makes the alarming suggestion that power should be acquired to consign all four of these classes, that is, the whole community, certifiable and non-certifiable, to mental hospitals, that is, asylums. And in order to render its alarming recommendation more workable, the Commission considers it advisable to create a new Order and adopt new procedures, whilst incidentally it seeks to vary the present basis or "definition" of legal insanity. Certification, it suggests, should rest on the ability of an individual A (not being a minor) to write a letter, which in effect would mean, in many cases, the ability of B by means of suggestion, pressure, hypnotism, or threats, to get A to write a letter.

The British Medical Association[1] would vary the present basis for certification but not as the Royal Commission would do so, and whilst suggesting a classification differing somewhat from that of the Commission the Association agrees with its recommendation that powers should be sought for consigning not only the certifiable but also the non-certifiable sections of the community to asylums. I would ask the question: "Whence have we come and whither are we tending?" Is the answer above a reductio ad absurdum or not?

As I pointed out in the discussion at Cardiff on July 27th, to send non-certifiable patients to mental hospitals is not justifiable since it would stigmatise them and their relatives unnecessarily. Since then three cases referred to me by relatives within a week have confirmed my opinion, had it needed confirming, that if the views of the nearest relatives go unheeded we must expect more complaints than there have been in the past. I suggest that the following are the real problems we have to face in relation to legislation:—

1. Can we do away entirely with certification? If not, apart from alterations in the wording of certificates, do we wish to alter the present basis or "definition" for certification, and, if so, can we suggest one more scientific or reasonable than the present medico-legal one? In my opinion those hitherto suggested certainly are not.

2. Do we, for purposes of disposal, wish to recognise a class intermediate between certifiable and non-certifiable, and is there need of establishments where such patients can be sent?

I am, Sir, yours faithfully,
C. A. MORTLOCK-BROWN.

Braunton, N. Devon, August 31st, 1928.

THE LATER RESULTS OF PARTIAL GASTRECTOMY FOR GASTRIC AND DUODENAL ULCER.

To the Editor of THE LANCET.

SIR,—The letters of Dr. A. F. Hurst and Mr. E. R. Flint reveal a difference of opinion upon the value of gastro-enterostomy in the treatment of duodenal ulcer which is a reproach to medicine, and at the same time illustrate the existence of great difficulties and perplexities which beset the investigator of what on the surface would seem to be a very simple issue. Why should two acute observers come to such diametrically opposed views? Obviously because it is usually well-nigh impossible actually, and certainly impossible socially, to perform crucial experiments in medicine in the sense that the physicist does in his own branch of knowledge. For such an experiment there should be one variant only, but in medicine the uncontrollable factors are numerous and some of the significant factors often unknown.

When Dr. Hurst states that gastro-enterostomy is the commonest cause of gastric disorder to-day,

MEDICINE AND THE LAW.

THE LAW OF INCEST.

On a charge of incest, brought against an uncle and his niece by marriage, the accused were found guilty in the Glasgow High Court on August 28th after some debate regarding the degrees of relationship within which marriage is illegal. Though ancient history contains hints that in certain royal dynasties the marriage of brother and sister was not unknown, society has placed its taboo upon in-breeding, and the laws of England and Scotland reflect the specific inhibitions of the Old Testament. A Scots Act of 1567 declares incest to be a high crime and offence (a phrase which is equivalent to a "felony" in English law) and defines it by allusion to Chapter 18 of Leviticus—an early example of legislation by reference. When Parliament permitted a man to marry his deceased wife's sister (in 1907) and his deceased brother's widow (in 1921), Scots law must have ceased to regard these particular unions as criminal. In the recent case at Glasgow the uncle and niece, by marriage, had apparently been unaware that they stood within the prohibited degrees. As the prosecution observed, if public sentiment no longer sees objection to the matrimonial relationship of an uncle with his niece by marriage, Parliament will no doubt alter the law.

The same ignorance of the offence of incest has been freely noticed in England. Originally the offence —i.e., of sexual intercourse between persons within the prohibited degrees of affinity or consanguinity as annexed to the Book of Common Prayer—was a matter for the ecclesiastical courts only; it was there punishable by excommunication and penance. In the case of criminal assault the ordinary courts might take note of the fact that the assault had been incestuous in character and might on that account increase the punishment within the court's discretion; but the ordinary criminal courts had no jurisdiction to try incest as such until it was made a misdemeanour in 1908. The 1908 Act, which applied to England and Ireland, concerned the relations of a man with his grand-daughter, daughter, sister, or mother. The natural hesitation to give publicity to the evidence in trials of this nature resulted in the insertion of a clause providing that all proceedings under the Act should be held in camera. But this restriction was found to be ill-considered, as might also probably be said of the restrictions regarding divorce court reports under the 1926 Act. Lord Darling and other judges recorded their experience at assizes and declared that the secrecy led to widespread popular ignorance of the law. Eventually, in 1922, the clause was, as respects England, repealed. Prosecutions are rare; the cases, when they occur, usually seem to be due to inadequate housing and a drunken father. So far as concerns the marriage of persons within the degrees at present prohibited, it will be remembered that a Bill specially dealing with the case of uncles and nieces by marriage was narrowly defeated last session, mainly on the appeal of the veteran Archbishop of Canterbury, who was making his final official utterance in the House of Lords. Ecclesiastical opinion is against any relaxation of existing limits; what does medical opinion say?

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt. R. W. Mussen to be Surg. Lt.-Comdr.

J. G. Paley as Surg. Lt. *for short service*, and apptd. to *Victory* for Haslar Hospl.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Sub-Lt. H. G. Ungley to be Surg. Lt.

H. A. M. Whitby entered as Proby. Surg. Lt., and attached to List 2 of the London Division.

Proby. Surg. Sub-Lt. J. M. Ridyard to *Victory*, for R.N. Hospl., Haslar, for training.

ROYAL ARMY MEDICAL CORPS.

Col. O. I. Stockwell is granted the temp. rank of Brigadier whilst Comdt., Sen. Offrs. Sch., India.

Col. N. J. C. Rutherford, late R.A.M.C., is placed on half-pay under the provisions of Arts. 139 and 486, Royal Warrant for Pay and Promotion, 1926.

Lt.-Col. B. B. Burke, *from* the R.A.M.C., to be Col., vice Col. N. J. C. Rutherford.

Maj. J. S. Wallace to be Lt.-Col., vice Lt.-*Col.* B. B. Burke, promoted.

and Mr. Flint that only 10 per cent. ill-results follow the operation, they are both giving a true account of their own experiences, but they are certainly not talking about comparable things. To maintain as much would be nothing less than an intellectual affront to the reader. The controversy over the merits of medicine and surgery in the treatment of gastro-duodenal ulceration has proceeded in this fashion for far too long a period, and, difficult as the subject is, I am convinced it is possible to arrive much more nearly at the essentials of the matter. Collected statistics always suffer from a difference of outlook of the several observers who have, as a rule, dealt with material selected in different ways. There is a common language but no identity of concepts denoted by its terms. For deductions made from massed statistics of very specialised physicians and surgeons should be substituted the judgments of men who have adequate experience of the several methods under investigation.

In the Surgical Unit at St. Mary's Hospital an attempt to evaluate the different surgical methods used in the treatment of ulcer has been made, and my close association with Prof. F. S. Langmead, of the Medical Unit, where a like work on medical methods is being carried out, has enabled me in some way to settle that larger question as to when surgery should be considered at all. I have been criticised adversely for advocating partial duodenectomy for duodenal ulcer in suitable cases, but not one of my critics seems to have treated parallel series of cases, the one with gastro-enterostomy, the other by partial duodenectomy. The time is not ripe yet to make dogmatic statements upon such a question, but I can say that amongst the patients coming under my care the results I get with the larger operation are better than those with gastro-enterostomy. From the section in my book on the dangers of injury to the bile-duct, Mr. Flint has got an impression that I did not mean to convey. I have once only injured the bile-duct in 63 duodenectomies, and the victim is happily well some years after the accident. The danger of the operation can be fairly accurately assessed. Amongst my duodenectomies there have been two deaths, both from lung complications.

Finally, may I state my beliefs about the treatment of gastric ulcer? Surgery is an evanescent phenomenon in the treatment of this disease. Almost certainly the future will provide a method of treatment which will avoid the physiological disturbance which surgery entails and which is so distasteful to the thoughtful surgeon. A very large proportion of cases, even now, are amenable to medical treatment. But there is a residue which only surgery can help, and amongst these a very large majority is restored to health.—I am, Sir, yours faithfully,

CHARLES A. PANNETT.

Pensford-avenue, Kew, August 31st, 1928.

LICENSING IN MIDWIFERY.

To the Editor of THE LANCET.

SIR,—In his "History of British Midwifery," p. 7, Dr. Herbert Spencer thinks it remarkable that, in spite of the clause in the Act 32 Henry VIII., cap. 40, which gave to Fellows of the College of Physicians the right to practise physic "in all and every its members and parts," Dr. Peter Chamberlen, the third, a Fellow of the College, should have been required to obtain a licence to practise midwifery. But that midwifery was not considered by the College to be included in physic is clear from the fact that his father, a barber-surgeon, had been brought before the College, not for practising midwifery, but for prescribing physic, and was warned not to practise medicine. The licence for midwifery was at that time granted by the Bishop of London; it was not until 1783 that the College of Physicians took cognisance of practitioners in midwifery, and instituted a distinct order of Licentiates in Midwifery; the grant of these and other special licences, long previously practised, was abandoned by the College in 1800.

Dr. Peter Chamberlen, the third, although he was a Fellow of the College, had not obtained the Bishop's licence to practise midwifery, and on the petition to the King, of the midwives over whom Chamberlen had endeavoured to assert his self-constituted authority, the inquiry was handed over, not to the College, but to the Archbishop, who, by virtue of the Act 3 Henry VIII., cap. 11, exercised the episcopal authority, and ordered Chamberlen to apply to the Bishop of London for a licence to practise midwifery.

I am, Sir, yours faithfully,

GEORGE C. PEACHEY.

Randolph-crescent, W., Sept. 2nd, 1928.

TOTAL DEATH-RATES, NORTH AND SOUTH.

To the Editor of THE LANCET.

SIR,—I have observed with interest, on p. 470 of your last issue, a paragraph drawing attention to the differences between the total death-rates of the North and South of England. Some 20 years ago[1] I discussed the percentage of the total population which survived to 75 and over, in every registration district of England and Wales, and showed the astonishing differences which existed, as deduced from the Registrar-General's decennial report for 1891 to 1900. Thus, whereas in the Devonshire district of South Molton 27·5 per cent. reached those ages, in the district of Manchester only 2·2 per cent. did so. It at once became apparent that the largest survivals were in country districts and the smallest in towns. I considered the fallacies which might be introduced by (1) infant death-rates, and (2) the movement of population from country to town, and concluded as follows:—

1. That there is a very remarkable disparity of longevity in different districts of England and Wales.
2. That this disparity in closely related to density of population.
3. That mere movement of population from country to town, whilst probably tending to make the disparity appear greater than it really is, has on the other hand probably no very considerable effect upon the figures.

I would point out that the differences were by no means a matter of "north" or "south," since some of the worst districts in respect of longevity were in London, and some of the best were in Yorkshire. Social conditions seem the most likely chief cause of the disparities.—I am, Sir, yours faithfully,

Exeter, Sept. 1st, 1928. W. GORDON.

NEW SOLVENTS FOR SKIN ANTISEPSIS.

To the Editor of THE LANCET.

SIR,—In your last issue (p. 444) Dr. Macdonald and Mr. Peck state that "it is on account of the heavy annual cost to hospitals that we have searched for a solvent that would replace" rectified spirit. But is isopropyl alcohol, the solvent suggested, really cheaper? The answer to this question depends upon the net cost of rectified spirit. The authors state this to be £2 13*s*. after deduction of rebate. I suggest this figure is inaccurate. Actually the cost per gallon after deduction of rebate is 26*s*. Moreover, I fail to find a reference in the paper to "The Grant in Aid in respect of duty paid by voluntary hospitals on spirit used in their dispensaries for medicinal purposes" which is received from the Government through the Ministry of Health. In 1927 this averaged 16*s*. 4*d*. per gallon of rectified spirit at the London Hospital, thus reducing the cost to 9*s*. 8*d*. per gallon. As the authors state that the cost of 70 per cent. isopropyl alcohol would be 10*s*. 6*d*. per gallon, it appears that the promise of a saving of 85 per cent. is a dream. It is not to be expected that the Chancellor of the Exchequer will continue the grant in aid if the use of spirit is abandoned.

I am, Sir, yours faithfully,

F. A. HOCKING,

Sept. 4th, 1928. Pharmaceutist to the London Hospital.

Obituary.

ALBERT ARTHUR NAPPER, M.R.C.S. ENG., L.S.A. LOND.

WE regret to announce the death of Dr. A. Arthur Napper, which occurred on August 22nd at his residence, Rallywood, Reigate, in the eighty-fourth year of his age. Arthur Napper was born in 1845, the son of Dr. Albert Napper, a practitioner at Cranleigh, and a member of one of the oldest Sussex families, a band of which had migrated in the eighteenth century to Surrey. He received his general education at Epsom College, which was founded in 1855, being the second boy to enter, and proceeded to the medical school of King's College Hospital, where Sir William Fergusson, Dr. Lionel Beale, Sir George Johnson, and Dr. W. A. Guy, the famous toxicologist, were among the prominent members of the staff. He qualified M.R.C.S. Eng. as soon as he had reached the age of 21, served as house-surgeon at the hospital, obtained the L.S.A. three years later, and joined his father in the family practice at Cranleigh. This was a good practice, and the father was a well-known man in public as well as professional life, who took a deep interest in professional problems, writing on the relation of medicine to the public, on village hospitals, and on rural sanitation. Young Napper was soon associated closely with this side of the work, becoming medical officer of health of the district, a post which he continued to hold when his father retired some ten years later. For nearly 50 years Mr. Napper practised at Cranleigh, latterly as senior partner in a large firm, and he only retired in advanced years owing to failing eyesight. His popularity as a doctor was earned by skill and clinical accomplishment, but the wide personal acquaintance which he enjoyed in the district was due also, and largely, to his life-long and ardent devotion to field sports.

His association with his old school was a long and close one. The second boy to enter Epsom College upon its foundation, when he was but 10 years old, his first wife, Elinor Walker, was the sister of Dr. John Walker, who was the first entrant to the school. Napper was at Epsom for six years as a scholar, was for 45 years a governor, and during most of that period a local secretary; he was a member for varying periods of the finance, works, and school committees, and when he retired from the Council, in 1926, was elected a vice-president.

ALAN ADAIR DIGHTON, L.R.C.P. AND S. EDIN.

THE death occurred at his home near Cheltenham, on August 28th, of Dr. Alan Adair Dighton, a well-known general practitioner and sportsman in the neighbourhood, and esteemed equally by all classes represented in the large professional connexions. Alan Adair Dighton was born in 1861, the son of the ev. C. E. Dighton, Vicar of Maisemore, was educated Clifton and St. George's Hospital, and obtained the ottish double diploma in 1884. After qualification took a post as resident surgeon at the Cheltenham Branch Dispensary, and from that date for the next 35 years he practised in that city both as medical officer to various friendly societies and among a large clientele of private patients. For his repute as an obstetrician was high, while many of his male patients were his personal friends and associated with him in his full life as sportsman and especially cricketer. He was deeply interested, also, in the local affairs of Cheltenham, was a town councillor, and a prominent political worker in the Conservative cause. After the war he left Cheltenham for Ross, where he practised for a short time until failing health led to his retirement, but he retained his keen interest in sport, and was one of the founders of the Ross Race Meeting.

FRANCIS EDWARD ATKINSON, M.R.C.S. ENG.

Dr. F. E. Atkinson, who died on Sept. 2nd at Ilkley, had been for nearly half a century medical officer to the combined sanitary authorities of the upland district in the West Riding of Yorkshire known as Craven. He studied medicine at the Yorkshire College, Leeds, where he was Thorp scholar in forensic medicine and hygiene, completing his course at University College, London, from which he took his M.R.C.S. in 1874 and L.R.C.P. in the following year. After holding resident appointments at Leeds General Infirmary and the Bradford Infirmary, he went to live at Settle as medical officer to the Skipton and Sedbergh rural districts, and began to issue the series of annual reports which are the chief monument to his industry and accuracy. In 1884 he traced an epidemic of dysenteric diarrhœa to contaminated water-supply, and 15 years later made a comprehensive survey of typhoid fever at Kildwick. Dr. Atkinson was senior member and a past president of the Yorkshire branch of the Society of Medical Officers of Health, and at the time of his death the oldest medical officer in the North of England.

JAMES ERNEST MOORHOUSE, M.D., C.M.EDIN., B.SC. ST. AND.

THE death occurred on August 17th in Stirling of Dr. J. E. Moorhouse, a well-known practitioner in the town. Born in Yorkshire in 1870, Dr. Moorhouse went to live in Scotland as a boy, and it was at the University of St. Andrews that he took a science degree in 1889, proceeding to Edinburgh to study medicine. He qualified M.B., B.S. in 1892, and held a resident post at the Royal Maternity and Simpson Memorial Hospital, Edinburgh. In 1893 he set up practice in Stirling, where he was appointed surgeon to the Stirling Royal Infirmary, returning to Edinburgh to take his M.D. in 1895. Dr. Moorhouse became popular, and his work increased so rapidly that it soon became necessary to take a partner. He held the posts of medical officer to the Argyll and Sutherland Highlanders' depôt at Stirling Castle and to Stirling Combination Poorhouse. During the war he was attached to the R.A.M.C., taking charge of the wounded in the local military hospital, and since has acted as referee for the Ministry of Pensions. Of recent years professional activities left Dr. Moorhouse little leisure for games, but he was at one time a keen golfer and a skilful chess player. His attractive personality brought him many friends in Stirling, and he will be remembered with deep regret by his patients and colleagues in the town.

UNIVERSITY OF EDINBURGH ANIMAL-BREEDI RESEARCH.—A new building, to cost £30,000, is to erected to extend the animal-breeding research departmen of which Prof. A. E. Crew is the director. Towards the cos of the building and its equipment and the endowment o the chair, the University has received the following contributions: £20,000 from the International Education Board, New York; £16,000 and an annual grant from the Development Commission; £10,000 from Lord Woolavington; and £10,000 from the Empire Marketing Board.

CHARING CROSS HOSPITAL.—The annual report is one of the most satisfactory that has ever been presented. Charing Cross has a lower cost per bed than any metropolitan hospital; the average stay of the 4118 in-patients was 21 days, and the average cost £11 10*s.* 3*d.* There were 25,596 new out-patients, whose average cost was 8*s.* 1*d.* The income of £59,000 (expenses £55,000) included £12,000 paid by patients.

CONTRIBUTORY SCHEME AT FALMOUTH HOSPITAL.—It has been agreed between the governing body and the medical staff that all those contributors to the weekly scheme whose income does not exceed £200 a year shall receive free medical and surgical treatment for themselves and their dependants. Where the income exceeds that amount patients are to make their own arrangements with their medical attendants. Last year out of 4947 "bed-days" 3103 were allocated to members of the contributory scheme.

Medical News.

LONDON (ROYAL FREE HOSPITAL) SCHOOL OF MEDICINE FOR WOMEN.—The following scholarships have been awarded during the session 1927–28:—

St. Dunstan's Medical Exhibition: Miss M. Louden (St. Paul's Girls' School). Isabel Thorne Scholarship: Miss M. Mayeur (St. Paul's Girls' School). Sir Owen Roberts Memorial Scholarship: Miss M. Tate (Retford High School, Notts). Mabel Sharman Crawford Scholarship and Lieutenant Edmund Lewis (R.A.F.) and Lieut. Alan Lewis (R.N.A.S.) Memorial Scholarship: Miss B. F. Goldsmith (L.S.M.W.). School Jubilee Bursary: Miss N. I. Faux (L.S.M.W.). Alfred Langton Scholarship: Miss D. Woodman, M.Sc. (L.S.M.W.). Ellen Walker Bursary: Miss H. B. Burt (L.S.M.W.). Flora Murray Bursary: Miss M. N. Lunn and Miss E. M. Newham (divided). Dr. Edith Pechey Phipson Post-Graduate Scholarship: Dr. Annie Price.

METROPOLITAN ASYLUMS BOARD.—At a meeting of the Board held on Sept. 1st it was announced that the Board of Control had accepted in principle the view that the mental hospitals under the direction of the M.A.B. should henceforward be reserved to meet the needs of London itself. Arrangements will be made for the gradual removal of cases from other counties, so that in any event none of them will be retained after September, 1930.

KING'S COLLEGE HOSPITAL.—The annual dinner of past and present students will be held at 7.30 P.M. at the Trocadero Restaurant, Piccadilly-circus, London, W. 1, on Oct. 3rd. Dr. B. R. Turner will be in the chair. The dinner secretaries are Dr. Ernest Playfair and Dr. H. A. Richards.

GIFTS TO UNIVERSITIES.—Lord Haldane made the following public bequests, all free of Government duties: University of Edinburgh, £1000; University of Bristol, £2000; Birkbeck College, London, £1000; University of Göttingen, £1000; British Institute of Adult Education, £200.

SOCIETY FOR THE STUDY OF INEBRIETY.—A meeting will be held in the rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, London, W., on Oct. 9th, 1928, at 4 P.M., when Dr. Hubert J. Norman will open a discussion on "Alcohol and Drug Addiction in Relation to Mental Disorders."

ASSOCIATION OF SPECIAL LIBRARIES AND INFORMATION BUREAUX.—The fifth annual conference will be held at New College, Oxford, from Sept. 14th–17th. Among the subjects to be discussed are Existing Types of Indexes to Technical Periodicals, the Librarian as Archivist, Vocational Selection and Guidance, Scientific Abstracts, Information on Accident Prevention, and the Necessity for the Standardisation of Bibliographical Methods.

THE LATE DR. F. P. HUGHES.—Frank Percival Hughes, who died at Bristol following operation on August 23rd, was a Guy's man, who qualified in 1904, taking his London degrees in 1907. He held a series of house appointments at Guy's Hospital, and, deciding to specialise in mental disease, he obtained resident posts at Bethlem Royal Hospital, and then at the Three Counties Asylum. Later he settled at Pinner, where he acted as assistant bacteriologist to the Government lymph establishment at Hendon.

PHARMACOLOGICAL CONGRESS AT HAMBURG.—The eighth annual session of the German Pharmacological Society takes place at Hamburg from Sept. 12th to 15th in the Pharmacological Institute at the Hospital St. Georg. After formal meetings on Wednesday evening, Thursday is given up entirely to a series of papers on the heart and great vessels in honour of William Harvey, Dr. G. V. Anrep (Cambridge) having accepted an invitation to lecture on new investigations into the physiology and pharmacology of the coronary vessels. Other major communications will be made by Prof. G. Liljestrand (Stockholm), A. Jarisch (Innsbruck), H. Straub (Göttingen), and H. Eppinger (Freiburg i/Br.). On Friday the subject of modern industrial poisoning will be introduced by Prof. F. Flury (Würzburg) and H. Zangger (Zürich). On Saturday Prof. G. Barger (Edinburgh) will give an address entitled Old and New about Ergot, to be followed by A. Stoll (Basle). More than 40 separate papers will be read on a wide range of subjects. Excursions will be made in common with other sections of the 90th Congress of the Society of German Naturalists and Doctors which is meeting at the same time. The director of the Congress is Prof. Hermann Wieland, of Heidelberg.

ST. GEORGE'S HOSPITAL.—The annual report for 1927 lays stress upon the great increase in the cost of maintenance which, at £83,000, was more than double that of 1913, and more than £5000 in excess of the income. Unless at least £20,000 a year of additional income is obtained it may be necessary greatly to curtail the hospital's activities. Last year 5364 in-patients were treated at a cost of £13 12*s.* 4*d.* each for an average stay of nearly 22 days. New out-patients numbered nearly 37,000 and cost 7*s.* each.

THE LATE DR. J. H. WISEMAN.—James Harry Wiseman, who died at Sheffield on August 23rd, took his medical studies at Sheffield University and London Hospital, qualifying M.R.C.S. in 1917, and straighway entering the R.A.M.C. Special Reserve. He was in partnership with his father, Dr. Charles Wiseman, and well known in the Crookes and Walkley districts of Sheffield.

ABERDEEN INFIRMARY.—On August 28th the Prince of Wales laid the foundation-stone of the new Royal Infirmary. The buildings will cost £400,000, of which over £340,000 has been collected in rather less than 18 months. On the new site, some two miles from the centre of the city, will eventually be massed the Royal Infirmary itself, the Aberdeen Sick Children's Hospital, the Maternity Hospital, the Public Health Department, and the University Medical School. The Infirmary will consist of five wings holding 500 beds, and there will be a large nurses' home. The adjacent Burnside Home for Mothers is to be enlarged from 56 to 150 beds, while the Maternity Hospital will have 70 beds.

THE LATE DR. O. W. B. BROWNING.—Dr. Browning, whose career has been cut short at the age of 27 years, was a son of the late Dr. Samuel Browning, of Birmingham, and a nephew of Dr. J. O. W. Barratt. He qualified from University College Hospital in 1925, and was a steady worker who was regarded by his teachers as likely to attain distinction. Encephalitis lethargica attacked him while studying for the London M.B. examination, and after considerable improvement had given hope of his resuming an active existence, death occurred unexpectedly nearly three years after the initial attack.

A CANADIAN MEDICAL TOUR.—Some 40 members of the Canadian Tuberculosis Association, accompanied by their President, Dr. J. H. Elliott, and Executive Secretary, Dr. R. E. Wodehouse, reached Liverpool last Sunday for a study of tuberculosis and its methods of prevention and treatment as practised in this country and on the continent. After a visit to Liverpool Cathedral they went on by road to Birmingham where they received a civic welcome and visited the Yardley-road and Romsley Hill Sanatoria and some of the garden extensions. Their next objectives were Cardiff, under the ægis of the Welsh National Memorial Association, and Alton Park, Hants, where Sir Henry Gauvain was to show them the pioneer institution for surgical tubercle. On Oct. 16th the party will be entertained in London by their colleagues of the British National Association for the Prevention of Tuberculosis, and the return home will be made from Glasgow on Oct. 27th by the White Star liner *Calgaric.*

Corrigendum.—In some copies of THE LANCET issued last week a misprint occurred in the brief account of the First International Congress of Oto-Rhino-Laryngology held at Copenhagen. The opinion of Dr. A. Pohlman, speaking on "minimal audition," that lengthened bone conduction is apparently not real, was actually *opposed* by clinical observers of the German school present at the Congress.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W. 1.
TUESDAY, Sept. 11th, and SATURDAY, Sept. 15th.—BETHLEM ROYAL HOSPITAL, St. George's Fields, S.E. Post-graduate Course in Psychological Medicine.

ROYAL NORTHERN HOSPITAL, HOLLOWAY-ROAD, N.
TUESDAY, Sept. 11th.—3.15 P.M., Mr. A. M. Zamora: Antral Infections.

Notes, Comments, and Abstracts.

INSTITUTES OF LEGAL MEDICINE.

IN THE LANCET of July 26th we commented on the need for the establishment of a medico-legal institute in London. A detailed study of the duties, functions, and responsibilities of such institutes in other countries shows that in some of them the centre of medico-legal education is also an integral part of the machinery of justice, assisting it at all points; in some it is merely a department of the biological or pathological section of a university, administered as a minor part of the activities of the professors of those subjects and housed in odd corners and unwanted rooms. The object of this article is to indicate the position that medico-legal nstitutes occupy in various civilised countries and the ontribution they make to the national life. The information drawn from the ninth series of the invaluable Rockefeller rochures on Methods and Problems of Medical Education, hich contains nearly thirty articles describing as many edico-legal foundations throughout the world.

Their Origin and Functions.

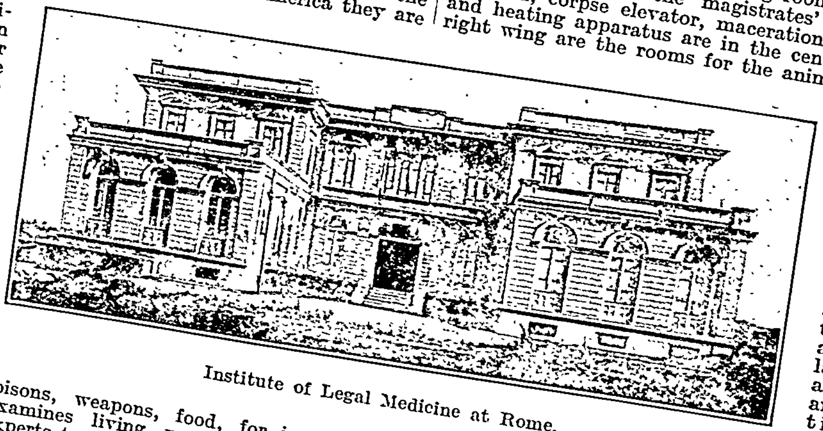
As a general rule, medico-legal institutes originate either annexes to the public morgue or as departments of the hological section of a university. In America they are lly an accre- round the e of the medi- xaminer, an al peculiar, or almost so, to the New World, who is responsible for the investigation of all suspicious deaths. The functions of a medico-legal institute are extremely wide, for. in addition to the post-mortem work which forms so large a part of its obligations, it investigates specimens of all kinds—human delicta, poisons, weapons, food, for instance—for the police, examines living persons for injury or disease, provides experts to assist courts of law, studies the psychology of criminals and others, builds museums of specimens and photographs, and teaches legal medicine to medical graduates and undergraduates, lawyers, and public officers. The head of the institute is often, as in America, a public officer himself, and, as in many countries, professor of forensic medicine at the local university. Since the scope of the work includes every branch of medicine, from anatomy and physiology to biochemistry and psychiatry, it is obvious that a medico-legal expert must be extremely versatile. In addition to all these routine duties the staff must, if it is to maintain a live and creative institution, devote itself to research and the recording of its results in papers and books.

It is strange that by far the most highly evolved medico-legal system in existence should be that of a relatively uncivilised country—Egypt. The vital need for protection against as large and as ruthless a criminal population as any in the world, together with the genius of one or two Englishmen, has made the Medico-Legal Institute in Cairo an essential part of the organisation for the investigation of crime. It is made use of daily, quite apart from medical or chemical considerations, and practically no case of importance occurs in which it is not consulted. All cases of sudden death, accident, sexual assault, and serious injury occurring in Cairo are examined at the mortuary or head office, and all cases of poisoning throughout the country, all specimens for examination, all claims for compensation after injury, permanent infirmities, and appeals against the decision of other medical officers are referred to the Institute. Experts are sent to the provinces on demand, but the Institute is in touch with the provincial medical officers of the Department of Public Health, who are consulted in all minor cases of crime. Few persons in Egypt know their own age, and the Institute has to apply special methods, including X ray examination of the epiphyses, for estimating the age of young offenders, girls who have been the victims of rape, prostitutes who apply for licence, and others. Its technique for identifying bullets and cartridge-cases is exceptionally fine. The principal medico-legal expert is also the professor of legal medicine in the University; the course of instruction takes six months, and the examinations form part of the final test for medical qualification. The standard is higher than in most European countries, as a great part of the work of a provincial general practitioner is medico-legal. The mortuary is situated in the School of Medicine, and daily compulsory demonstrations of cases of accident, murder, and suicide are given.

Medico-Legal Institutes of Europe.

Europe is well provided with medico-legal institutes. Vienna had a chair of legal medicine in 1804, and Hungary, which boasts of being a nation of lawyers, claims that its universities have taught legal medicine as a compulsory subject for several centuries. Not only the capitals, but other large towns as well in Austria, Hungary, Poland. and Roumania have medico-legal institutes housed in separate buildings with the most modern equipment, and engaged in active coöperation with the forces of law.

Italy is making great strides towards the realisation of the most modern medico-legal ideas, and the new Institute at the Royal University of Rome, which is almost the last word in convenience and completeness, might serve as a model for all such foundations. The public morgue is in the basement of the building; the left wing contains refrigerator cells, identification and dressing rooms, rooms for autopsy, photography, and the magistrates' investigation. The museum, corpse elevator, maceration room, service room, and heating apparatus are in the centre block, and in the right wing are the rooms for the animals' and their custodians' quarters, animal autopsy, and experimental laboratory. On the ground level are two large lecture rooms, each served by an elevator, one fitted for microscopic demonstration, and one for autopsy; a chemical and microscopical laboratory, examination rooms, and accommodation for the medical staff and visitors. On the first floor are laboratories for psychology and chemistry, bacteriology, and histology; anthropology rooms, a library, the director's room, and the professor's own laboratory.



Institute of Legal Medicine at Rome.

Many quite small countries have large up-to-date institutes. That at Lisbon, which is just nearing completion, rivals all but the finest European ones; Roumania has an autonomous institute conducted on original lines by the versatile Prof. Mina Minovici, and Cuba is building one with first-class equipment combined with a morgue. Havana is the world's paradise of medical jurists, for the judiciary system includes a corps of 20 doctors of legal medicine who attend all courts and give evidence on all matters in which medical knowledge is material, who examine all persons who have met with violence, perform all legal autopsies, and visit wounded men every five days to inspect their condition and treatment. In 95 per cent. of trials, according to Drs. Raimundo de Castro and Antonio Barreras, the judgment goes according to the medical evidence.

The Position in England.

This excellent collection of the Rockefeller Foundation shows that the medico-legal institute is a feature of most civilised States, even the smallest, and that this country is in this respect seriously behind its neighbours. We have the best judicial system in the world, and allow practically no place in it to medicine. Glasgow and Edinburgh, thanks to the Scottish legal system, have departments of forensic medicine of which the directors are also "casualty surgeons" of the city, and to that extent in touch with the administration of law, but in England, where law and medicine stand individually as high as anywhere in the world, there is no recognition of any link between them. Autopsies are done by local police surgeons or by practitioners called in by the coroner; these officers have no specialised training to approach that of their continental colleagues, and their results are, as far as collective usefulness goes, buried with the corpse. The amount of scientific material that goes to waste from our courts for want of a centre in which to collect and use it is depressingly great. A few gifted individuals have acquired great knowledge of the subject, and they expound it to students for a few hours knowing that in all probability no medico-legal questions will be set in the examination. Consequently, the average standard of knowledge of legal medicine among medical men is not as high as it should be. Yet the science of medicine touches the administration of law at many points. If a crime of violence is committed, an examination of wound or weapon often yields indispensable evidence. If human remains are found, the identity of the corpse, the cause of death, and the circumstances surrounding it are often questions only answerable by a medical man. The insurance office calls medical aid to the making of its contracts with its clients; the probate court is often guided by the advice of the alienist in its disposal of disputed wills. The development of legal medicine is thus extremely helpful, if not indispensable, to the administration of justice, and we can think of no better way of promoting it than the establishment in London of a medico-legal institute.

THE PREVENTION OF DROWNING.

FROM a statement just issued by the life-saving service of the American Red Cross we learn that between 6000 and 8000 persons are drowned each year in the United States. Mr. H. F. Enlows, who directs this service, claims that 80 per cent. of these fatalities are preventable. Many drowning accidents, he says, occur within a comparatively short distance of safety, few of them happen in mid-stream or far out from shore. Lives are lost through people losing their heads. If they find themselves out of their depth unexpectedly for the first time, they become so panic-stricken that they are unable to save themselves. Therefore the Red Cross beginner's test arranges for this class of swimmer to jump into water that is over their heads and swim for safety. Having learned to do this under supervision, they are safeguarded against panic. Under the ægis of the American Red Cross more than 168,000 swimmers have already been taught life-saving methods. During June of this year 14 training schools in various part of the country gave a 10-day intensive course in life-saving to nearly 1000 swimmers. Upwards of 5000 examiners and a special corps of 24 travelling instructors are now at work throughout the country. During the summer season special demonstrations are given at hundreds of resorts. During the winter the campaign is carried on at in-door swimming pools, with special attention to those of the universities and colleges.

RATS AND RED SQUILL.

REFERENCE was recently made to the efficacy of red squill in the destruction of rodents without endangering the lives of other animals, and our attention has been drawn to a leaflet issued by the Rural Information Bureau of Sidmouth, in which it is remarked that although Government and municipal authorities obviously cannot recommend anything of a proprietary nature, no matter how efficient such may be, it is an open secret that the ideal form of red squill is available under the registered name of Nomorats. The one-pint tin of this preparation at 7*s.* 6*d.* net is sufficient for about 400 baits, and special rates can be quoted for large consumers. We can testify to its efficacy from actual experience. Nomorats is distributed by Messrs. Abol, Ltd., of Paddock Wood.

Appointments.

SLOAN, ALLEN THOMSON, M.B., Ch.B. Edin., has been appointed Medical Officer of Edinburgh Prison.

Surgeons under the Factory and Workshop Acts: CAITHNESS. H. P., M.D. Edin., D.P.H. (Linlithgow District of the County of West Lothian); AINSCOW, A. E., M.B., Ch.B. Vict. (Melbourne District of the County of Derby).

Manchestsr Royal Infirmary. Resident Appointments: SHEPPARD, R. F., M.B., Ch.B.; LONGWORTH, J. A., M.B., Ch.B.; WILKINSON, J. F., M.B., Ch.B.; HARDMAN, G. B., M.B., Ch.B., House ... M.R.C.S.; OSBORNE, R. P., ... Ch.B.; TICKLE, H., M.I ... Ch.B.; HUGHES, I. M., ... KIE, Miss M., M.B., Ch.B., ... (Central Branch). BEAL, J. R., M.D., Clinical Parhologist. Non-resident Appointments: CLEGG, S. F., M.B., Ch.B., Surgical Registrar (Second). ... M.B., Ch.B.; DAVIES, Miss M. G. ... cal Assistants (Surgical). BODOANO, ... B.: HERBERT, Miss A., M.B., Ch.B.,

Vacancies.

For further information refer to the advertisement columns.

All Saints' Hospital, 49–55, Vauxhall Bridge-road, S.W.—H.S. At rate of £150.

Albert Dock ... ital, Connaught-road, E.—Res. Med. O. At rate of £110.

Ashton-under-Lyne, District Infirmary.—H.S. At rate of £150.

Birmingham City.—Asst. M.O. £750.

Birmingham and Midland Eye Hospital, Church-street.—H.S. £110.

Blackburn Union Institution and Infirmary.—Res. Asst. M.O. £200.

Brighton Education Committee.—Asst. Sch. M.O. £600.

Cheltenham Borough.—M.O.H. and Sch. M.O. £850.

Chester, East Lancashire Tuberculosis Colony, Barrowmore Hall Gt. Barrow.—Assist. M.O. £250.

Connaught Hospital, Walthamstow, E.—Sen. Res. H.S. At rate of £150. Also Jun. Res. H.S. and Res. H.P. Each at rate of £100.

Denbigh (near), North Wales Sanatorium.—Male Asst. Res. M.O. At rate of £200.

Derby, Derbyshire County Council.—Tuberculosis Officer. £750.

Dreadnought Hospital, Greenwich, S.E.—H.P. and H.S. Each at rate of £110.

Exeter, Wonford House.—Deputy Medical Supt.

Gloucester, Gloucestershire Royal Infirmary, &c.—Second H.S. At rate of £100.

Hospital for Sick Children, Great Ormond-street, W.C.—H.S. Also H.P. Each at rate of £50. Also Part-Time Jun. Cas. O. At rate of £75.

Ipswich, East Suffolk and Ipswich Hospital.—H.S. £100.

London Lock Hosp., 91, Dean-st., W.—H.S. At rate of £200.

Manchester, Ancoats Hospital.—H.S. At rate of £100.

Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Res. M.O. At rate of £125.

Manchester Ear Hospital, Grosvenor-square, All Saints.—Two H.S.'s. At rate of £150 and £120.

Births, Marriages, and Deaths.

BIRTHS.

CAIRD.—On August 24th, at Glastonbury, wife of Karl F. Caird, M.B., of a son.

JOHNSTON.—On August 26th, at Forest-road, Birkenhead, to Mary Murray Johnston, M.B., Ch.B., D.P.H. (*née* Jack), wife of F. B. Johnston, M.A., of a son.

LEON.—On August 30th, at Clarence Gate-gardens, the wife of Kenneth Leon, M.R.C.S. Eng., of a daughter.

MAYBURY.—On August 10th, at Siota, Gela, British Solomon Islands, the wife of Lysander Montague Maybury, M.A., M.B., of a son.

DEATHS.

ATKINSON.—On Sept. 2nd, at Ilkley, Francis Edward Atkinson, M.R.C.S., L.R.C.P., of Bowerley, Settle, medical officer of health, Cr ...

BROWNING.—O ...). W. B. Browning, M.R.C.S., ... aged 27 years.

HAWKE.—On August 31st, suddenly, of heart failure, Edward Drummond Hay Hawke, M.R.C.S., of Shortlands, Kent.

MORGAN.—On August 26th, at a nursing home in Newcastle, George Frederic Elliot Morgan, M.R.C.S., of West Hartlepool, aged 64 years.

NEWELL.—On August 30th, at Moville, Co. Donegal, Edwin G. Newell, M.D. Dub.

NICHOLLS.—On Sept. 1st, at a nursing home, Francis John Nicholls, M.B., B.Ch. Camb., of Eastbourne, aged 58 years.

OSLER.—On August 31st, at Norham-gardens, Oxford, Grace Revere Osler, wife of the late Sir William Osler, Bart.

PRITCHARD.—On August 31st, at a nursing home in London, after an operation, Owen Pritchard, M.D. Brux., of Gloucester-square, aged 74 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

An Address

[ABRIDGED]

ON THE

RELATION OF PHYSIOLOGY TO OTHER SCIENCES.

Delivered before the Section of Physiology of the British Association at Glasgow on Sept. 11th

BY PROF. C. LOVATT EVANS, F.R.S.,
PRESIDENT OF THE SECTION.

[AFTER reviewing the close association between physiology and clinical medicine and their mutual debt, Prof. Lovatt Evans deplored the regrettable estrangement between the two subjects which arose in the latter part of last century, when physiologists were concerned with matters such as nerve-muscle physiology, which appeared to be chiefly of academic interest. At the present day it was admitted that the knowledge then gathered has proved of great value in directing physiological inquiry along scientific lines, from which the science of medicine has profited as much as physiology itself. The interesting revival of the study of the same subjects by more accurate methods within the past few years had further enriched our insight into the fundamental phenomena of life and vindicated the opinions of our predecessors as to the value of such investigations. The development of physiological chemistry, largely due to the influence of Prof. W. D. Halliburton, and of such sciences as neurology, histology, embryology, organic chemistry, physical chemistry, experimental physiology, and pharmacology was the great dilemma of the medical curriculum. Prof. Lovatt Evans continued :—]

The solution to the difficulty lies, in my opinion, in two directions : first in the extensive modification of the present system of examinations, and secondly in the exercise of a sympathetic understanding on the part of specialist teachers of the difficulties of the student and a proper perspective of the relation of his own subject to the requirements of the curriculum as a whole.

THE UTILISATION OF PHYSIOLOGICAL METHODS IN CLINICAL MEDICINE.

It is, in my opinion, quite impossible, and perhaps undesirable, at the present time to frame instruction in physiology so as adequately to equip the ordinary medical student to proceed directly to the prosecution of research in any of its branches ; this can only be achieved by a further year or two of study of the subject, such as by a science course for an honours degree. One of the objects of instruction is to enable the latest results of physiological investigation to be utilised in the clinic, and it seems to me that one of the best ways for this to be effected is for some workers specially trained in physiological methods to enter the staff of clinical units where facilities for research work are at hand. The opinion was at one time prevalent among many clinicians that if their problems required the use of methods similar to those of experimental physiology these should be farmed out to a physiologist, and although there are cases where this procedure may be followed with advantage, the rich harvest which has already been reaped by the importation of physiological knowledge and methods into, rather than the export of problems from, the clinic, is adequate justification for the former. It is in any case encouraging to note the present-day decline of the attitude that experimental investigation is work of a lower order, which can be put out like so much washing, for the employment of an inferior caste. We at the present day, however we may be labelled, are not merely willing to admit, but eager to assert, that we cannot recognise fundamentally distinct methods of physiology, of psychology, of medicine, of chemistry, or of physics ; we only admit a method of experimental inquiry common to all science and slightly modified to suit particular cases.

THE APPLICATION OF MATHEMATICS TO PHYSIOLOGICAL PROBLEMS.

[In discussing the scientific aspects of physiology, the lecturer advocated mathematics as one of the collateral subjects of study which might be chosen by the young physiologist, for the following reasons :—]

The qualitative observations of one generation tend to become quantitative at a later stage of development of a science, and the degree of development of a science can indeed to some extent be judged by the extent to which it falls into a scheme of the unity of science by giving results which are capable of mathematical treatment and of expression in broad general principles. Mathematics and mathematical physics have been of considerable use to physiology in increasing the accuracy of its experimental data, and this in two ways. First, by bringing the accurate experimental and intellectual methods of physics to bear on the construction and use of the numerous physical instruments which it employs. It has been said by Prof. A. V. Hill that many of the early investigations on muscle were in reality studies of the properties of levers, and it is certain that similar remarks apply to only too many investigations in which the properties of the apparatus used have not been suitably investigated. As illustrations of the value of mathematical-physical study of apparatus one may mention the classical investigations of Frank on hæmodynamical recording apparatus, the fundamental treatment of string galvanometers and similar instruments by Einthoven, the correction of capillary electrometer records by Keith Lucas, and the vast improvements in galvanometer systems effected by Downing and Hill.

Even when the apparatus at the disposal of the physiologist is unexceptionable, however, it is often the fact that, owing to the nature of the subject, results ar [illegible] epetition with the same ease and [illegible] of chemical or physical experime [illegible] of the results is due in such cases to what are called *accidental circumstances*, a term which in reality means circumstances over which we have no control, owing either to our ignorance of their nature, or else to our inability to alter them. In those cases where further study provides methods of mo [illegible] and therefore more adequatel [illegible] cumstances, valuable results [illegible] For instance, certain of the obscure causes of different behaviour under particular conditions are inborn, and can be controlled by the use of inbred strains of animals such as those of the standard inbred white rats ; or again, one may mention the far-reaching results of the observation by Pavlov that the utmost care must be exercised when studying the conditioned reflexes to exclude all stimuli, however trivial they may appear, except the one under consideration.

Under the most favourable conditions, however, it has up to the present been usual to find a considerable unavoidable margin of variation in the results of many physiological experiments. By regarding these provisionally as "*chance*" variations, considerable help may be obtained by the application of the theory of errors, based on the theory of probability. In reality this is an empirical method, of which Poincaré has said that "everybody firmly believes in it, because mathematicians imagine that it is a fact of obervation, and observers that it is a theorem of mathematics," but nevertheless, although it cannot, as seems sometimes to be assumed, be used to replace accurate observation, it does enable a result to be brought out which might otherwise be obscured by small variations beyond our control. Research by such statistical methods provides a useful method of investigation, as, for instance, in the study of the toxic or other action of drugs, the data of the œstrus cycle, &c. An elementary deduction which can be drawn from the consideration of these facts is that, where only a few experiments of any kind are performed, important conclusions cannot be drawn unless it can be shown that the conditions are so controlled, and the accuracy of the actual observations so high that the sum of the individual "chance" variations must be small. Observation of this precaution would, in my opinion, reduce the bulk of contemporary physiological literature very materially, with a corresponding improvement in its quality.

Lastly, as a means for evolving generalisations out of experimental data, and of bringing these into relation with the generalisations of other branches of science, the use of mathematics is incontestable. One need only mention as examples the fresh outlook which has been provided for further investigation by the exact study of the data relative to the segregation and recombination of hereditary factors, the beautiful investigations of L. J. Henderson on the equilibria in the blood, the theoretical study of the phenomena of excitation, the employment of thermodynamics, and the numerous other applications of physico-chemical theory.

[Prof. Lovatt Evans then commented on the reunion between physiology and chemistry, which had given rise to the science of biochemistry, and briefly outlined the relations of physiology to zoology, botany, anatomy, and psychology. From his concluding section on the philosophical position we select a few stimulating paragraphs :—]

PHILOSOPHICAL CONSIDERATIONS.

Although the application of those sciences which are called "exact" is of immense value to physiology, we must be under no misapprehension as to their real relation, which is merely that they enable the phenomena of life to be described more accurately. They in no way furnish an explanation of those phenomena or enable us, without direct reference to physiological facts, to forecast them. The so-called exact sciences appear to be so because of the simplifications of which they are capable, by reason of which problems can readily be formulated and attacked. Disturbing conditions can provisionally be ignored or allowed for, and a first approximation reached which can be corrected later. In biology this can less readily be done. It is the failure to appreciate this elementary fact which leads some of those trained only in the methods of the exact sciences into the most palpable and unpardonable blunders when they attack biological problems. To take a simple illustration, no amount of pure physics, chemistry, and mathematics would have enabled the intricate and beautiful physico-chemical adaptations which have been shown by L. J. Henderson to happen in blood, to have been predicted, because these adaptations depend, among other things, on the presence of membranes round the red cells, fashioned by the living cells and having properties incapable of prediction. The investigation of the equilibria themselves, in their physiological significance, was a necessary preliminary to the introduction of physico-chemical theory. When these phenomena, and deductions from them, became known, it was possible for the physical chemist to step in, apply the appropriate theories, and thus enable the phenomena to be more accurately described in his own language.

But the fact remains that this description turns entirely on the postulated physico-chemical properties of the membranes as deduced from their actual behaviour under given conditions in what are in reality physiological experiments. It brings us no nearer to an explanation, perhaps, but it certainly does enable us to link up some of the phenomena of life with phenomena in the non-living, and so to describe them in terms which we think we understand better, because for some reason we regard physics and chemistry as more fundamental sciences than biology. Whether they are really more exact, however, is a point which might be debated.

The process of application of the exact sciences to physiology consists in reality of studying the phenomena themselves and then adopting the most plausible explanation capable of formulation in terms of the exact science. There is no other way. But let us be under no illusion about finding final explanations of what life is by this or any other methods.

Physiologists, in attempting to know what life is, have in my opinion attempted too much, and I think that a new standpoint is essential. One of the greatest of contemporary thinkers, L. J. Henderson, has recently submitted an argument with which I venture humbly to agree. The idea of adaptation, urged by Claude Bernard, should be adopted by physiology as its basal principle, as the chemist accepts the conservation of matter or the physicist the conservation of energy. We need not seek to know why it is so : that is the province of the philosopher ; all our experience tells us that it is so. It is not a definition of what life is, but a brief statement of its way, which is valuable, stimulating, and true. But we must treat the organism and its environment as one if we are to gain a proper insight into the adaptations manifested by the former. Life is conserved by adaptation, and I venture to think that this conception will be useful alike to general biology, to physiology, and perhaps most of all to pathology. For there is no fact in biology, pathology, or therapeutics which may not profitably be viewed from this fundamental physiological standpoint.

THE TREND OF MODERN PHYSIOLOGY.

In many ways a great future lies before physiology. Utilising the other sciences as its tools and itself reacting powerfully on them, we can confidently predict progress to undreamt-of heights, an enormous development of experimental pathology and medicine, and far-reaching effects on economic and sociological conditions. Yet, implicit in these very potentialities, there is another and a gloomier side to the picture. The rapidly accumulating wealth of detailed knowledge and of special technique demands an increased specialisation ; unless there is a periodic intellectual stocktaking there must inevitably be a loss of perspective and of grasp of great general principles. But how can this stocktaking be done ? Can team work ever reach that harmony of action which distinguishes the individual ? Any scientific subject is capable of indefinite expansion, and with the biological sciences it is hard to foresee what the ultimate end of *mere* expansion can be. How will scientific literature develop ? Will there have to be abstracts of abstract journals and reviews of reviews ? Will the subdivision of the subject necessitate in the long run the creation of lectureships or professorships to deal, for example, with the special physical chemistry of heterogeneous equilibria in biological systems, with intermediary metabolism, with the problems of hæmodynamics, or growth, or reproduction ? If so, how will the results of their special investigations be brought to common ground if no great unifying principles come to light ? Can we expect that such unifying principles will appear ; if they do not, will the progress of science be brought to an end by the accumulation of its own products ?

The establishment of special research professorships, however profitable in isolated cases, cannot in my opinion make good this growing specialisation, because it will tend to divorce research and teaching and place the teaching professor on a level of real or apparent inferiority. The idolisation of research for the sake of the advancement it brings is another of the dangers which threaten us. If there is one thing worse than "a mediocrity who does no research" it is "a mediocrity who does." There are at the present time a large number of junior research posts available, but not enough well-trained people adequately to fill them. This is all to the good provided that those who on trial show no aptitude for the work can be ruthlessly eliminated. As they often cannot, there are in consequence a number of young people who drift from one research scholarship to another, perhaps not aimlessly, but with no better objective than the manufacture of papers designed to justify their employment. The hapless editors of each of the swelling tide of journals are coaxed, hoodwinked and, if necessary, bullied, to ensure that these papers see the light of day. In the fullness of time the list of short-time research posts is exhausted, and the young investigator must now either turn to some entirely different occupation or else, as one of my friends expressed it, "subside into a professorial chair" for which, incidentally, he is probably entirely unfitted. The pursuit of science is nowadays, perhaps unfortunately, a career, and one in which moreover it pays to advertise. Science, we are often told, is the cream of civilisation. If we believe this let us use all our endeavours to ensure that it be not a whipped cream, specious, puffed up with wind, and presenting a fictitious appearance of solidity.

Lettsomian Lectures

ON

RHEUMATIC HEART DISEASE IN CHILDHOOD.

Delivered before the Medical Society of London

BY F. JOHN POYNTON, M.D., F.R.C.P. LOND.,
PHYSICIAN TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET; PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL.

LECTURE I.

Delivered on Feb. 20th, 1928.

IN these three lectures I shall pursue three particular themes. The first is the correlation of the pathological lesions of the heart with other rheumatic lesions; the second the clinical manifestations of rheumatic heart disease; the third the treatment of the heart disease. This lecture deals with the first theme, and the pathological lesions will be considered under two headings: (1) Those in the connective tissue skeleton. (2) Those in the "noble" tissues—for example, the heart muscle and nervous tissues.

There is general agreement that acute rheumatism is the result of an infection and that this infection is dependent upon various predisposing causes. These, however, are not generally agreed upon and are in process of careful investigation. In accordance with my own conviction, I shall assume the infection to be a diplococcus of the streptococcal group, though I admit that medical opinion generally inclines to the view that the cause is not yet known, and I recognise that the next great scientific move must be further extensive research in this direction.

1. THE LESIONS OF THE CONNECTIVE TISSUE SKELETON.

The earliest lesions in the myocardium, as shown in histological sections demonstrated before the Royal Medico-chirurgical Society in 1899, are scattered foci of cellular infiltration and the appearance of multi-nucleated cells between the muscular fibres. These are, in my opinion, the antecedents of the Aschoff nodule.

Aschoff's nodule has been the basis of extensive and world-wide research, in this country particularly by Dr. Carey Coombs, who says: "The submiliary nodules in myocardial rheumatism consist of rounded or fusiform areas formed by large spindle-shaped cells lying in the intermuscular trabeculæ of connective tissue." The average length he would estimate as somewhat less than 400 ft. "The special cells," he says, "are much larger than the fibroblasts of ordinary inflammatory reactions, to which in other respects they closely approximate. They are multinucleated, the chromatin substance of the nuclei in most cases appearing as a sharply defined margin with a small central mass or masses; the rest of the nucleus takes no stain and thus gives the cell a vacuolated appearance. They are surrounded by plasma cells and leucocytes, chiefly of the mononuclear variety. The nodules frequently arise in connexion with an arteriole, either around it or even in the wall itself, and their eventual fate appears to be cloudy swelling or cicatrisation." My view is that these nodules are the first signs of healing in a rheumatic lesion, and that they are probably evidence of a streptococcal infection, but that their absence from the lesions of a fatal acute rheumatism is no proof that the condition is not rheumatic.

When there is a severe infection the changes in the connective tissues, be it subcutaneous nodule, pericardium, cardiac valve, or synovial membrane, are all built on the same plan. The subcutaneous nodule is the best illustration, because it affords a complete example on a small scale. In the centre of the infected area there is necrosis, in the adjoining zone leucocytic infiltration and cell proliferation, in the outer zone vascular dilatation and swollen and often gelatinous-looking connective tissue fibres. Identical nodules were demonstrated by Sir Thomas Barlow in the pericardium and endocardium more than 40 years ago, and in the original paper on the rheumatic nodule, published in 1881, Warner and Barlow said: "Such nodules belong strictly to the fibrous tissues, and in nature are probably homologous with the inflammatory exudation which forms the basis of a vegetation on a cardiac valve." The results of the healing of these lesions are also clear; the necrotic tissue must be replaced by scar tissue, which in the nodules is negligible, but which in the pericardium may lead to adhesion or to great thickening of the layers, and in the valves to deformity.

The Necrotic Areas in Rheumatic Lesions.

The point on which to focus attention now and in the future must be the degree of perfection of the healing of the necrotic areas in the connective tissue skeleton. This is very difficult while the nature of the infective agent remains doubtful, and will continue difficult even should it prove to be streptococcal.

All my investigations with Dr. A. Paine, into the morbid anatomy, suggested that the infective agent would most probably be found where the zone of cell exudation merges into the dead tissue, for just at this point the infection has killed the resistance of the cells, but has not become, as it were, buried in the necrosis that it has produced. We need to know the frequency, duration, and extent of these unhealed lesions, especially in the connective tissue of the heart. We want, still more, to know whether they contain the infective agent in some form or another. I purposely say "in some form or another," because if the infection is unknown it may, when discovered, be found to assume some resting phase in such areas. Dr. Paine and I showed, at a pathological meeting of this society in 1911, that the diplo-streptococcus could be converted, by alterations in media in vitro, into very long chains or into a micrococcus indistinguishable in appearance from a staphylococcus. If a section of a gross streptococcal endocarditis is made in a region where there has been an effort at healing, we find the micrococci toward the healing area staining red, not blue, with methylene-blue, and later still becoming unstained refractile specks in the light blue fluffy necrotic tissue. The question is: are they then dead? If we watch a culture growing on such a medium as milk under the highest [illegible] ite refractile dots, [illegible] the fully developed diplo-streptococcus. If the infection is streptococcal these areas of necrosis are weak links in our knowledge of the morbid anatomy. Though I may seem to be dwelling upon recondite details, I am really only echoing the difficulties of the clinician who asks: When is an attack of rheumatism cured? How can

I ascertain this? What is the importance of unexplained fever in acute rheumatism? When we look at these questions from the aspect of morbid anatomy we can well understand how much further investigation is required to answer them, and how much our difficulties are increased by the great rarity of fatal rheumatic heart disease in the very earliest phases of the illness in man.

Some light is thrown, however, upon the destruction of the rheumatic infection by experiment and by some observations made by Dr. Paine and myself in 1911 upon experimental appendicitis in young rabbits; and in 1912 upon acute appendicitis in man associated with follicular tonsillitis. The same streptococcus was isolated from the tonsils and the appendix, and produced a series of cases of multiple arthritis and appendicitis in rabbits. The advantages of these investigations were that the animals could be killed in the early stage of illness and that the human appendix was in an early phase of acute infection. We hardly ever obtain such a lesion as rheumatic endocarditis at this early stage.

Possibly the rapid recovery of arthritic, compared with cardiac lesions, is due to the extreme vascularity of the synovial membranes and the profuse leucocytic reaction in them, combined with our ability to keep joints at rest. The cardiac valves are under great disadvantage, but a mitral valve which has been slightly damaged by a row of marginal vegetations will, in course of time, heal with slight thickening only; this in turn may smooth down and become of no functional importance, as clinical experience has amply demonstrated.

Every investigator of acute rheumatism must be struck by its general resemblance to tuberculosis, and I would compare the acute phases of the two infections.

Chronic Rheumatic Infection: Mitral Stenosis.

I now come to another type of lesion in which the invasion of the connective tissue skeleton is subacute and distinguished by a slow process of fibrosis. This type we all know too well as the cause of what is probably the most serious form of organic heart disease: mitral stenosis. Our efforts to ameliorate rheumatic heart disease must depend to a considerable extent upon a better understanding of the life history of this type of rheumatic infection.

At the onset we are met by two puzzling problems. Why is this type so much more frequent in the female? and does the process of fibrosis depend entirely upon the infective agent or is there also some tendency in the individual tissues to react in this fashion? This second question is of great clinical importance and may be put in another form: does a severe mitral stenosis result from a single prolonged attack of rheumatism, or does it more frequently result from repeated and often unrecognised reinfection or recrudescence? The brutal attacks and the gross injuries of infective processes in human beings we comprehend, but it is the quiet, stealthy movements of infection that are so baffling and so likely to lead to wild theories and sometimes equally wild methods of treatment. The chordæ tendineæ of the mitral valve of a rabbit is but a mere thread of connective tissue, yet by intravenous inoculation we can demonstrate that the infection fastens upon one segment of this slender cord.

In one little girl who died of rheumatic myocarditis in a first attack, I traced at the bedside, in the short period of five months, the development of the physical signs of mitral stenosis in a valve at first apparently healthy. The cusps after death were greatly thickened throughout, but showed no projecting marginal vegetations. The sections showed a condition identical with that found in a rheumatic nodule.

Dr. Carey Coombs, in his valuable monograph upon rheumatic heart disease, gives excellent illustrations of similar changes in the musculi papillares. Such extreme damage to the cusps of a valve as occurred in the small child might well, if she had survived and had no further attack, have caused sufficient contraction to produce a grave stenosis. There are, however, many cases in which one suspects obstinate recurrent infection as a more probable cause of severe stenosis. This is shown, for example, by repeated attacks of chorea as evidence of recurrent activity of the rheumatism. Let us hope that recurrent rheumatism is more usual, for upon this hypothesis there is more encouragement to efforts at prevention. This chronic process of fibrosis is sometimes met with in the aortic and tricuspid valves, and also in the myocardium.

Many physicians have noticed the occurrence of a chronic arthritis of the hands in association with advanced mitral stenosis, and there is also a considerable number of examples of fibrosis of the kidneys with the same association. It is difficult to speak with any certainty of a chronic arthritis of rheumatic origin in the child, although I suspect that it may occur in exceptional cases. Rheumatic nodules may undoubtedly remain for long periods of time, reach a considerable size and show much fibrous change under the microscope, as also may a chronic fibrositis and tenosynovitis in the palms of the hands. Some cases of chronic arthritis I have seen have been complicated with sclerodermia and with endocarditis of the sclerotic type, but these are very rare and their rheumatic origin may be questioned.

My experimental observations, made with Dr. Paine on endocarditis, suggested that infection of the valves takes place from the coronary circulation and not from the blood in the heart chambers, and that morbid changes begin within the structure of the valve as they do within the wall of the vermiform appendix.

The Pericardium.

The morbid changes in the pericardium also begin within the pericardial tissues beneath the endothelium. When the inflammation is severe, an infinite number of necrotic areas appear and destroy the endothelium, thus producing the shaggy appearance. In the subendothelial pericardial tissue there are vast numbers of blood capillaries, and their distension and rupture explain the fact that acute rheumatism is the most frequent cause of hæmorrhagic pericarditis. The numerous foci of inflammation account both for pericardial adhesion and for the fact that when a pericardium has been thought to be generally adherent a renewed outburst of infection may lead to a localised but unexpected reappearance of friction in some area which has not become glued down by the earlier attack. The chronic fibrotic type of pericarditis, in which nodules of considerable size may be found and in which great thickening may occur, is of clinical interest, because it may very closely simulate a pericardial effusion, and thus prove a pitfall to the clinician or radiologist who is not well acquainted with the possibilities of rheumatic infection.

It is generally accepted that an extensive pericardial effusion in childhood—i.e., one sufficient in itself to strangle the cardiac movements—is altogether exceptional. However extreme the area of cardiac dullness, the physician's first thought must always be: is this the result of cardiac dilatation, or of dilatation with a thickened and adherent pericardium?

Prolonged periods of pericardial friction and its reappearance when, after a latent phase, the infection again becomes active, make it easier to prove that an obstinate but active infection is the cause of a thickened and fibrotic pericardium, than that it is the cause of a chronic valve lesion. In some exceptional cases the process may affect not only the pericardium but both pleuræ, and the result is the remarkable sequence of events met with in multiple serositis. These are: strangling of the heart, much enlargement of the liver and spleen, and recurrent and severe ascites. In childhood, however, this is more frequently due to a chronic tuberculous infection of the serous membranes. In other cases chronic infection of the pericardium, pleuræ and mediastinal tissues causes an indurative mediastino-pericarditis which eventually, by gross mechanical shackling of the heart, produces fatal consequences without the repeated outbursts of active infection that occur in multiple serositis. The healing of a severe pericarditis is and must be slow, and the presence of partially healed and dangerous necrotic areas in the pericardium is of interest.

A girl admitted to hospital in the middle of January, with severe pericarditis, eventually recovered from all active signs of the disease, but the heart was so greatly injured that she died in the middle of April. The post-mortem examination showed that, although the pericardium was becoming generally adherent, the adhesions at the back were still soft and only partially formed. This gives definite information upon the slowness of the process of healing of a severe pericarditis. Even if the adhesions had been sound and firm, the recovery of the cardiac muscle would still have to be reckoned with. This proved to very imperfect, and extensive fatty change was present throughout the heart wall. The bearing of these observations upon treatment is obvious.

The danger of active foci is well illustrated by another child who was in hospital eight and a half months with repeated outbreaks of recurrent pericarditis, persistent fever and recurring subcutaneous nodules. After death great thickening of the pericardium was found, but there was no fluid in the sac and only a few recent adhesions were present. Here there was continual activity and a condition which I should term a malignant rheumatic pericarditis.

Interstitial Lesions in the Myocardium.

The interstitial tissues of the myocardium are damaged in rheumatism much as the endocardium and pericardium are. In my experience it is unusual to see the extensive scar formation such as occurs, for example, in syphilis of the heart, but in inveterate cases extending beyond the age of childhood this may occur, and the resulting perivascular fibrosis is exactly comparable with that seen in chronic appendicitis and in rheumatic arthritis, which affects the vessels of the synovial membranes and doubtless interferes with their normal function. .

Clinical investigation has proved that from time to time the miliary lesions in the connective tissue closely connected with minute arterioles may damage in some degree the conducting fibres of the cardiac mechanism Temporary heart-block is an example.

Malignant Endocarditis.

There is another problem in the morbid anatomy of acute rheumatism which in some respects is the most important of all. Can the infection develop a local virulence and then obtain almost complete mastery of the situation? or, when a local predominating bacterial virulence occurs, is it because the rheumatic disease has prepared the way for other infections? No one can possibly answer this question until the cause of acute rheumatism is decided, and for this reason alone I look upon the problem as one not for controversy but for research. It is essential that the facts should be thoroughly understood. For example it is common knowledge that in "subacute bacterial endocarditis" a patient often complains of rheumatic pains. This may or may not be evidence of the rheumatic nature of the disease. It is well known that rheumatism often attacks more than one valve, and it is interesting to find the overwhelming frequency of the combination of the mitral and aortic lesions, that is, of damage to two valves in close proximity. This combination is very frequent in childhood and of the greatest clinical importance. If these cases are traced into adolescence, and some of them suffer from repeated attacks of rheumatism, they may die of malignant endocarditis. It is this combined lesion which in my experience most often develops malignant endocarditis. Among cases with a rheumatic history are found not only malignant endocarditis and fugitive pains, but also multiple arthritis, nodules, Osler's spots, and pericarditis. Further, as post-mortem and clinical evidence show, the arthritis and the pericarditis may subside but the endocarditis come gradually to the fore and prove to be of the malignant type. Streptococci may be recovered from the blood in severe rheumatism and yet the patient may recover. Sir William Willcox recorded the case of a man from whom Dr. Paine had isolated the micrococcus from the blood during an attack of pericarditis, and who was at work seven years later; I have had other examples in childhood. It is well known, on the other hand, that in many cases of malignant endocarditis the streptococcus cannot be isolated from the blood for long periods and sometimes not at all. In 1912 I showed at this society the heart of a boy, aged 7, who died in his first attack of acute carditis. On the mitral valve was a large fungating vegetation, and there had been arthritis and severe pericarditis with an unusually copious hæmorrhagic effusion. Large subcutaneous nodules may also occur in cases of malignant endocarditis associated with rheumatism; in one of these we demonstrated the micrococci in a minute blood capillary.

I lay stress upon these points because it is of the utmost importance for the future of the treatment of heart disease, and for the elucidation of the cause of acute rheumatism, that a decision should be reached as to whether or not there is a malignant type of rheumatic endocarditis. If there is, then it will mean that the cause of the disease "acute rheumatism" is ascertained; if there is not, we are left with two difficulties for solution. The first is the discovery of the real cause, and the second is the reason for the frequent association of a streptococcus with the lesions of acute rheumatism, for the appearance of this micrococcus has perplexed investigators all over the world. In the cases of the type of which I am speaking the only difference in the morbid anatomy of the valve from that of a simple rheumatic endocarditis lies in the necrotic tissue of the vegetation. In the first it is crowded with the micrococci, but in the simple form they are destroyed or apparently destroyed, and must be searched for in the zone abutting on the necrotic area, where they will only be found in scanty numbers. This difference seems to me the essential factor in the problem, and all the secondary consequences of an active local focus impinging on the blood stream merely confuse the issue by producing a general septicæmia and diverse symptoms from infarctions, which naturally lead us to believe that we are dealing with a disease of different nature from acute rheumatism. The alternative explanation, that this form of endocarditis is the result of a secondary infection attacking damaged valves, is undoubtedly much more easily comprehended, because it is most difficult to find the micrococci post mortem in the valve of simple endocarditis, but in the malignant endocarditis they abound.

Is rheumatic endocarditis frequent in the young? and are the possibilities of secondary infections fro tonsillitis, from septic sores, from otitis media, fro empyemata and broncho-pneumonia, frequent? A we are compelled to answer both questions in th affirmative, malignant endocarditis should be frequen in the rheumatic child, and yet, as a fact, it is exceptional. Fatal rheumatism and tuberculosis in the young have almost invariably a widespread distribution. It is in later life that, in both diseases, a local lesion comes to the front and overpowers all resistance. We have to explain the exceptional cases of malignant endocarditis in the rheumatic child by supposing that other lesions, such as the pericarditis, the arthritis and the nodules, may behave in the usual fashion of acute rheumatism and subside, and yet the endocarditis progress. Have we, then, two acute processes occurring simultaneously, one undoubtedly streptococcal and the other the mysterious rheumatic infection? If the damaged valve—the result of past attacks of rheumatism—only serves to give a foothold to the secondary infection, why should the rheumatic infection become active in other organs simultaneously? When we consider malignant endocarditis and rheumatism, it becomes apparent how vital the bearing of streptococcal infection is on the problem of causation. Twenty-five years ago Dr. Paine and I remarked to one another that the great battle as to causation would be fought not over acute rheumatism but over this form of endocarditis, and I still hold that view.

Recent Investigations.

A recent paper by K. E. B. Birkhaugh[1] is one that must arouse attention. Here, again, a streptococcus is the centre of interest. When we brought forward our first paper in September, 1900, we were faced by the difficulty that if we called the micrococcus a streptococcus the reception would be: "These gentlemen have rediscovered the streptococcus pyogenes"! There was then no general realisation of the complexity of the streptococcal group. That difficulty has long passed away, to be supplanted by the converse and formidable problem of how to distinguish the various groups of streptococci. The researches of Swift and Kinsella, Andrewes and Derick, could find no specific type of streptococcus in acute rheumatism. Then came the work on scarlet fever, and the development of the Dick test. Here, again, we find the streptococcal group in evidence, and we must remember the association of scarlet fever and rheumatism. Birkhaugh isolated, from an acutely fatal case of juvenile rheumatism, what he terms "a new species of non-methæmoglobin forming, inulin-fermenting, bile-insoluble and toxigenic Gram-positive streptococcus." This he also isolated from the tonsillar crypts, blood and cardiac vegetations, fæces and urine. He groups it apart from the *Streptococcus hæmolyticus* and *Streptococcus viridans*. Among 68 strains of this streptococcus 72 per cent. were found to produce a soluble toxic filtrate with which 76 per cent. of rheumatic children gave positive skin reactions. Intramuscular injections of increasing doses in laboratory animals and in human beings susceptible to the toxin produced a neutralising antitoxin. The micro-organism injected into rabbits produced the various manifestations of rheumatism. Finally, the author of the paper, who had previously given a strong positive intradermal reaction, produced in himself, by intra-articular and intramuscular injections of large doses of the soluble toxic filtrate, an acute polyarthritis of the rheumatic type. This is a research which, if it meets with confirmation from other investigators, will mark a definite step forward in our knowledge of the causation of acute rheumatism, but it clearly needs very thorough confirmation, and at the moment I use it chiefly as an illustration of the modern lines of thought on the problem of the streptococci.

In association with rheumatic carditis we sometimes meet with unusual rheumatic manifestations such as phlebitis. I believe this to be of the same type as the other lesions: an interstitial inflammation in the wall of the affected veins. Similarly the peritonitis is strictly akin to the pericarditis, pleurisy, mediastinitis, arthritis and tenosynovitis. Again the tonsillitis, when severe and still more when recurrent, will lead to fibrosis and, as a result, the penning up of foci of infection deep from the surface. Surgery has now demonstrated this incontrovertibly. The involvement of the tonsillar cervical glands is easily understood, and the study of the morbid anatomy of the disease leads us to believe that in these glands there will be great destruction of the infective agent if it is streptococcal. Clinical observation bears out the morbid anatomy, for there is a large group of mild rheumatic infections which show themselves in sore-throat, enlargement of the cervical glands, and a passing cardiac dilatation from the escape of the infection or its toxin into the system.

2. LESIONS OF "NOBLE TISSUES."

In the second group of lesions caused by the rheumatic infection we are once again confronted by a large unexplored field, and realise how essential it is to decide the exciting cause of the disease. We know nothing fundamental about the nature of the poisons in acute rheumatism, or to what extent they act by direct injury to the tissues or by the more subtle process of building themselves into them and thus producing some more or less permanent alteration in the normal metabolism. The bacteriologist and biochemist will no doubt slowly solve some of these essential problems which the clinician and morbid anatomist can but dimly recognise. We know with certainty that direct damage is done to the muscle of the heart and to a lesser degree to the nervous system, as shown by the meningo-encephalitis of chorea. We suspect from the highly nervous temperament and the occasional thyroid enlargement of many rheumatic children that an attack of acute rheumatism may possibly alter the metabolism or, at any rate, the normal functioning of the tissues long after any active sign of infection has disappeared.

I am a firm believer in the hereditary factor in acute rheumatism. Upon this the private case-books of the late Dr. W. B. Cheadle, dealing with educated patients, gave clear evidence: in 30 consecutive cases 23 gave a family history, and in 103 out of 180 there was also family history in parents or near relatives. Again, when acute rheumatism attacks children under 5, there may be striking examples of this hereditary factor.

A female, aged 2, had severe rheumatic carditis with arthritis. Her father had had rheumatic fever, and her maternal uncle died of the disease. A female, aged 4½, had acute rheumatic arthritis, and her mother had three attacks of acute rheumatism and suffered from heart disease. A female, aged 3½, died from acute carditis. Her father had suffered from acute rheumatism, and her paternal uncle had died of the disease. A male, aged 4½, had an attack of acute rheumatism with arthritis and carditis. His father had also had an attack of acute rheumatism.

It is my belief that some peculiarity of constitution is transmitted to such children, rendering them less resistant to the infection, but it is impossible to speak with any certainty in our ignorance of the rheumatic toxins.

We know that the cardiac muscle may be terribly injured. Fatty changes are the most easily demonstrated, and on two occasions I have seen small cardiac aneurysms of the right ventricle, the blood in the cavity of the chamber being separated from the pericardial cavity only by the visceral pericardium. When there are also extensive and scattered lesions in the interstitial tissue, it can be readily understood how grave the results must be. It is most exceptional for this condition of the heart to be unattended by some degree of pericarditis, but cases have been recorded and death has resulted from acute asystole due to a primary rheumatic myocarditis.

Injury to the Nervous System.

I spoke of chorea as a rheumatic meningo-encephalitis—a view held by Dr. Paine and myself as the result of our investigations, further upheld by Dr. Gordon Holmes and myself, and again supported by the distinguished pathologist to the National Hospital for Nervous Diseases, Dr. J. G. Greenfield, in a detailed investigation of a fatal case of chorea, published in THE LANCET (1922, ii., 603). It is supported also by various Continental investigators. From the standpoint of morbid anatomy all are agreed that the lesions in the nervous tissues are comparatively slight. Recent years have, however, revealed to us much that was unknown before, for the appearance of encephalitis lethargica has shown us conclusively what devastation apparently insignificant lesions may produce in such a highly evolved organ as the brain. Not only may the physical disabilities be great, but the character of the patient may be entirely altered. We know that chorea is an outstanding result of rheumatism and attracts the attention of the most superficial observer. We also know that the rheumatic child is exceedingly nervous, and that in chorea there may be delusions and even a condition bordering on dementia. Rheumatic children may also, between attacks of acute rheumatism, suffer from prostrating headaches, from paroxysmal attacks of cyanosis of a limb, or spasms of the muscles, or intense neuralgic pains. Still more remarkable are attacks of anginal pain, in which there is undoubtedly a so-called functional element, but which nevertheless may prove fatal if there is organic disease of the valves. We cannot deal satisfactorily with heart disease in the young if we do not realise how important a part the nervous system takes in its management and treatment.

---

[1] Journal of Infectious Diseases, May, 1927.

Chorea is the most frequent solitary manifestation of rheumatism, and yet it may be a precursor of and a manifestation in the most severe attacks. I believe that injury to the nervous system not possible to appraise in the terms of morbid anatomy may lower the resistance of children to the rheumatic infection, and that continual strain from brain work, not perhaps of any high degree of excellence, tells upon this kind of child much more than we recognise. On account of their keenness and lack of reserve nerve power, these children require more rest than others, and if they do not get it they are more likely to be attacked by the disease. I look upon lowered nerve tone as an important predisposing cause. Certainly no children with a severe attack of heart disease require more care and tact in nursing and handling. In many cases, also, excitability of the heart's action, which adds much to the difficulty of obtaining complete recovery, is by no means dependent upon an active myocarditis, but upon some damage in the nervous system.

Injury to the Blood.

Sometimes the streptococcus can be isolated from the blood stream and at other times it may be demonstrated in the diplococcal form in the [illegible] leucocytes. It would surprise me [illegible] these events were frequent, because the lesions produced are chiefly focal and the tissue-resistance to the infection is great, so that the micrococci are destroyed more or less completely in the lesions. The red cells suffer severely and the hæmoglobin in particular is damaged by the rheumatic poisons. The anæmia may be very slow in abating, and I suspect th[illegible] associated in adolescence with [illegible] favours the development of malignant endocarditis. Swift and J. R. Miller, junior, have recently investigated the white cells, and find that the leucocytosis may reach to 10,000 per c.mm. Their researches have been very careful and detailed, and they hold that anti-rheumatic drugs will control this leucocytosis, which will again assert itself should they be discontinued while the [illegible]. I am anxious to corroborate [illegible] clearly it may help us in estimating the progress of a case.

There may be other and more subtle changes in the blood plasma as a result of the rheumatic infection, but of such I have no knowledge.

SUMMARY.

I have endeavoured in this lecture to bring into prominence the two chief ways in which acute rheumatism damages the heart and other organs, basing my argument upon experimental and pathological investigations, with a streptococcus as the assumed cause. There are the local interstitial lesions which tend to necrosis and fibrosis, and there are the toxic effects of the circulating poisons. The interstitial lesions seem to me to produce results which clinical observation at the bedside corroborates: valvular lesions, pericarditis and local myocardial disturbances. The toxic effects of the infection, though well recognised at the bedside in the profound anæmia and damage to the cardiac muscle and nervous system, cannot yet be correlated with any definite poison, though I believe it would be difficult to prove that a streptococcal infection could not produce such results. I can imagine no more difficult problem than the isolation of these poisons, some of which may possibly only be produced in the living organism and not in vitro. If the exciting cause of the disease is still unknown, it is at least apparent that we must expect it when discovered to give us an explanation for the many ascertained facts of the morbid anatomy, and all who are interested in the great problem of rheumatism must look forward with eagerness to the solution. Whatever it may be, I should like to take this opportunity to say of my friend and co-worker, Alexander Paine, what that great genius from my native county of Somerset, Roger Bacon, said of Peter of Maricourt: "Of discourses and battles of words he took no heed, he followed the works of wisdom and in them found rest. Through experiment he gained knowledge of natural things."

CAROTID CAVERNOUS SINUS ANEURYSM.

BY G. P. B. HUDDY, M.S. LOND., F.R.C.S. ENG.,
SURGEON TO THE DUDLEY-ROAD HOSPITAL, BIRMINGHAM.

IN this article I refer particularly to carotid cavernous sinus aneurysm, but many of the references and figures relate to articles on "pulsating exophthalmos," a condition in which the exact pathological lesion is often unknown though the majority of cases are due to carotid cavernous sinus aneurysm. This condition, although uncommon, is not one of the rarities of medicine. There are still many points which require elucidating, and as it rarely falls to the lot of any one person to see more than one or two cases their record is valuable.

Classification and Ætiology.

The cases are classified into traumatic and spontaneous.

In the traumatic group the injury may be direct, such as a gunshot wound, but it is more usually caused by indirect violence, often a fracture of the skull.

In spontaneous cases the main factor is disease of the artery resulting either in its rupture or in the formation of a true aneurysm, which ruptures secondarily. A large proportion of these cases occur in females, and Hart,[1] writing in 1862, pointed out the ætiological significance of weakness after fever or childbirth. De Schweinitz and Holloway[2] found that the onset occurred during pregnancy in 14 out of 49 women suffering from pulsating exophthalmos. Strain may also excite the condition, although sometimes the onset occurs while the patient is at rest. Locke, in an important article[3] on pulsating exophthalmos, gave figures from which it appears that approximately three-quarters of the cases are traumatic, that three-quarters of the traumatic cases occur in men, and that three-quarters of the spontaneous cases occur in women.

The average age for the traumatic group is towards the end of the third decade, and for the spontaneous towards the end of the fifth decade.

The trauma may be very slight. Picqué[4] recorded a case in which the patient received a blow on the right eye which caused neither loss of consciousness nor any serious contusion to the eye. Cases of this kind probably belong ætiologically to the spontaneous group, the trauma acting as the final factor.

Anatomy.

The cavernous sinus is situated on the side of the body of the sphenoid and extends from the sphenoidal fissure to the apex of the petrous portion of the temporal bone. The superior ophthalmic vein drains into the anterior end of the sinus through the sphenoidal fissure, communication being thus established between the angular vein and the sinus. The inferior ophthalmic vein may enter the sinus or may join the superior ophthalmic vein. Posteriorly the cavernous sinus drains into the superior and inferior petrosal sinuses, which are closed in by rigid structures—bone and dura mater—and thus the effects of the arterio-venous communication are chiefly thrown on the veins draining into the sinus. Some of the cerebral veins drain into the sinus, which also communicates with the pterygoid venous plexus. Running through the sinus is the internal carotid artery, accompanied by filaments of the carotid plexus and the sixth nerve. Situated on the outer wall are the third and fourth nerves, with the ophthalmic and superior maxillary divisions of the fifth. The cavernous sinuses are connected by the circular sinus.

The ophthalmic vein, the third, fourth, and sixth nerves, and the branches of the ophthalmic division of the fifth pass through the sphenoidal fissure. The superior maxillary division of the fifth nerve passes through the foramen rotundum. The optic nerve, in close relationship to the anterior end of the cavernous sinus, passes through the optic foramen accompanied by the ophthalmic artery.

Symptoms and Signs.

The severity of these varies considerably with the size of the arterial rupture and the presence or absence of clotting. When arterio-venous communication is established the blood pressure in the cavernous sinus is raised, reversing the flow of blood in the ophthalmic veins. These pressure changes are also transmitted to the sinus of the opposite side, so that the symptoms and signs are occasionally bilateral.

The Bruit.—As a rule the first symptom is a noise in the head, which has been variously described as "humming," "buzzing" or "puffing." This noise may be either (1) continuous, with increase at each systole; (2) intermittent, corresponding to the heart systoles; or (3) continuous; it is a source of great annoyance to the patient and interferes with his sleep. The note varies with the size of the communication, and the intensity with the alterations in blood pressure, due to change of posture, exercise, &c. The noise may be so loud that it is audible to people near at hand; it may be heard in the temporal, parietal, and occipital regions, and in the ear and orbit. Pressure on the affected artery will usually stop it, but occasionally bilateral carotid pressure is necessary. Pressure at the inner canthus may stop the bruit. On auscultation it can be heard over the affected eye, usually over the whole head, over the facial bones, and along the course of the carotid artery involved. In traumatic cases it may be heard immediately the patient regains consciousness, but if the tear is a small one or if it is blocked by clot it may not become audible for some time. According to Rhodes[5] the average interval is 21 days, but the onset may be delayed for months or even years. In spontaneous cases it is usually sudden.

Exophthalmos is generally the next symptom to appear, and is classically but not invariably present. Typically it is of the pulsating type, but this again is not invariable, as is shown by the example of Delore, Aurand, and Roland.[6] The pulsation may be very slight, and detected only by pressure on the eye. At times the exophthalmos becomes so extreme that dislocation of the eye results. Williamson[7] writes: "On raising the upper eyelid to gain a better view, the eye suddenly shot out in front of the lids, like the forward dislocation that takes place when the speculum is pressed back after division of the tendons in the operation of excision."

Corneal ulceration may follow severe exophthalmos, and endanger the integrity of the eye. This is more likely to occur on account of the neurotrophic changes mentioned below.

Dilatation of Veins and Venules.—As a result of the increased blood pressure, dilatation and subsequent thickening of these vessels occurs at times with a pulsatile tumour, possibly with a thrill, situated typically in the upper and inner portion of the orbit on the affected side. Cauchoix[8] states that this tumour is present in from one-quarter to one-third of the cases. The dilatation may extend to the veins in the supra-orbital region or to the veins of the face as in Williamson's case,[7] in which pulsation and a thrill could be felt along these veins as far as the angle of the jaw. The congestion of the smaller vessels causes great vascularity and œdema of the conjunctiva. This chemosis may be so severe that the eye is hidden from view and ulceration of the conjunctiva ensue. Retinal examination shows dilatation and often pulsation of the veins, while the optic disc may be swollen.

Nerve Involvement.—Sometimes a nerve lesion is caused, either directly by the injury or indirectly by pressure and stretching in the sinus, in the sphenoidal fissure, or in the supra-orbital notch. In the two latter cases the superior maxillary division of the fifth nerve escapes. Stretching of the optic nerve follows the exophthalmos. Diminished vision or blindness, paralysis of the eye movements, ptosis, a dilated and fixed pupil, and loss of corneal sensation result. De Schweinitz and Holloway[2] state that 20·4 per cent. of cases of pulsating exophthalmos terminate in blindness, others have diminished vision, and not more than 11·1 per cent. retain normal vision. Of the nerves running in the sinus and its wall the sixth is that most commonly involved. Injury to the branches of the fifth nerve, which is the one least commonly affected, results in pain, as in Taylor's case[9] or in numbness, as in a case recorded by Berry.[10]

The symptoms described are typical of the condition, but are not necessarily all present. In Murray's case[11] there was bilateral exophthalmos, but no interference with the eye movements and no blindness. This is possibly accounted for by the presence of an unusually large communication between the two sinuses, causing bilateral exophthalmos while relieving pressure. Holmes[12] refers to a case in which the swelling of the conjunctiva was so great that the lower eyelid was covered and yet the eye was movable and the vision perfect.

In rare cases the eye-changes first appear on the side opposite to the lesion. This is difficult to explain, but possibly occurs when the arterial rupture is situated immediately opposite the opening of the circular sinus and the blood, as it is forced through the hole in the artery, transmits its pressure directly to the opposite side.

Differential Diagnosis.

The following conditions have to be differentiated from a carotid cavernous sinus aneurysm: (1) Pulsating orbital tumours—e.g., malignant tumours or cirsoid aneurysms. (2) Aneurysms of the ophthalmic artery in the orbit or within the skull. (3) Orbital arterio-venous communications—Lansdown's case.[13] (4) Orbital cellulitis. (5) Cavernous sinus thrombosis. (6) True aneurysms of the internal carotid artery in the cavernous sinus. These are much more rare than carotid cavernous sinus aneurysms and may, as in the case of Morax and Ducamp,[14] give rise to no symptoms unless the aneurysm ruptures. Barnard and Rigby[15] state that it is the aneurysm of the internal carotid alone which gives rise to the intermittent bruit. Holmes[16] and Adams[17] record examples of this condition, in each of which there was involvement of branches of the fifth nerve, but no mention is made of any exophthalmos, pulsation, or bruit. (7) Maynard[18] reported a peculiar case with pulsation and exophthalmos in which œdema of the optic nerve accompanied internal hydrocephalus.

There are a few cases on record which appeared clinically to be examples of this condition, but which at necropsy showed no communication between the carotid artery and the cavernous sinus.

Treatment.

Procedures adopted in the treatment of this condition are not without risk, and therefore one has to consider carefully whether these measures are justifiable. Rarely a spontaneous cure occurs. The condition may remain stationary, as in Williamson's case,[7] in which there was no alteration during a period of 23 years. A stationary case may again become progressive, as in the example of Bonnamour, Bujadoux, and Lyonnet,[19] where this occurred after an interval of eight years. Typically, however, the condition is steadily progressive and, although later the swelling and exophthalmos may diminish, there is a very grave risk of loss of sight. Further, the persistent noise in the head is a source of great annoyance to the patient from which he may demand relief in spite of the risk.

General measures are rest in bed on a light, dry diet, and the use of such drugs as iron lactate, potassium iodide, acetate of ammonia, and belladonna. Under such treatment cures have been recorded, but the results are so uncertain that the patient must be under careful observation so that an operation can be performed whenever necessary. If improvement occurs the patient must be warned of the danger of recurrence and advised to report at once any change in the condition. If the exophthalmos is very marked the eyes may be protected by suture of the lids. The subcutaneous or intramuscular injection, repeated every four to eight days, of 100 to 250 c.cm. of warm 2 per cent. gelatin solution in serum has been advocated.

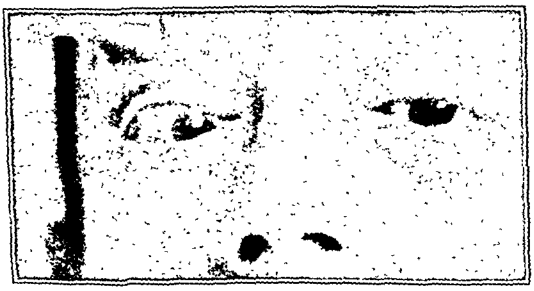
Direct attack on the aneurysm has been suggested but never attempted.

Measures applied to the carotid artery carry a greater risk in the spontaneous than in the traumatic group, as the patient is older and the conditions for surgical interference not so favourable. Further, as there is generalised disease of the blood-vessels, an efficient collateral circulation is less likely to become established.

1. Carotid compression by digital or mechanical means is tedious, and the results are uncertain. Clotting is more likely to ensue in the diseased vessel of the spontaneous cases than in the healthy vessel of the traumatic cases. Compression of the carotid is sometimes useful as an indication of the risks of ligature, for if it produces vertigo, motor, or sensory disturbances of the limbs or loss of consciousness, a preliminary course of carotid compression should be carried out in order to improve the collateral circulation.

2. Ligature of the common carotid is attended with risk both to life and to the normal functioning of the brain, as immediate ischæmia or later embolism may cause temporary or permanent hemiplegia or aphasia. The mortality-rate of this operation for this condition is under 10 per cent., whereas ligature of the vessel in cases of wounds, tumours of the neck, &c., carries a much higher death-rate. Local anæsthesia diminishes the risk of cerebral complications, as if any ill-effect is noted the ligature can then be loosened. The occlusion of the vessel should be carried out very slowly and gradually during a period of some minutes, or a Crile's clamp may be temporarily applied. A disadvantage of this operation is that a collateral circulation may be rapidly set up through the external carotid artery; to avoid this the latter may be ligatured at the same time.

FIG. 1.

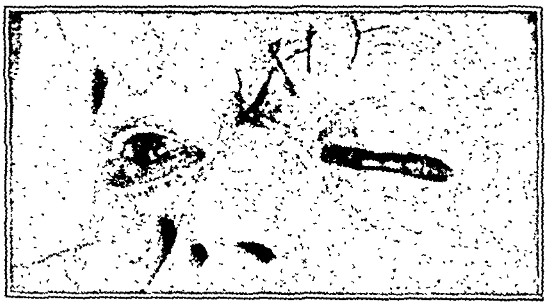


Condition before operation.

3. Ligature of the internal carotid artery avoids the disadvantage of ligature of the common carotid which has just been mentioned. The operation is rather more difficult, and for this reason it has been held that common carotid ligature is preferable in the spontaneous cases, as the vessel is probably diseased and there is risk of emboli becoming detached. A double ligature of the internal carotid has been attempted, the first ligature being applied in the neck and the second immediately proximal to the origin of the ophthalmic artery, but the result was fatal.

4. Bilateral carotid ligature. Following the ligature of the carotid artery the bruit usually ceases, but at intervals varying from hours to months it may return in a diminished form or with an altered note, and may then persist or increase in intensity or disappear again. With the return of the bruit the question of ligature of the opposite carotid artery arises. This should not be carried out until several months after the first operation, when the risk is apparently not greater than that attached to ligature of one carotid. Even then cure does not always result.

FIG. 2.



After ligature of veins at the inner canthus.

It has been stated that there is an ultimate diminution of cerebral function after ligature of both carotids, but this has not been confirmed.

Procedures on the orbital veins are of three kinds:—

1. Compression has been used alone or in combination with medical treatment, or combined with compression or ligature of the carotid artery. An interesting example of mechanical pressure in treatment is afforded by a case recently sent to see me.

A woman, aged 39 years, had suddenly noticed, after telephoning, a noise "like steam being let off" in the left occipital region. This was followed two weeks later by a swelling below the left eye. Five weeks after the onset there was ptos[illegible] diplopia with increased swelling. On [illegible] as a bruit which ceased on pressure ov[illegible] carotid and at the inner canthus of the left eye. The patient, who had noticed that pressure at the inner canthus gave some relief, was wearing pince-nez spectacles, and had had made a metal prolongation with a small pad to cause pressure at the inner angle of the left eye.

2. Other measures calculated to induce clotting, such as electrolysis, puncture with hot needles, and the injection of [illegible] iron lactate hav[illegible] and cure, but [illegible] whole have been considered dangerous. Now that the injection treatment of varicose veins has become popular, this method may receive more favourable consideration.

3. Operation on the orbital veins was first carried out by Lansdown[13] for a case of pulsating exophthalmos not due to carotid cavernous sinus aneurysm. This operation has been used (*a*) as a primary method of treatment; (*b*) combined with or secondary to carotid ligature.

Locke[3] says that under no condition should an attempt be made to perform an orbital vein ligature and a carotid artery ligature at the same sitting, as the results have been unfortunate.

The following types of operation have been used: (*a*) ligature of the veins at the inner canthus; (*b*) ligature of the superior ophthalmic vein far back in the orbit; (*c*) ligature of the inferior ophthalmic vein, which has been performed on one occasion.

I adopted the first of these methods in a case which came under my care.

A male, aged 40 years, was admitted on July 9th, 1927, with severe concussion and a fracture of the skull. An X ray examination confirmed the presence of a fracture in the right parieto-occipital region, but there was no evidence of involvement of the body of the sphenoid. He was discharged on the twenty-third day. Three weeks later he returned, stating that a few days before discharge he had noticed a throbbing noise in the left ear but had not mentioned it. It had persisted since, and was less marked on sitting up, while he noticed that it disappeared with pressure on the upper and inner part of the orbit. Three days after discharge he had noticed swelling of the lower eyelids "like bladders," and three days later double vision on looking to the right; 16 days after discharge both eyes were bulging, the right more than the left.

On readmission there was a paresis of both external recti with congestion of the conjunctivæ, more marked on the right than on the left. The vision and fundi were normal. A bruit could be heard over the whole head, maxillæ and left mandible, and the left common carotid artery. It ceased on pressure over the left common carotid or on the upper and inner part of the left orbit. There was no pulsation of the eyes, no exophthalmos, and no pulsating tumour. The branches of the fifth nerve were not involved.

As pressure on the upper and inner angle of the orbit caused cessation of the bruit, the supra-orbital and angular veins were ligatured under local anæsthesia. The bruit did not cease, and there was considerable hæmorrhage which had to be controlled by packing. Soon after this operation there was a double pulsating exophthalmos with great œdema and congestion of the conjunctivæ, which bulged forward between the eyelids. The pupils were dilated and irregular, and there was paralysis of all the eye movements. The noise in the head varied in intensity and at times ceased. Vision of both eyes failed rapidly. On the fifth day after operation it was decided, on account of the failing vision, to ligature the internal carotid artery, using a fascial graft from the thigh as a ligature. This operation reduced the noise in the head so that the patient stated "it takes me all my time to hear it." No bruit could be heard over the head or over the left carotid, but there seemed to be a very faint one audible over the right carotid. The œdema of the conjunctivæ persisted for some time, but one month later it had lessened considerably, and after another three weeks had completely disappeared, although there was still great vascular congestion of the conjunctivæ on both sides.

At present there is no exophthalmos and no pulsation. He has lost the sight of both eyes. There is still slight increased vascularity of the conjunctivæ. The pupils are semi-dilated and fixed and the discs show optic atrophy. There is a slight degree of ptosis of the left upper lid; the eye movements are normal except for a very slight degree of weakness of elevation of the left eye.

In 1906 Jameson Evans[20] reported a case of pulsating exophthalmos in a child of 6 after a puncture wound of the lower lid. Improvement followed treatment by rest, potassium iodide, and calcium chloride. Mr. Jameson Evans informs me in a personal communication that in April, 1907, he ligatured the angular vein as a primary procedure and cured the exophthalmos and bruit. From the nature of the wound this case was probably one of arterio-venous communication in the orbit.

Ligature of these vessels in cases of carotid cavernous sinus aneurysm is not to be regarded lightly, as the control of hæmorrhage may be difficult on account of the extreme vascularity. This has been noted by other authors—e.g., Flemming[21] and Cauchoix.[8] The latter states that the operation is of use only if a dilated vein is to be seen. My case suggests that the severity of the condition may even be increased by this operation. This may be accounted for by the presence of a resulting thrombosis in the cavernous sinus or by the partial cutting off of the means of escape of blood from the sinus, resulting in further congestion of the ocular and orbital vessels. An exaggeration of the condition has occurred in other cases, but not to such an extreme degree. Pritchard and Burghard[22] found that after ligature of the right internal angular vein, which was accompanied by severe hæmorrhage, there was no perception of light for some days. Gifford[23] recorded a case in which, after ligature of the common carotid and a much dilated vein in the upper lid, there was a temporary increase in the severity of the symptoms with increased exophthalmos and ulceration of the cornea. In the same article he refers to five cases of pulsating exophthalmos, including his own, in which this operation was performed; in three of these there were "alarming symptoms." This operation appears to give the best results in cases of arterio-venous communications in the orbit, but in carotid cavernous sinus aneurysm the results may prove less satisfactory than those of carotid ligature.

Pollet and Decherf[24] used periarterial sympathectomy in one case, with a short temporary improvement followed by a rapid increase in severity.

Resection of the cervical sympathetic, combined with carotid ligature, has been advised in order to produce a vasodilatation and so diminish the risk of cerebral complications. The use of vasodilator drugs for the same purpose has also been advocated.

Ridley[25] refers as follows to a case in which common carotid ligature had failed: "In this case, long after ligation of the common carotid, the facial artery dilated until it became as thick as one's little finger, where it joined the orbital arteries. It was tied. The proptosis and the pulsation all ceased, and that patient, although she lost her vision under pressure, had no trouble and practically no proptosis now."

Progress.

In favourable cases the bruit disappears immediately but may return, to disappear again later. Rivington,[26] in an excellent article, referred to a case in which Corner ligatured the right common carotid artery; the bruit persisted for 12 years and then disappeared. The interval here was so long that the cure would appear to be spontaneous rather than a direct result of the operation. The remaining symptoms improve slowly, the exophthalmos and chemosis taking a period of three to six weeks to disappear. The conjunctival congestion persists for a still longer period. The muscular paralysis and vision improve slowly.

De Schweinitz and Holloway[2] state that cerebral complications occur in 9·8 per cent. of common carotid ligations. This complication may arise at a considerable interval after operation, and convalescence must therefore be slow.

Below is a table taken from Locke's article[3] which tabulates the results. In comparing the mortality of common carotid and internal carotid artery ligatures in this table it is to be remembered that only the former was used in the earlier days, when infection increased the number of fatal cases.

Pulsating Exophthalmos: 1809 to 1923.

THE AFTER-CARE OF EPILEPTIC CHILDREN.

A SURVEY OF CHILDREN WHO HAVE ATTENDED A RESIDENTIAL SCHOOL FOR EPILEPTICS.

BY J. TYLOR FOX, M.D. CAMB., D.P.M.,
MEDICAL SUPERINTENDENT, LINGFIELD EPILEPTIC COLONY, SURREY.

THIS survey has to deal with a total of 351 children who left the Lingfield Colony school during the period of eight years between Oct. 1st, 1919, and Sept. 30th, 1927. Children who attended the school for periods shorter than six months are not included.

Preliminary Note.

It is essential first to define the type of child dealt with. It would be a mistake to suppose that in a certified residential school any and every child subject to epileptic fits may find a place. The Board of Education divides epileptic children into two classes: those whose disease is so severe that it precludes them from attending ordinary elementary schools, and those whose disease is, in this sense, "not severe." The latter class outnumber the former by about two to one.[1] Only "severe" cases are eligible for residential special schools and, as a matter of fact, only one-fifth of all the severe cases are accommodated there. Of the remainder a few are retained at elementary schools, some drift into poor-law and other institutions, while half of them, numbering in England and Wales at least 1350, are allowed to remain at home receiving no education at all.[1] The principal reason for this unsatisfactory state of affairs is deficient residential school accommodation; other reasons are unwillingness on the part of parents to let their children leave home, or neglect on the part of local education authorities.

It will be understood that the parents of children who are a bother to them on account of frequent fits or difficult temperament will press for their admission to a residential special school; and there is, no doubt, an unduly high proportion of such cases in the group under review.

Only "educable" children can be admitted. In this connexion the "educable" class includes, roughly speaking, all normal, dull and backward and feeble-minded children, but excludes imbeciles and idiots. By Binet or similar mental tests the lower limit of educability is reached with an intelligence quotient in the neighbourhood of 50. It must be remembered, however, that there are among epileptics a certain number of children whose intelligence either remains stationary or actually deteriorates, so that from time to time children in a school for epileptics fall from the educable into the ineducable class, and have to be discharged.

A further point with regard to the type of child requires mention. Most of the certified schools for epileptics are, like Lingfield, voluntary in character. As the demand for places much exceeds the accommodation the authorities have considerable powers of choice, and can exclude, if they wish to, children of lower mental grade or antisocial tendencies. Obviously the more carefully the cases are chosen the better will the after-care statistics be. For this reason it is very probable that other special schools might be able to show results rather more favourable than those recorded here.

To sum up, we are here dealing with a group of educable children of school age, all of them certified by medical officers specially approved by the Board of Education to be suffering from severe epilepsy. The mental grade of these children varies from normal down to feeble-minded, and the group probably contains an undue proportion of cases liable to frequent fits or antisocial conduct.

General Results.

Of the 351 children who left our school between 1919 and 1927, 4 died at school, 3 of them of epilepsy, and 1 of pneumonia. It has been found impossible to trace 15 others, so that there remain 332 cases, upon whose after-career report can be made. The present whereabouts of these 332 cases is shown in Table I.

— *Died.*	43	21·0	12	9·4	55	16·6
Total	205		127		332	

Perhaps the most remarkable finding in this table is the number of deaths. The average length of time since these children left school is four and a half years, and during that period 1 in 6 of them have died; the average stay of the 351 children at school was exactly three and a half years, and during that period only 1 in 88 died. The annual death-rate per 100 among those at school was 0·3, among those who have left 3·7. In the latter group the death-rate among boys is more than twice that among girls, a fact for which it is difficult to account. If the children who have died were excluded from the table the remaining percentage differences between the sexes would be less marked. The larger proportion of girls living at home without employment is, of course, what one would expect. Where there is reason to think that the girls are of material help in the work of the house they are included in the partly self-supporting class.

The small number of children still attending day school are likely to become self-supporting in the future, and may fairly be added to that group. If this is done the table may be summarised as follows:—

	Per cent.
Wholly or partly self-supporting..	28·0
At home, unemployed	13·8
In colonies or other institutions for epileptics ..	20·0
In mental hospitals, Mental Deficiency Act Institutions, or poor-law institutions ..	21·6
Dead	16·6

Or, roughly speaking, of every 14 children who have passed through our school 4 are more or less self-supporting, 2 are at home without work, 3 are in epileptic colonies, 3 in other institutions, and 2 have died.

---

Nature of Employment.

In the majority of cases the nature of the employment of those who are self-supporting has been ascertained. Thus among the males there are 8 labourers, 7 shop assistants, 5 farm workers, 4 carpenters, 4 gardeners, 3 errand boys, 2 clerks, 2 soldiers, and 1 each of the following occupations: baker, boot repairer, coalman, decorator, fur trade, golf caddie, laundryman, lino factory, milkman, motor driver, motor mechanic, hotel porter, sailor, signwriter, and stoker in the Navy. Among the females there are 11 in domestic service, 3 waitresses, and 1 each of the following: coil winder, companion, laundress, mantle maker, ornamental flower worker, shop assistant, and ticket stamper. It will be seen that the occupations are mostly pretty simple in nature, and the list is worthy of study by those who are responsible for the education and training of epileptics.

It is interesting to note that one-half of the children who have subsequently become self-supporting, never received any bromide, luminal, or other anticonvulsive medicine at Lingfield. This surely suggests that the most effective therapy for epileptics is to be found outside the medicine chest.

Marriage.—Only one case in the series, a girl, is known to be married, and so far as our information goes there is no record of illegitimate children. It must be remembered, of course, that there is no one over 25 years old in the series, and that the average present age is about 19.

Influence of Fits.

The serious handicap that fits provide in the quest for employment is sufficiently shown in Table I. This handicap is further demonstrated if the present state of the patients is shown in relation to the fit incidence before they left Lingfield. The series was divided into three groups, comprising those who had no fits in their last two years at school, those who had occasional fits (less than one major fit a month or a few momentary attacks), and those who had more frequent fits. The results are shown in percentages in Table II.

In other institutions	28	12	12
Dead	22	9	5

* Cases (also in Table III.).

It will be seen that the number of fits has a profound effect both upon the death-rate and the prospect of employment.

Influence of Intelligence.

The epileptic is subject to two other serious handicaps besides his fits. First, many epileptics are difficult to get on with, or may even possess marked antisocial tendencies. Secondly, a defect of intelligence is often present. The temperamental handicap does not lend itself to measurement, but the handicap of intelligence can be fairly accurately measured by mental tests. For the last seven years every child's intelligence has been assessed annually by a Binet (Burt's London Revision) test, and an intelligence quotient (I.Q.), obtained by dividing the mental by the physical age. The relation between the intelligence quotient last obtained before each child left the school and his present state is shown in the following table (Table III.), which demonstrates that the degree of intelligence also has a profound effect on the death-rate and on the prospect of employment. The number of young adult epileptics of low grade who are living at home again calls for comment.

There is, generally speaking, a fairly close, but by no means uniform, relation between fit incidence and mental retardation, and this is evidenced by the similarity between Tables II. and III. Investigations to find out whether the age of onset of the disease had any influence upon the likelihood of an epileptic becoming self-supporting proved somewhat unexpectedly to be inconclusive. Similarly the presence of a family history of epilepsy or insanity seems to have little influence on the social outlook.

TABLE III.

—	Normal. I.Q. 90 or over (23*).	Dull and backward. I.Q. 70–89 (92*).	Feeble-minded. I.Q. 50–69 (80*).	Imbecile. I.Q. below 50 (42*).
	Per cent.			
Partly or wholly self-supporting	78	39	12·5	2
At home, unemployed ..	9	15	20	29
In epileptic institutions	4	27	26	—
In other institutions ..	—	10	27·5	45
Dead	9	9	14	24

There are 26 cases of hemiplegia in the series. These patients have a heavy additional physical handicap, and it is not surprising to find that only three of them are in the self-supporting group.

Ineducable Children.

For the most part children remain at the Colony school until they attain the age of 16. They may leave before that age for a variety of reasons. The school authorities may discharge a child, as explained above, because he is incapable of further education, and he should then be dealt with by the appropriate mental deficiency authority. As a matter of fact, out of 37 cases in the present series discharged during their school career as ineducable, less than one-third are in mental deficiency institutions. One-quarter have died, and the remainder are either at home or in some other form of institution, not one of them being able to contribute in any degree to his own support.

Promising Cases.

At the age of 16 it is the policy to discharge to their homes children whose fits are infrequent or have been arrested altogether, and whose intelligence and temperament are near enough to the normal to enable them, in our judgment, to earn a living. Sixty-three children in this series were discharged on these grounds, 55 of whom are now wholly or partly self-supporting. One has died, four are out of work, three have got back to epileptic colonies, but none are in mental hospitals, mental deficiency, or poor-law institutions. It may be claimed, therefore, that authorities in residential schools are fair judges of social efficiency.

Cases Recommended for Notification at the Age of Sixteen.

In other cases the parents are advised that a transfer should be made to one of the adult homes at Lingfield or at another colony for epileptics, or, where occasion demands it, notification to the appropriate mental deficiency authority is recommended. Unfortunately these recommendations are frequently disregarded. Parents prefer that children should return home, while certification under the Mental Deficiency Acts is not carried out, because of the deplorable lack of institutional accommodation for defective epileptics. Certification will no doubt become more common under the new Act which allows certified cases to remain at their homes under supervision, but for epileptics this is a doubtful blessing, for of all classes of certifiable or certified mental defectives, probably they stand most in need of institutional treatment. There are in this series 48 cases where notification to mental deficiency authorities was recommended at the age of 16, but less than one-third of them are in mental deficiency institutions. One-quarter have died, and the remainder are either in other forms of institution or unemployed at home, and among the 48 only one is able to contribute, and that slightly, to his own support.

Methods of Inquiry.

This investigation was carried out by inquiries addressed to the patients themselves or to their parents in the first instance. Failing a reply from this source application was made to local education or poor-law authorities, who, in many cases, were good enough to go to considerable trouble to follow up the children. The reading of the letters and reports brings one into very close touch with the life of epileptics and their relation to the community. The presence of an epileptic in a home often means unhappiness to the family. Many letters testify to this, and go to show the inadequacy of our present arrangements for meeting the need. Extracts from two letters and a report may be quoted here. The letters refer to children who had been discharged from Lingfield as incapable of further education.

"I am sorry to say she is getting worse every day and very violent in her temper, she has got me. also her father bruised and scratched and pieces took out of us. She is really getting too much for us. We have tried everything to see if she could alter her fit of passion, but we can't, so our doctor said she will have to go away because my health is getting too bad. They took her to our mental hospital on Xmas Eve but brought her back, she wasn't bad enough for there."

"… his mental condition is much worse, also the fits about 40 or 50 a month, he is in bed days at a time, he is at home with us, we have tried at quite a number of homes for such cases but we have not been able to get him in anywhere, as I have four other children he is getting past my management as he has grown quite a big boy."

The report is of an intelligent girl, who at her nother's request left here at the age of 16. When her nother realised her mistake she was advised to apply o the local guardians to place the girl in a home for pileptics.

"After the girl came home from Lingfield the mother plied to the Guardians but they placed her in a ward h blind senile old women and she was so unhappy that she was taken home again after a few days. Her mother refused to consider the idea of reapplying, but there does not seem any other means of solving the difficulty."

Such letters and reports are not at all uncommon in this series.

Conclusions.

This investigation shows that the death-rate rises very rapidly after children have left a residential school for epileptics. Rather more than one-quarter become wholly or partly self-supporting, and this group contains a large proportion of those whose intelligence was high and fit incidence low at the time they left the colony. About 1 in 7 of the cases are living at home without employment of any kind. Most of these would be better cared for in institutions, and many of them, especially the lower-grade cases, are urgently in need of institutional care.

Over 40 per cent. are in institutions. Most of those in poor-law institutions would probably be more suitably placed either in epileptic colonies or in mental deficiency institutions. Doubtless some of the lower grade cases in epileptic colonies should be dealt with under the Mental Deficiency Acts were suitable accommodation available for them.

Epilepsy is usually a lifelong disease, which carries with it marked social handicaps. Its victims, in our country, run into many thousands. Few would be found now to endorse the teaching of Gowers that epilepsy is one of the diseases most amenable to treatment by drugs. Both before and since the time of Gowers there has been much laborious research into the causation and nature of the complaint, but with little definite outcome. Failing advances in therapy, empirical or based on more extended knowledge of the underlying pathology of epilepsy, it behoves us to inquire what is the social treatment meted out to the various classes of epileptics, and along what lines they can be most happily and effectively dealt with. To such an inquiry the present paper is intended to be a small contribution.

Clinical and Laboratory Notes.

A FATAL CASE OF POST-VACCINAL ENCEPHALITIS.

By A. E. Russell, M.D., B.S., F.R.C.P. Lond.,
SENIOR PHYSICIAN, ST. THOMAS'S HOSPITAL;
AND
R. Oddie, B.M., B.Ch. Oxf.,
HOUSE PHYSICIAN TO THE HOSPITAL.

In the case under review the exact relationship of the fatal illness to the preceding vaccination is very obscure. Other cases have been observed and are being investigated, but this one is recorded now since it shows unusual features of special interest. We use the term encephalitis for convenience rather than in any narrow specific sense.

History of the Case.

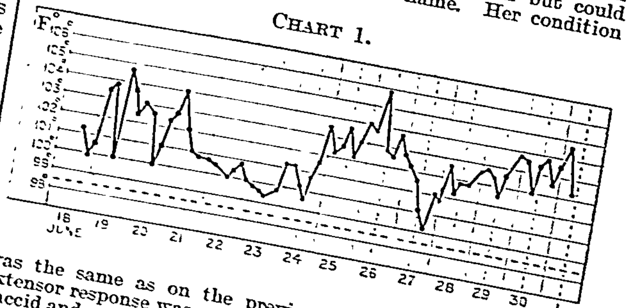
S. C., female, aged 9 years. Admitted to St. Thomas's Hospital June 18th, 1928. Died July 1st.

Apart from an attack of chicken-pox at the age of 7 years, this child's previous history was unimportant. She had not been previously vaccinated. Vaccination was performed by Dr. C. J. E. Edmonds on June 5th, and took a normal course. On June 12th she was sent home from school on account of headache and dizziness and she vomited once. The headache persisted, she became drowsy, and on the 15th vomited. Thereafter she was confined to bed. On the 16th her condition was unchanged, but the temperature rose to 102·5° F. and she vomited again. On the 17th her temperature rose to 105° F. Retention of urine occurred for the first time, and from that day onwards regular catheterisation was required.

She was seen by one of us (A. E. R.) on June 17th. She was then practically unconscious with a flushed face, pulse 128, pupils small and reacting to light. She could not be made to talk, but did put out her tongue when asked. Pharynx, heart, lungs, and abdomen were normal. Both knee-jerks were absent but there was an extensor response in the right big toe. The abdominal reflexes were absent. There was no retraction of neck and no rigidity of neck muscles. Temperature at 11 P.M. was 103° F.

Condition on Admission.—She was admitted into the hospital on the following day, June 18th. Chart 1 gives a record of her temperature up to the time of her death. She was practically unconscious on admission but could just be roused and did murmur her name. Her condition was the same as on the previous day, although now an extensor response was present on both sides. Her legs were flaccid and painful stimulation only evoked slight contraction of extensor muscles of thighs. Arms were slightly spastic and responded more readily to stimulation. Her eyes were half closed. No paralysis of ocular muscles was observed and the optic discs were normal. Tongue furred. Her pulse was rapid throughout, generally speaking between 120 and 140. Respirations varied from 24 to 40. No changes developed in the cardiovascular system, lungs, and gastro-intestinal system.

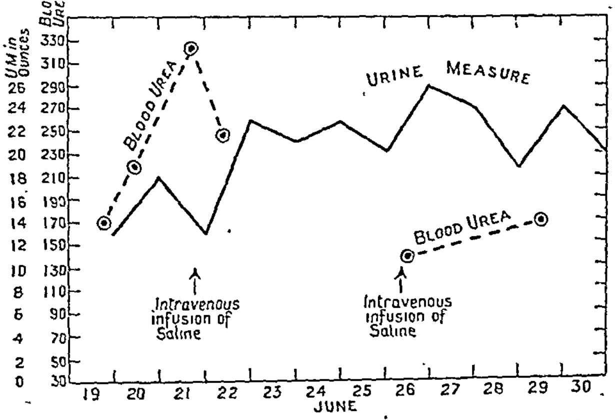
CHART 1.



She remained in practically the same condition until her death. At the best she was profoundly lethargic when not absolutely comatose. At times, however, a slight glimmer of consciousness did return. She appeared, for instance, to recognise her parents and murmured "mother," and one day asked for a drink. Her position hardly varied from day to day. She never moved her legs at all and they were quite flaccid throughout. Her arms were slightly spastic, the left more so than the right. They were, as a rule, pressed across her chest, but if they were displaced she would slowly bring them back. Only on one or two occasions was there any indication of voluntary movement of arms Her head was usually slightly inclined to the left, but there was no conjugate deviation of eyeballs. If the head were displaced to the right it would in time make its way back to the left. At times there seemed slight rigidity of the neck muscles. Her eyes were never closed, leaving a gap of about an eighth of an inch, which was probably the cause of a slight corneal ulceration. Independent movements of eyeballs took place. The child lost flesh, but did not become emaciated, weighing 42 lb. at death. The urine was free from albumin on admission, but a trace appeared after a few days and a few pus cells were observed. Leucocyte count 5400.

Lumbar puncture was performed on June 19th, 27th, and 30th; there was no increase of pressure and the fluid was quite transparent. Its urea content was very high, 180 mg. per cent. Owing to the fact that in some cases a high blood-urea had been recorded, this was investigated on June 19th, although the urine was then free from albumin. The urea was found to amount to 170 mg. per cent. Six estimations of the blood-urea were made by one of us (R. O.), and the records are shown in Chart 2, which also shows the daily volume of urine excreted. In view of the high urea concentration an intravenous infusion of 1 pint of saline was given on June 21st, and again on June 25th, with temporary benefit. Rectal injections of normal saline were administered every eight hours, but these had to be discontinued after three days, as they were not retained. The percentage of urea in the urine was 3·5 on June 21st and 4 per cent. two days before death. No casts were present with the exception of an occasional granular cast at the end, together with a little pus. *B. coli* was grown from the urine on July 2nd.

CHART 2.



On admission, the inner side of both knees presented a reddish spot about the size of a sixpence, and over the lower end of each tibia there was also present an elongated patch of redness about 1½ in. in length by ¼ in. in width. These patches were surrounded by a sharply defined white areola. Within a day or two of her admission a blister slowly developed on three of these patches. From their position these were explainable as the result of pressure, those on the knees being situated exactly where the knees come into contact when the legs are lying side by side and those lower down where the legs naturally cross each other.

Treatment.—As it was almost impossible to get her to swallow anything, the child was fed throughout by the nasal tube. She was put on hexamine grs. v. three times daily for ten days. She was also given an injection of 0·3 g. of stabilarsan on the day of admission.

The *post-mortem examination* was performed by Dr. J. F. Taylor, who contributes the following notes:—

The brain showed no definite increase of cerebro-spinal fluid. The fluid was clear and no meningitis was present. The convolutions were normally defined. General congestion of surface vessels was noticeable, rather more marked at the base. Sections through all parts of the hemispheres, mid-brain, cerebellum, &c., showed congestion but no hæmorrhages. No areas of softening were to be detected. The spinal cord presented a similar appearance.

The kidneys weighed 4¼ oz. They were congested; the capsules stripped readily, and there was no obvious inflammation. The bladder contained turbid urine and showed signs of recent cystitis. Nothing abnormal was detected in the remaining organs and the vaccination scabs were normal. Microscopical examination was made of portions of cortex, basal ganglia, crura cerebri, pons, medulla, cervical and lumbar cord—with almost negative results. A moderate congestion was found, but no perivascular or diffuse infiltration. No hæmorrhages, thromboses, or other pathological changes were observed. The condition of the kidneys was interesting, though evidence of definite nephritis was very scanty. The glomeruli were slightly swollen and showed a multiplication of nuclei, and there was some cloudiness and swelling of the tubular epithelium. A curious feature was the deposition of minute collections of calcium salts in many of the convoluted tubules.

Remarks.

Two other children in the family were vaccinated at the same time as this one. A sister did not take, but a brother went through a mild illness from which he has made a good recovery. He was vaccinated on the same day, June 5th, and on June 14th and for several days afterwards, he was out-of-sorts, feverish, and drowsy, with occasional vomiting, symptoms which it is not unreasonable to suppose represented a mild attack of the same illness from which the patient died.

1. The patient suffered from a short febrile illness, the earliest symptoms of which appeared on June 12th, seven days after vaccination, and death occurred on July 1st after an illness of 19 days.

2. The main symptoms were indicative of a profound disturbance of the nervous system. The striking clinical feature of the case was the profound lethargy, and we would emphasise the remarkable immobility of this child throughout her whole illness. Seen day after day, she lay in exactly the same position, with the same slightly flushed cheek and slightly open eyes, giving no indication of life whatever other than her faint respiratory movements. She never moved her legs at all, and her arms were almost as motionless. Lethargy is, of course, a well-known feature in some cases of encephalitis, but the profound immobility of this child was very striking.

3. The scanty pathological changes in the brain and spinal cord are noteworthy. The post-mortem examination revealed nothing more—both to naked eye and microscopical examination—than general congestion.

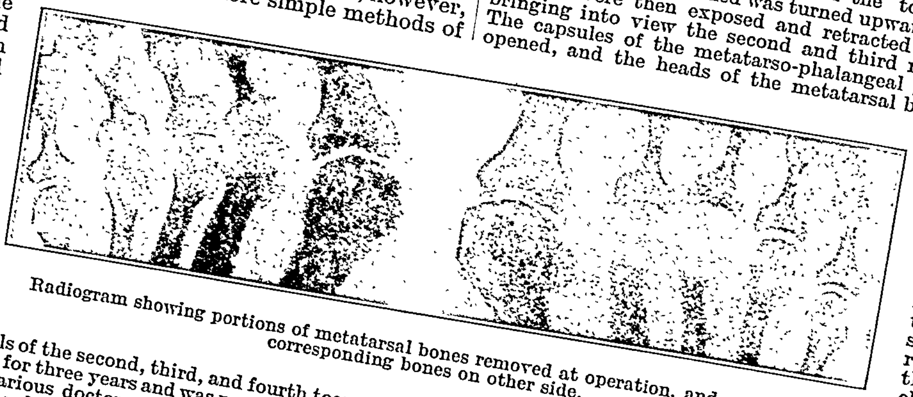
4. Marked urea retention. The blood-urea was 170 mg. per cent. at the first estimation; it rose as high as 318 on June 21st, and three days before death it amounted to 170. The cerebro-spinal fluid also showed a high percentage of urea, 180 mg. per cent. on June 19th. This marked retention of urea, together with profound coma, naturally suggested uræmia, but the percentage of urea in the urine on two estimations amounted to 3·5 and 4 per cent., and at the beginning the urine was absolutely free from albumin, nor was there at any time more albumin than could be accounted for by the mild cystitis. Dr. Taylor's report on the microscopical condition of the kidneys shows, moreover, an absence of any real nephritis. The high urea percentage may, therefore, arise in some manner hitherto unsuspected. We conferred with Dr. O. L. de Wesselow on this point, and he suggested that it might be due to desiccation of the child, coupled, perhaps, with increased metabolism. Some loss of flesh certainly took place, but death occurred before any real emaciation. This high concentration of urea in the blood has been noted in other cases, but it would appear from ours that it may occur without any convincing evidence of nephritis.

The absence of any gross changes in the brain characteristic of encephalitis may, on the other hand, lend support to the view that the symptoms were more allied to those of uræmia, and due to a failure on the part of the kidneys to fulfil their functions, despite the absence of gross evidence of nephritis. Further observations on similar cases may throw light on this curious feature.

A CASE OF PERSISTENT METATARSALGIA TREATED BY OPERATIVE MEASURES.

By R. Brooke, M.B. Lond., F.R.C.S. Eng.,
HON. ORTHOPÆDIC SURGEON TO THE ROYAL WEST SUSSEX HOSPITAL.

True Morton's metatarsalgia with dropping of the anterior arch of the foot can be treated very satisfactorily and with good results by the usual orthopædic corrective appliances. Now and again, however, cases do not respond to these more simple methods of treatment. An example is detailed below, with the method used to overcome the deformity.



Radiogram showing portions of metatarsal bones removed at operation, and condition of corresponding bones on other side.

An unmarried woman, aged 42 years, gave a history of pain, neuralgic in type, on the dorsum of both feet and in the balls of the second, third, and fourth toes. The pain had persisted for three years and was progressive, in spite of treatment by various doctors who had supplied her with metatarsal bars to her boots and various forms of arch supports. On examination the patient—a not unduly heavy or fat woman—was found to have marked bilateral dropping of the anterior arches with hallux valgus. There was some tenderness on pressure on the under-surface of the balls of the second, third, and fourth toes, more marked in the right foot than the left. Both feet were quite soft and supple and X ray examination revealed no arthritic changes. She was measured for, and supplied by an instrument maker with, a pair of boots of the correct size and a pair of transverse arch supports. Supplementary treatment consisted of massage, radiant heat applications, and foot drill three times a week.

At the end of two months the condition was unimproved. In fact, her feet were if anything rather worse than they were before. It was therefore decided to operate. Using Esmarch's bandages and a tourniquet, the operation was practically bloodless. A small semilunar incision was made on the dorsum of the right foot (the worse foot) half an inch proximal to the junction of the toes with the foot. The skin flap thus formed was turned upwards. The extensor tendons were then exposed and retracted out of the way, bringing into view the second and third metatarsal bones. The capsules of the metatarso-phalangeal joints were then opened, and the heads of the metatarsal bones, freed from surrounding structures, were removed by cutting through the shafts proximal to the heads with bone-cutting forceps. The tendons were subsequently replaced and the wound closed. The operation took only a few minutes. Ten days later the patient was walking about in comfort with transverse arch supports in her boots and without a stick. At the present time, three months after operation, the right foot is entirely free from pain, and she is asking that the other foot should be similarly treated.

Although in this operation the transverse arch of the foot was permanently weakened, the end-results seem to have justified the means taken. The small amount of arch which the patient had before the operation is now more than reconstituted by the mechanical arch support which she is wearing, and—what is more important—she is free from pain.

DIPHTHERIA AND THE "PROTECTIVE" POWER OF SERUM.

By John Gordon, M.D. Leeds, D.P.H.,
and
Jack Science, M.D. Leeds, D.P.H.
(From the Department of Pathology and Bacteriology, University of Leeds, and the City Infectious Diseases Hospital, Seacroft.)

In a previous paper[1] describing a study of 25 cases we showed that serum from patients suffering from diphtheria may be deficient in the property of protecting red blood corpuscles from the hæmolytic action of sodium ricinoleate, a property normally present in human serum. The marked hæmolytic action of sodium ricinoleate on red cells is markedly diminished on addition of serum, and this action (protective action) of serum has been attributed by E. Ponder[2] to the protein components of serum. It was shown that this protective power returned in simple uncomplicated cases of diphtheria by the end of the third week. While in a few cases of diphtheria with developing paralysis there was no marked interference with the protective power of the serum, in most cases of diphtheria where paralysis occurred this diminished protective power lasted for some time and even up to 80 days, and it was suggested that the protective power of the serum of a patient with diphtheria should be tested against a hæmolysin at different stages of the disease, and compared with a normal serum with a view to assisting prognosis with regard to the possible development of paralysis.

In this paper a further series of 50 cases of diphtheria were examined with a view to confirming and extending the previous observations. The experimental details were the same as in the previous paper.

The patients were bled from the arm and the serum separated. The serum was tested as soon as possible on the same day, being kept in the refrigerator till required. The test was carried out in the following way: to each of three narrow tubes were added 0·5 c.cm. of the patient's serum, and to three other tubes 0·5 c.cm. of a healthy person's serum. To tube 1 was added 0·1 c.cm. of a 1 per cent. solution of sodium ricinoleate in normal saline; to tube 2, 0·2 c.cm.; and to tube 3 was added 0·3 c.cm. The mixtures were shaken and allowed to stand at room temperature for half an hour. Then 0·2 c.cm., 0·1 c.cm., and 0·05 c.cm. were taken from each tube and added to 0·5 c.cm. of a 3 per cent. suspension of washed ox blood cells. These were put in the incubator at 37° C. for one hour, and then the varying degrees of hæmolysis were read.

Amount of 1 per cent. sodium ricinoleate added to 0·5 c.cm. serum.

—	0·1 c.cm.			0·2 c.cm.			0·3 c.cm.		
	c.cm. of mixture.								
	0·2	0·1	0·05	0·2	0·1	0·05	0·2	0·1	0·05
Patient's serum	††	–	–	†††	†	–	††††	†††	–
Control serum	–	–	–	–	–	–	†	–	–

†††† = complete hæmolysis. ††† = almost complete hæmolysis.
†† = partial hæmolysis. † = trace of hæmolysis.
– = no hæmolysis.

The patient's serum showed marked lack of protection.

An example of the reading obtained from a case of diphtheria that developed palate and ocular paralysis is here given. The blood was taken on the twenty-fifth day of the illness.

Fifty consecutive cases of diphtheria were tested, including cases of moderate and severe throat lesions,

---

[1] Quart. Jour. Med., 1928, xxi., 345.

[2] Ponder, E.: Proc. Roy. Soc. B. London, 1923, xcv., 42; Ibid., London, 1925, xcviii., 481.

Of these 39, or 78 per cent., showed complete protection by the second to the third week, and these cases did not develop paralysis. Of the remaining 11 who showed lack of protection prolonged beyond the third week, 8 developed paralysis. In one of the cases developing paralysis, lack of protection continued up to five weeks after the onset of the disease.

This series of cases, taken in conjunction with the 25 already described, indicate that a knowledge of the protective power of the serum about the third week might be useful in assessing the possible development of paralysis in a case of diphtheria, from which the ordinary clinical symptoms have already disappeared, the probability being that this lack of protection of the serum is in some way related to the action of the diphtheria toxin.

Public Health Services.

LIVERPOOL PORT SANITARY AUTHORITY.

In his report for 1927 Dr. A. A. Mussen mentions 5644 visits of inspection paid to ships, of which 948 (930 last year) had nuisances on board; there were 3297 (3099) dirty forecastles and 409 (254) foul water-closets. The men are being more considered; the Board of Trade, the Port Sanitary Authority, the unions, the shipping companies, all coöperating. Quarters are being put at the after-end of ships, cubic space is being increased, bunks are better, vermin-proofing better, washing places more usual, hospital accommodation more frequent, and, thanks in large measure to the Board of Trade, food is much better. But plans of new ships should be approved by authority, and when as much attention is given to the health of seamen as to that of any other section of the community, standards of accommodation will be international. Cleanliness of crew spaces depends on discipline and should be examined daily. Of 38 cases of enteric fever mentioned as occurring in voyages that brought ships to Liverpool, 34 were in seamen; of 18 cases of dysentery 12 were among the crews, 1 was a military passenger, the other 5 were "distressed British subjects." Of tubercle 39 cases were landed (origin unstated) this year, and two cases of encephalitis lethargica. No cases of plague, cholera, or yellow fever were landed. The prevalence of these diseases through the world in 1925–27 is stated with a most interesting map. Plague was an anxiety in 1927 in the Indian Ocean, Levant, West Africa, and South America; cholera in the Indian and China seas; yellow fever in West Africa, Rio, and there were single cases reported in Bangkok and Rangoon, a very important matter if the diagnoses were beyond cavil. Plague is being constantly watched for; the docks are made as nearly rat-proof as possible, ships from suspected ports are searched for rats; 6781 rats from ships and quays were pathologically examined and all were plague-free.

The seamen's dispensary served more patients in 1927, fresh cases 1842 (1360), total attendances 55,063 (41,720); evening clinics are now held twice a week. Cures are reported, 421, "an improvement of 80 per cent."; as last year, of every 10 cases 6 were gonorrhœa, 3 syphilis, and 1 soft chancre, but gonorrhœa cases are apt to delay attending till they have become chronic; 20 per cent. of the syphilis cases are in the pre-Wassermann stage. Of 20,121 alien arrivals examined to see if they have any disease dangerous to the public health or likely to cause a public charge, 6 were certified, 3 for venereal disease, 2 for mental deficiency, 1 for phthisis. Medical officers of the Board of Trade inspect all emigrants, second class or steerage, and crews of vessels bound for America. There were 123,801 emigrants and 16 were rejected for infectious disease. Of 80 cases of trachoma or conjunctivitis 77 sailed later; 3 returned home.

The recent regulations in regard to preservatives in food and imported food seem to work well, for there are no complaints of difficulty. Far less unsound food had to be condemned and "utilised under supervision" this year, 2621 (5482) tons, although the amount is still enormous. Everything is done to ensure that the functions of the port medical officer shall be effectively discharged with the least possible delay to ships. Now that, owing to the opening of the new Gladstone Dock, vessels can enter the docks at all states of the tide, a medical officer is on duty day and night to deal at once with infectious diseases. Ships from infected ports can be promptly dealt with, as the authority has a new motor launch with a speed of 11½ knots, and good accommodation for crew, a medical officer, and four patients on the way to hospital. It is named the *Moyles*, after Dr. J. G. Moyles, who has long been the chairman of the port authority.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are some of the 1927 statistics of two Scottish and five English towns:—

Name of district and estimated mid-year population.	Birth-rate.	Death-rates per 1000 of the population. All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Death-rates per 1000 births. Infant and neonatal mortality.	Diarrhœa, &c., under 2 years.	Maternal mortality from childbirth.
Edinburgh C. .. (425,147)	17·9	14·3	1·20	1·68	2·4	1·8	80/33	5·5	6·9

Edinburgh.

Dr. William Robertson, referring to the reduction in infant mortality, says improved housing conditions ought to save many more lives of children. Four whole-time lady clinical medical officers have been appointed in order to get into more intimate and personal touch with the mothers in the various districts of the city. An effort is also being made to provide instruction in cookery and the preparation of nourishing meals with rudimentary apparatus. The fact that there must be a delay in the provision of good houses is felt to be no reason for the delay in the provision of good food. A beginning has been made with the St. Leonard's slum clearance area, and the dispossessed tenants will have accommodation provided on the Prestonfield housing site. The contrast between the old and the new housing conditions is well illustrated by photographs of St. Leonard's ward and of a model of the lay-out of the Prestonfield housing scheme. The hugeness of the Edinburgh housing problem is brought out by the fact that out of 104,488 inhabited houses there are 7328 single-room habitations and that there are approximately 12,000 houses with rentals below £10 and 22,922 with rentals between £10 and £15. This means that many tenants accustomed to pay small rents have to be induced to pay higher rents. Dr. Robertson emphasises the relationship between an excessive death-rate from tuberculosis and the prevalence of the bad type of house in certain of the wards.

During the year out of 219 deaths caused by epidemic diseases 114 were due to whooping-cough and measles, and here again the new housing methods, taking the place of old town properties, consisting of 10, 12, or even more houses branching off each common stair, ought to gradually produce a great result. The immunisation scheme against diphtheria makes good progress. There has not been one bad result and in the overwhelming majority of children the injection never causes a moment's discomfort. Among 11,608 children, 7608 of whom were immunised and 4000 of whom were Schick-negative, there occurred 58 cases of diphtheria. but not a single death. During the four years 1924 to 1927 there were 2741 notifications of diphtheria with 242 deaths. Full particulars are given in the report of the circumstances under which the 58 mild cases of diphtheria occurred among the immunised or partially immunised children.

Dr. Robertson expresses his regret that the House of Commons rejected the Edinburgh proposal to enforce the treatment of sufferers from venereal diseases. The patients who ceased treatment before being cured numbered 985 during 1927, giving a percentage of defaulters to the total cases treated of 13·8—somewhat higher than in the previous year. The Scottish Board of Health estimates the percentage of default by the ratio of defaulters to the total cases leaving the centres for any reason and by this method the percentage of default in Edinburgh was 32. Every effort is made to follow up patients, by letters in the case of males and by visits from an almoner in the case of females. The almoners' task is a thankless one as frequently. after several visits. she secures the return of a patient for treatment to be followed again by a subsequent default.

Tribute is paid to the valuable work done by volunteers in connexion with the maternity and child welfare scheme. Dr. Robertson makes special reference to the five childs' gardens which are subsidised by the corporation and to the nurseries, which are provided to enable the mothers to attend the cookery demonstrations. A special investigation of shaving-brushes has shown that such brushes may be infected with a bacillus resembling the bacillus of anthrax. Attention has also been given to improving the technique of the virulence test of the diphtheria bacillus, and it is claimed that an intracutaneous test gives a satisfactory and more rapid result.

The cows stalled in the city number 3732, and during the year 26 were dealt with under the Tuberculosis Order. Of these 15 had tubercle of the udder, tuberculous emaciation, and 8 a chronic cough with other evidence. In 10 cases the udder infection was diagnosed by microscopical examination, and in 5 more by the biological test. In addition to these 26 18 cows came under suspicion as the result of the routine examinations. These animals did not come within the scope of the Tuberculosis Order, but the owners were persuaded to remove them from the dairy herds. The incidence of tuberculosis among the dairy cows of the district, as judged by post-mortem results at the abattoirs. showed no material change when compared with former years; out of 1585 cows slaughtered 43 per cent. were affected with tubercle. The tubercle-free herd of about 50 cows run in connexion with the Royal Victoria Hospital had no reactors at the half-yearly testings. The samples of outside milk examined for tuberculous infection numbered 122, and 7 of these gave a positive result.

Paisley.

Dr. G. V. T. McMichael estimates the houses required at the end of 1927 at 947. The municipal houses sanctioned by the Board of Health number 2010. of which 1306 have been completed and occupied. Despite the encouraging progress made with housing schemes the clamant problem of the slum dwellers, who cannot afford to pay the rents of corporation houses, has not been faced. Dr. McMichael suggests for these two- and three-roomed houses built in three-storied tenement blocks and of the simplest possible character. He definitely opposes the erection of any one-roomed houses, of which there are already too many. It is. in fact. the high proportion of one- and two-roomed houses which makes the domiciliary treatment of the respiratory diseases, including tuberculosis, so difficult in Paisley. During 1927 412 cases of acute primary and influenzal pneumonia were treated in the three hospitals. The case fatality in the fever hospital was 15·6 per cent. and in the Royal Alexandra Infirmary 13·5 per cent.; whilst among the 149 cases treated at home the case mortality was 34·2 per cent. The new probationers at the fever hospital are subjected to the Dick and Schick tests and immunised if necessary.

The Russell Institute, opened in March by H.R.H. Princess Mary, provides in an up-to-date manner for the various municipal health services, including artificial sunlight, X rays, a dental and a remedial exercise clinic. The public has shown an extraordinary interest in the institution and 10,000 people passed through it on the one day when it was opened for inspection. Dr. McMichael is enthusiastic as to the result of light treatment both for rickets and practically all types of surgical tuberculosis, though he is much disappointed at the irregular attendance of the mothers, whose children suffer from rickets. The antenatal work makes good progress and is largely helped by the beds available for antenatal cases at Barshaw Hospital. During 1927 525 mothers attended the antenatal clinics and 206 antenatal cases were admitted to Barshaw Hospital. The total births numbered 1791.

East Ham.

Dr. W. Benton refers to the inadequacy of the isolation hospital. As far back as 1914 this matter was considered and plans were prepared and submitted to the Ministry, but the outbreak of war stopped further progress. In 1922 the Ministry made certain suggestions for temporary improvements and for the preparation of a complete scheme to be carried out in stages as circumstances permitted. Much of the accommodation is of a temporary nature—e.g.. military huts. According to the usual standard per 1000 of the population there should be 150 beds, whereas without overcrowding there are only 100. The report shows that at present there is overcrowding to the extent of 40 beds. During 1927 epidemic prevalence of diphtheria and scarlet fever put pressure on the hospital. Over 10 per cent. of the scarlet fever cases admitted were also infected with diphtheria. Scarlet fever antitoxin was used for 20 patients with severe septic and toxic symptoms and, with one exception, the results were highly satisfactory. The persistence of nasal. pharyngeal, and aural complications has given trouble. There is the usual complaint of delay in giving antitoxin for diphtheria. The average duration of illness of 27 fatal cases prior to admission to hospital was four days, and the successful use of antitoxin at this stage is hopeless. Towards the end of the year diphtheria assumed an unusually septic and toxic type. Of the 30 fatal cases of diphtheria 23 of the deaths occurred under 8 years of age. Six members of the staff contracted diphtheria and two scarlet fever. Prophylactic immunisation has not yet been adopted.

The staff of health visitors has been brought up to the level of five years ago by the belated filling of a vacancy, but Dr. Benton points out that a further increase of staff is needed in order to cope with the supervision of the pre-school child. He summarises the needs of East Ham children as follows: (1) A more intensive health campaign with regard to the pre-school child (already good work is being done for these children at the aural, dental, and ophthalmic clinics). (2) Practical and interesting instruction in hygiene in the elementary schools. (3) The erection of a day open-air school to accommodate 500 children. (4) The provision of a special school to accommodate 200 physically defective children. (5) The improvement of home conditions, especially in the direction of reducing overcrowding.

Coventry.

Dr. E. H. Snell mentions that during the latter half of the year there were two sharp outbreaks of diphtheria, each associated with a large school. In a

Of these 39, or 78 per cent., showed complete protection by the second to the third week, and these cases did not develop paralysis. Of the remaining 11 who showed lack of protection prolonged beyond the third week, 8 developed paralysis. In one of the cases developing paralysis, lack of protection continued up to five weeks after the onset of the disease.

This series of cases, taken in conjunction with the 25 already described, indicate that a knowledge of the protective power of the serum about the third week might be useful in assessing the possible development of paralysis in a case of diphtheria, from which the ordinary clinical symptoms have already disappeared, the probability being that this lack of protection of the serum is in some way related to the action of the diphtheria toxin.

Public Health Services.

LIVERPOOL PORT SANITARY AUTHORITY.

In his report for 1927 Dr. A. A. Mussen mentions 5644 visits of inspection paid to ships, of which 948 (930 last year) had nuisances on board; there were 3297 (3099) dirty forecastles and 409 (254) foul water-closets. The men are being more considered; the Board of Trade, the Port Sanitary Authority, the unions, the shipping companies, all coöperating. Quarters are being put at the after-end of ships, cubic space is being increased, bunks are better, vermin-proofing better, washing places more usual, hospital accommodation more frequent, and, thanks in large measure to the Board of Trade, food is much better. But plans of new ships should be approved by authority, and when as much attention is given to the health of seamen as to that of any other section of the community, standards of accommodation will be international. Cleanliness of crew spaces depends on discipline and should be examined daily. Of 38 cases of enteric fever mentioned as occurring in voyages that brought ships to Liverpool, 34 were in seamen; of 18 cases of dysentery 12 were among the crews, 1 was a military passenger, the other 5 were "distressed British subjects." Of tubercle 39 cases were landed (origin unstated) this year, and two cases of encephalitis lethargica. No cases of plague, cholera, or yellow fever were landed. The prevalence of these diseases through the world in 1925–27 is stated with a most interesting map. Plague was an anxiety in 1927 in the Indian Ocean, Levant, West Africa, and South America; cholera in the Indian and China seas; yellow fever in West Africa, Rio, and there were single cases reported in Bangkok and Rangoon, a very important matter if the diagnoses were beyond cavil. Plague is being constantly watched for; the docks are made as nearly rat-proof as possible, ships from suspected ports are searched for rats; 6781 rats from ships and quays were pathologically examined and all were plague-free.

The seamen's dispensary served more patients in 1927, fresh cases 1842 (1360), total attendances 55,063 (41,720); evening clinics are now held twice a week. Cures are reported, 421, "an improvement of 80 per cent."; as last year, of every 10 cases 6 were gonorrhœa, 3 syphilis, and 1 soft chancre, but gonorrhœa cases are apt to delay attending till they have become chronic; 20 per cent. of the syphilis cases are in the pre-Wassermann stage. Of 20,121 alien arrivals examined to see if they have any disease dangerous to the public health or likely to cause a public charge, 6 were certified, 3 for venereal disease, 2 for mental deficiency, 1 for phthisis. Medical officers of the Board of Trade inspect all emigrants, second class or steerage, and crews of vessels bound for America. There were 123,801 emigrants and 16 were rejected for infectious disease. Of 80 cases of trachoma or conjunctivitis 77 sailed later; 3 returned home.

The recent regulations in regard to preservatives in food and imported food seem to work well, for there are no complaints of difficulty. Far less unsound food had to be condemned and "utilised under supervision" this year, 2621 (5482) tons, although the amount is still enormous. Everything is done to ensure that the functions of the port medical officer shall be effectively discharged with the least possible delay to ships. Now that, owing to the opening of the new Gladstone Dock, vessels can enter the docks at all states of the tide, a medical officer is on duty day and night to deal at once with infectious diseases. Ships from infected ports can be promptly dealt with, as the authority has a new motor launch with a speed of 11½ knots, and good accommodation for crew, a medical officer, and four patients on the way to hospital. It is named the *Moyles*, after Dr. J. G. Moyles, who has long been the chairman of the port authority.

Edinburgh.

Dr. William Robertson, referring to the reduction in infant mortality, says improved housing conditions ought to save many more lives of children. Four whole-time lady clinical medical officers have been appointed in order to get into more intimate and personal touch with the mothers in the various districts of the city. An effort is also being made to provide instruction in cookery and the preparation of nourishing meals with rudimentary apparatus. The fact that there must be a delay in the provision of good houses is felt to be no reason for the delay in the provision of good food. A beginning has been made with the St. Leonard's slum clearance area, and the dispossessed tenants will have accommodation provided on the Prestonfield housing site. The contrast between the old and the new housing conditions is well illustrated by photographs of St. Leonard's ward and of a model of the lay-out of the Prestonfield housing scheme. The hugeness of the Edinburgh housing problem is brought out by the fact that out of 104,488 inhabited houses there are 7328 single-room habitations and that there are approximately 12,000 houses with rentals below £10 and 22,922 with rentals between £10 and £15. This means that many tenants accustomed to pay small rents have to be induced to pay higher rents. Dr. Robertson emphasises the relationship between an excessive death-rate from tuberculosis and the prevalence of the bad type of house in certain of the wards.

During the year out of 219 deaths caused by epidemic diseases 114 were due to whooping-cough and measles, and here again the new housing methods, shock therapy, and in some cases their mental trouble was cut short by this means. Eight cases of general paralysis were treated by induced malaria; 3 were discharged "recovered," and 2 others improved. 65·5 per cent. of patients were usefully employed, the majority in the grounds, laundry, kitchen, and sewing-room. Electric light is to be installed throughout the building. There is some difficulty in keeping the number of female nurses up to establishment.

At *Rubery Hill and Hollymoor Mental Hospital* there were 1815 patients at the end of the year, including 146 epileptics. Of the admissions during 1927 nearly 15 per cent. were cases of general paralysis in an advanced and debilitated condition. The recovery-rate of 48·1 per cent. is therefore all the more encouraging. Over 64 per cent. of all cases admitted were totally discharged. The completion of a special treatment block, including an operating theatre and electrical and hydrotherapy rooms, has provided a most valuable adjunct to the care of the patients. Two bungalows are used as convalescent wards for women and a third will be available when a nurses' home is built. The general health of the patients was good, and only three cases of tuberculosis were under treatment at the end of the year. There was no typhoid fever; this may be partly due to the liberal use made of T.A.B. vaccine as a means of inducing protein shock. A routine test for intestinal organisms on admission showed that 25 per cent. of patients had had at some time a more or less severe intestinal infection. Some of these become carriers and originate outbreaks of dysentery or colitis in the institution. The medical superintendent makes the interesting observation that the deeper problems of mental disorder are also those of rheumatism and rheumatic disorder—states of low grade and chronic infectivity. The hydrotherapeutic department has therefore been augmented by four tables for continuous colon irrigation and two mercury-vapour lamps. The malarial treatment of general paralysis has been largely superseded by other forms of induced pyrexia, especially non-specific protein therapy. To the stress laid on removal of focal sepsis the Visiting Commissioners attribute the striking absence of noise and unrest among the patients; the removal of somatic irritation takes the place of sedatives. Parole on and off the estate is granted to over 200 patients, and most of those discharged are previously sent out on trial. Nearly 1000 patients are employed at trades or on the estate. Twenty-three male and 12 female nurses have passed the final examination for the M.P.A. certificate, 5 with distinction.

The *City of Cardiff Mental Hospital*, like the hospitals of Birmingham, publishes its statistics in the body of the medical superintendent's report, so that the discussion of them is almost swamped by the tables. There were 660 patients on the books at the end of last March. Twelve and a half per cent. of the patients admitted were suffering from general paralysis. The death-rate was 11·8 per cent. and the recovery-rate 41·2 per cent. The general health was good and there were only five cases of tuberculosis, two of erysipelas, and one of scarlet fever. Autopsies were held in all cases where permission was given. The dental surgeon made 540 examinations; the gynæcologist made 63, and the laryngologist 142. Research work has been continued on the distribution of nitrogenous compounds in the plasma and cerebro-spinal fluid, on cholesterol and glucose in the blood, and on the radiography of the alimentary tract. A series of films has been prepared showing characteristic motor manifestations in mental disorder. Two electrically heated ovens and a boiling table have been installed to replace gas-cooking apparatus. The dietary has been improved. Among recent additions to the equipment of the hospital is a fine bowling green. Limited parole is given to 20 patients. Twenty-three men and 30 women nurses are certified or registered.

The *Brighton County Borough Mental Hospital* at *Haywards Heath* had 847 patients resident at the end of the year and showed a recovery-rate of 39·37 and a death-rate of 8·6 per cent. There was a small epidemic of influenza in the spring, but no dysentery. Eighteen patients have tuberculosis. Over 50 patients have had full parole daily and another 50 have had parole in the grounds. Over 100 patients, mostly women, have attended weekly classes for country dancing and have benefited considerably. The women patients have formed a debating society; from their deliberations several suggestions for their comfort have arisen and many have been approved. Except in one ward all the women now have their own clothes, marked with their names, and they appreciate this very much. Twenty patients have been home for week-ends and eight men went home for Christmas. Over 50 have been allowed to visit Brighton, Eastbourne, and London for the day on parole; there has never been any trouble about return to hospital. Six wards have open doors. The Guardianship Society has given invaluable aid to discharged patients, finding them homes and employment. The out-patient clinic in Brighton has now treated 192 patients, only 12 of whom have had to be certified. The dental surgeon treated 690 patients during the year and extracted 694 teeth. Stress is laid on open-air treatment at this hospital. A cinema is being erected and a stable is being turned into a laboratory, while plans are being made for an admission hospital, which will meet the immediate threat of overcrowding. Sixty-five nurses are certificated or registered.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 1ST, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 102 (last week, 141); scarlet fever, 1376; diphtheria, 851; enteric fever 122; (last week, 153); pneumonia, 508; puerperal fever, 32; puerperal pyrexia, 89; cerebro-spinal fever, 4; acute poliomyelitis, 6; acute polio-encephalitis, 4; encephalitis lethargica, 27; continued fever, 2; dysentery, 6; ophthalmia neonatorum, 92. No case of cholera, plague, or typhus fever was notified during the week.

The following counties each notified 3 or more cases of enteric fever: London, 17; Berks, 3; Chester, 3; Devon, 4; Essex, 23 (of which Colchester 15); Huntingdon, 7 (of which St. Ives, U. and R. 6); Lancaster, 9; Middlesex, 7; Norfolk, 3; Sussex East, 3; Monmouth, 4; The total of 122 includes 42 cases of paratyphoid fever, of which 13 were notified in London and 6 in Huntingdonshire.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Sept. 4th and 5th was as follows: Small-pox under treatment, 7; scarlet fever, 1477; diphtheria, 1472; enteric fever, 112; measles, 118; whooping-cough, 244; puerperal fever, 14 (plus 7 babies); encephalitis lethargica, 71; poliomyelitis, 1; "other diseases" 20. At St. Margaret's Hospital there were 14 babies (plus 5 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns including London there was no death from small-pox, 6 (1) from enteric fever, 9 (0) from measles, 5 (5) from scarlet fever, 27 (3) from whooping-cough, 15 (1) from diphtheria, 86 (23) from diarrhœa and enteritis under two years, and 20 (4) from influenza. The figures in parentheses are those for London itself.

The fatal cases of enteric fever outside London were reported from Southend-on-Sea 2, Bolton, Manchester, and Salford, 1 each. Of the 9 fatal cases of measles, 2 each were reported from Wolverhampton, Liverpool, and Cardiff. There was no fatal case of scarlet fever outside London. Of the 24 fatal cases of whooping-cough outside London, 3 each were reported from Willesden and Leeds, while Glasgow reported 6 for the same week. Liverpool again reported 9 deaths from diarrhœa, Birmingham and Manchester 5 each, and Hull 4, while Glasgow and Dublin reported 6 and 8 respectively.

The number of stillbirths registered during the week was 250 in the great towns (corresponding to a rate of 36 per 1000 births), including 53 in London.

special report in September he recommended his committee to consider the question of providing immunisation facilities, and the consideration of the report was deferred until the medical staff had been strengthened by the appointment of an assistant medical officer of health. There were 14 notifications of encephalitis lethargica and seven deaths attributed to it. During the last nine years there have been 130 notifications and 56 deaths from this disease. The antenatal clinic is conducted by a gynæcologist, Dr. S. A. Ballantyne. Of the 265 cases seen 160 were maternity cases booked for the Coventry and Warwickshire Hospital and 45 booked for the Gulson-road (poor-law) hospital. Of the remainder 43 were sent by midwives, 10 came of their own accord, and 7 were not pregnant. The total births numbered 2065. The Council paid £1201 for maternity cases sent to the two hospitals mentioned and received back in contributions £696 16s. 6*d*. The chief health visitor, Miss Barratt, has been appointed infant protection visitor by the Coventry guardians. It has again been impossible to operate the sections of the Housing Acts relating to the closure of unfit houses, owing to the absence of alternative accommodation. In referring to the close association of the school medical and infant welfare services Dr. Snell emphasises the desirability of providing some leisure for the medical members of the staff to engage in research. The open-air residential school, situated on high ground about five miles from the city, has been rebuilt to accommodate 90 children, and was officially opened by the mayor in July. The day open-air school held on part of the roof of the Centaur-road school was much interfered with by the wet weather of 1927.

Halifax.

Dr. Cyril Banks says the issue of his report has been delayed owing to the full energy of the health department having been concentrated on the suppression of small-pox. During the year 1927 there were "three invasions" of the town by small-pox, amounting in all to 12 cases with no deaths. For the first time since 1921 the Registrar-General has estimated a slight increase in the population. The death-rate was higher than usual owing to a sharp outbreak of influenza in February and March. The deaths attributed to influenza numbered 65. The infant mortality-rate was 11 higher than in the previous year, and Dr. Banks discusses the reasons for the high neonatal and maternal mortalities from childbirth. Dr. Banks considers that the difficulty with regard to smoke from domestic chimneys need no longer exist. From his experience "Coalite" produces bright, clean, hot fires with no smoke, no dirty kettles and pans, and no need for the chimney sweep. The orthopædic scheme under the direction of Mr. F. W. Goyder, F.R.C.S., has done excellent work. Of the 44 cases under the school age treated 34 were rickets. Of the 222 of school age 62 were cases of flat-foot, 56 of stoop, 32 of lateral curvature, 11 of infantile paralysis, 11 of rickets, 6 of infantile hemiplegia, 5 of torticollis, and 4 of Erb's paralysis. Mr. Goyder points out that the staff of the clinic needs to be increased and that another masseuse should divide her time between the clinic, the schools, and the maternity and child welfare centre. In order to help the work a lamp for ultra-violet radiation has been installed at the Northgate centre.

Great Yarmouth.

Dr. A. N. Stevens draws attention to the fact that 50 per cent. of the deaths in the town during the year under review occurred at ages over 65, and 32 per cent. at ages over 75. The total rainfall was 31·96 in. and the hours of bright sunshine 1513·7. In discussing the work of the tuberculosis dispensary Dr. Stevens refers to the difficulty of getting contacts to submit themselves for examination. The notifications in 1927 numbered 133 and the average for the preceding five years was 87, but the number of contacts examined during 1927 was only 21. There are still 24 wells in the borough, many of which "are without doubt liable to pollution at times," but Dr. Stevens thinks that "unless the samples for analysis happen to be taken at one of such times" these wells cannot be dealt with. The new houses erected numbered 348 of which 276 received State assistance. Under the new milk regulations general shopkeepers are only to be permitted to sell milk in sealed bottles.

Dover.

Dr. A. B. McMaster records a severe epidemic of influenza in the first quarter of the year. At the end of 1927, after revision, the tuberculosis register contained 356 pulmonary and 99 non-pulmonary cases, the two sexes being in about equal proportions. The tuberculosis notifications numbered 91 and the deaths 51, so that the names on the register are five times the notifications for the year and nine times the deaths. Since the new scarlet fever antitoxin came into use at the isolation hospital (in 1926) the number of complications and the duration of stay at the hospital have been reduced. Dr. McMaster points out that the number of cases is too small to draw general conclusions from, but that the facts are suggestive of the value of the new antitoxin. The senior sanitary inspector attended the "clean milk" course at Wye Agricultural College. Greater use is being made of the hospital beds provided at the Royal Victoria Hospital for complicated maternity cases.

MENTAL HOSPITAL REPORTS.

THE annual report of the *City of Birmingham* Asylums Committee is of particular interest this year, as it opens with a report, from the chief medical officer, of the medical work in both institutions. The principal feature is an inquiry into the ravages of physical disease, particularly focal sepsis, among mental patients. Oral sepsis was found in 77 per cent. of the 531 cases admitted, and many of the remaining 23 per cent. were edentulous, so that a really healthy mouth was rare. The commonest type of septic mouth was gross suppurating periodontitis. Septic conditions of the ears, throat and air passages were found in half the patients, and 161 out of 180 examined revealed evidence of infection in one or more sinuses, while 40 had chronic suppurative inflammation of the ear. Operations by the laryngologist numbered 174, and no patient appeared to be worse after them, physically or mentally, while improvement followed by discharge was often recorded. Apart from the general toxic effect of these conditions, it is possible that infection passes directly to the brain from the nose and throat; certain work on two cases of advanced epilepsy and mental disorder has pointed to direct invasion of the cranial cavity through diseased bone. The gynæcologist has also played his part in the detection of sepsis, and has found T.A.B. vaccine useful for many resistant cases of septic cervicitis. A review of the ætiological rôle of influenza in mental disturbance suggests strongly that the virus plays a large part, both immediately and after a delay of several months.

After this interesting medical summary the reports of the two mental hospitals seem more than usually statistical. At *Winson Green* there were 763 patients at the end of the year. The recovery-rate was 41·4 per cent., with an additional "discharged relieved" rate of 11·1 per cent. More than half the patients admitted during the year were totally discharged, 68 of them after a preliminary month's trial. The death-rate of 6·45 per cent. is the lowest in the history of the hospital. Autopsy was performed in 84 per cent. of possible cases. The extensive parole allowed resulted in 12 escapes, but the superintendent regards the liberty as "well worth it." All were safely returned. The general health was very good and only two patients were under treatment for tuberculosis at the end of the year. A number of operations for septic foci were performed and most of them were followed by improvement, either directly or after a subsequent treatment by protein shock (T.A.B. vaccine). Nearly 100 patients received maintain a high standard of achievement. In his preface Mr. Ogilive states that the difficulty which confronted him was to decide what recent surgery is and what constitutes an advance. Advance in surgery is not commonly a thing of sudden birth and it must be rare indeed to find that the conception of a new method is followed rapidly by its evolution in a practical and useful form; this is usually a process lasting many years. In spite of obvious difficulties, however, the author has succeeded in writing a clear, concise, and systematic account of the latest work in all branches of surgery. The magnitude of his task may be estimated by the references to recent surgical iterature at the end of each chapter. These references hould be of very great value to the busy surgeon who ishes to consult a small number of modern papers on ny aspect of his subject. Much of the best surgical erature of the last few years is quoted here. One the most interesting chapters is that on plastic gery. The impetus given to this branch of surgery the war makes it obviously a recent advance; importance has hardly diminished in peace time is not likely to diminish while modern machinery motor-cars continue their devastating progress. In the section on the toxæmia of acute intestinal obstruction the use of bile as a therapeutic measure is not mentioned, perhaps because it has hardly yet emerged from the purely experimental stage. There is one serious blemish for which the author may not be entirely responsible—the frequency with which the reader is told that a full description of some test, with a distinct surgical application, is to be found in the companion volume on Medicine. There are some omissions which spoil the symmetry of the sections in which they occur. It is clear that the object is to save space by avoiding repetition and not to advertise a book which is far too popular to need such assistance. but a certain amount of overlapping is preferable to the need for simultaneous consultation of two volumes. We trust that in the next edition Mr. Ogilvie will supply these few pages which will make his excellent book complete by itself.

Latent Tuberculosis.

La tuberculose pulmonaire latente. By Prof. J. Rieux. Paris: Gaston and Co. Pp. 247 and plates. Fr.27.

The author has written this book out of the rich fullness of 35 years' experience as Médicin-Inspecteur of the French Army. During this long period he has had ample opportunity of studying the question of latent tuberculosis in the young adult male population of France as it passes into the ranks of the Army. Many terms have been devised to express this condition in French military parlance—"présuspecte, bronchite de sommets, sclérose de sommets"—but the author rejects them all as unsatisfactory and adheres to the term of latent tuberculosis. He lays down certain conditions for the definition. The lesion should be manifest and accessible to investigation, its tuberculous nature should be proved, but the stage of its evolution should not be capable of recognition. Prof. Rieux devotes six chapters to an exposition of his subject, including symptomatology, radiology, and clinical pathology. At the end of the volume a number of illustrative cases are cited and a collection of radiograms, which last appear to have suffered a little in the process of reproduction. No strikingly new work is described—there is, indeed, none to describe—but the book is comprehensively written and forms a lucid presentation of the subject.

Rules for Recovery from Pulmonary Tuberculosis.

Fifth edition, thoroughly revised. By Lawrason Brown, M.D. Philadelphia and New York: Lea and Febiger. 1928. Pp. 244. $1.50.

Dr. Lawrason Brown believes that in pulmonary tuberculosis the physician must not only be prepared to do what is right himself, but also to make the patient, the attendants, and externals coöperate. The well-tried book before us is therefore intended to supplement the care of the physician which can only carry the phthisical patient a short distance on the way to recovery. The physician of to-day must, the author recognises, *teach* in order to serve most intelligently, and his own teaching in this little book has saved countless lives of a type which are peculiarly worth saving. Not dramatically, as a surgeon saves lives, but with precept upon precept, line upon line, chosen for effect. The book is not intended for skimming but to be gone over chapter by chapter day by day, for, as the author remarks, with increasing knowledge new and important facts may be discovered in many of its paragraphs. The present edition lacks the illustrations of the earlier editions, but the reader is referred to the *Journal of the Outdoor Life*, where they may be found.

The Surgery of the Skin.

Chirurgie der Haut und des Unterhautzellgewebes. By Dr. F. R. Ascher. Being an instalment of *Die Chirurgie*, by Prof. Dr. M. Kirschner and Prof. Dr. O. Nordmann. Berlin and Vienna: Urban and Schwarzenberg. 1928. With 46 illustrations and 29 coloured plates. Pp. 263. M.22.

This production on the surgery of the skin and subcutaneous tissues forms a small part of a new text-book on surgery, both general and special, by numerous writers. It cannot be purchased separately. After a short historical and anatomical introduction, the subjects discussed include nævi and other congenital conditions, such as v. Recklinghausen's disease, the various types of skin wounds, including gunshot and caustic wounds, and dog-bites, with the lines of treatment specified. Damage of the skin by heat, light, and X rays, electricity, lightening, and radium are next considered, and then follow the surgical aspects of furunculosis, erysipelas, tuberculosis, actinomycosis, anthrax, &c. The circulatory disturbances of the Raynaud type, gangrene, erythromelagia, and ulcers of the leg are fully discussed, and also neoplasms, benign and malignant. The volume has been written by a surgeon for surgeons, and with such a title should, we think, contain a chapter on the plastic surgery of the skin and the modern methods of skin-grafting.

In other respects the work is satisfying. Th style is simple and succinct, and the publishers hav been generous with a number of excellent illustrations

---

Health and Cleanliness.

By W. A. Muir, M.D., D.P.H., Medical Officer of Health for Gillingham, Kent; and George H. Green, B.Sc., B.Litt., M.A., Ph.D., Lecturer in Education, University of Wales. London: The Health and Cleanliness Council. 1928. Pp. 63. Gratis.

This little text-book for teachers is still a further manifestation of the remarkable activity of the Health and Cleanliness Council, which seems to suffer from no shortage of funds for the free issue of educational material. After a brief foreword by Dr. George F. Buchan, M.O.H. of Willesden, and a concise introduction, it deals in nine lessons with the teaching of children about cleanliness of the person, of the home (especially the kitchen), of food, of personal and bed-clothing, and about the special problems of cleanliness while in camp or at picnics. The book is illustrated with reproductions of the now well-known posters of the Council, and is a model of its kind. How valuable this cleanliness propaganda would have been 50 or 100 years ago, when the dirt-diseases were really a serious menace! There is just a little danger now that too much stress on this one aspect of public health education may create an ill-balanced conception of the whole problem in the child-mind.

Reviews and Notices of Books.

THE OPIUM PROBLEM.

By CHARLES E. TERRY, M.D., and MILDRED PELLENS. New York: The Committee on Drug Addictions. 1928. Pp. 1042.

THIS work, though formidable in its dimension, is stated to be condensed from a report prepared under the direction of the Committee on Drug Addictions of New York, in collaboration with the Bureau of Social Hygiene. It presents a review of the literature of the Narcotic Drug Problem, drawn largely, but by no means exclusively, from American sources. It deals with the extent, development, ætiology, nature, pathology, symptomatology, and treatment of drug addiction, and finally discusses efforts at control of the commerce in opium and other narcotics, municipally, nationally, and internationally.

The probability that the Geneva Opium Convention of 1925, which implements The Hague Convention of 1912, will shortly come into operation, makes the appearance of this work opportune. By a review of standard works, treatises, and monographs, by questionaires directed to medical and administrative authorities, and by a digest of conventions, laws, and regulations, the authors have endeavoured to furnish students of the opium question with a "fairly composite picture of professional and official opinion and attitude of the day as to the medical and sociologic aspects of the problem." The authors are not prepared to confirm the assertion that the number of addicts in the United States exceeds a million, but are satisfied that their "surveys and estimates indicate sufficiently clearly the existence of a major medico-social problem" to be confronted. The early use of opium as an anodyne in Asia, its introduction into Western countries, and the discovery of its value for other than therapeutic purposes, the spread of the use of the hypodermic syringe, and the differentiation of the pharmacological properties of the alkaloids derived from opium are related. The view is expressed "that there are certain persons who, by reason of definite psychical characteristics, more readily become victims of the chronic use of the drugs"; but while discussing various attempts to elucidate the ætiology of narcotic addiction, the authors are not satisfied that a truly scientific explanation has yet been vouchsafed, and urge the need of further research into "the mechanism of the phenomena recorded." In a later chapter, however, the conclusion is reached that "there is no type which may be called the habitual user of opium," and that addiction is "not restricted to any social, economic, mental, or other group." In regard to treatment, the relative advantages of complete and partial withdrawal of the drug are stated, but the conclusion is arrived at "from the material reviewed that the treatment of this condition has not emerged from the state of empiricism."

Efforts at control of the foreign commerce in opium were made by the United States as early as the 'thirties and 'forties of last century, more especially in regard to China, Siam, and Japan. It was, however, after the acquisition of the Philippine Islands by the United States that American attention was more particularly directed to control of narcotic traffic in the Far East. Bishop Brent, who had become aware of the abuse of opium by the Philippinos, in 1906 urged President Roosevelt to international action, and this resulted in the Shanghai Commission of 1909. That Commission, to which representatives of America, Great Britain, Austro-Hungary, Germany, France, Italy, China, Japan, the Netherlands, Persia, Portugal, Russia, and Siam were invited, recognised the sincerity of China in grappling with the opium trade, the need for suppressing the smoking of opium, the necessity for controlling the manufacture and distribution of morphine and other drugs also liable to abuse, and, above all, that the question was not one for the Far East alone, but that the Occident as well as the Orient was suffering from the abuse of narcotics, and that any real control of the commerce in these dangerous drugs must be international and, indeed, world-wide. The United States followed up the report of the Shanghai Commission by inviting an international conference at The Hague to conventionalise the findings of the Commission. This Conference, after some demur by the British Government arising from their recent agreement with China to terminate the Indo-Chinese opium trade, met at The Hague in 1911–12, and further conferences were held there in 1913 and 1914. The International Opium Convention of 1912 marked not only a new departure in international effort, but bound its contracting parties to the introduction of legislation to give effect to its provisions. The Convention sought to regulate the production and distribution of raw opium, to suppress the use of opium "prepared" for smoking, and to limit the manufacture, sale, use, import, and export of morphine, heroin, and cocaine to "medical and legitimate purposes." Twelve powers only had taken part in the first Hague Conference, but by 1913 some 46 had signed it, and ratification was proceeding. The intervention of the Great War paralysed the progress of international coöperation from 1914 to 1918, but the Peace Treaties of 1919 secured the adhesion of Powers which had previously refused ratification. Great Britain, by the Dangerous Drugs Act of 1920 and 1923, gave legislative effect to The Hague Convention as regards the Mother Country. By an Act of 1914, known as the Harrison Narcotic Act, amended in 1918, 1926, and 1927, the United States put The Hague Convention into operation within its borders, and by the Jones-Miller Act of 1922 restricted foreign trade in narcotics. By the Covenant of the League of Nations, the supervision and execution of agreements in regard to the traffic in dangerous drugs was entrusted to the League. The story of the action of the Council and Assembly of the League and of its Advisory Opium Committee is related, and also that of the prolonged and contentious opium conferences at Geneva in 1922–23, which resulted in a fresh agreement among Powers with possession in the Far East, and a new Convention reproducing and supplementing The Hague Convention to which all States could adhere. It is this last instrument which will come into force on Sept. 25th, and although the United States and Chinese representatives withdrew from the Conference and are no parties to the Convention, it should, through the Central Board it sets up, increase the control of the traffic and reduce the scandalous amount of illicit trade.

This compendious work of Dr. C. E. Terry and Miss Pellens will prove a timely and serviceable aid to students of the opium problem and of the tangled story of efforts after international control of traffic in dangerous drugs.

RECENT ADVANCES IN SURGERY.

By W. HENEAGE OGILVIE, M.D., M.A., M.Ch. Oxf., F.R.C.S. Eng. Assistant Surgeon. Guy's Hospital, and Lecturer in Clinical Surgery to Guy's Hospital Medical School; Surgeon to Out-patients, Hampstead General and North-West London Hospital. *London: J. and A. Churchill.* 1928. Pp. 461. 15s.

THE success of "Recent Advances in Medicine," the first number of the series to which the present volume belongs, has encouraged the publishers in the production of several books which are widely read and admired. The surgical volume, which might reasonably have been the second volume to appear, actually comes no higher than tenth in the list, and has been eagerly anticipated. It is well worth waiting for. The burden of its preparation has fallen chiefly on the author whose name appears on the title page, but he has been ably assisted by some of his colleagues. The chapters on cancer, plastic surgery, chest surgery, and venereal disease have been written respectively by Mr. J. F. Carter Braine, Mr. T. P. Kilner, Mr. Grant Massie, and Mr. V. E. Lloyd, all of whom maintain a high standard of achievement. In his preface Mr. Ogilive states that the difficulty which confronted him was to decide what recent surgery is and what constitutes an advance. Advance in surgery is not commonly a thing of sudden birth and it must be rare indeed to find that the conception of a new method is followed rapidly by its evolution in a practical and useful form; this is usually a process lasting many years. In spite of obvious difficulties, however, the author has succeeded in writing a clear, concise, and systematic account of the latest work in all branches of surgery. The magnitude of his task may be estimated by the references to recent surgical literature at the end of each chapter. These references should be of very great value to the busy surgeon who wishes to consult a small number of modern papers on any aspect of his subject. Much of the best surgical literature of the last few years is quoted here. One of the most interesting chapters is that on plastic surgery. The impetus given to this branch of surgery by the war makes it obviously a recent advance; its importance has hardly diminished in peace time and is not likely to diminish while modern machinery and motor-cars continue their devastating progress. In the section on the toxæmia of acute intestinal obstruction the use of bile as a therapeutic measure is not mentioned, perhaps because it has hardly yet emerged from the purely experimental stage. There is one serious blemish for which the author may not be entirely responsible—the frequency with which the reader is told that a full description of some test, with a distinct surgical application, is to be found in the companion volume on Medicine. There are some omissions which spoil the symmetry of the sections in which they occur. It is clear that the object is to save space by avoiding repetition and not to advertise a book which is far too popular to need such assistance, but a certain amount of overlapping is preferable to the need for simultaneous consultation of two volumes. We trust that in the next edition Mr. Ogilvie will supply these few pages which will make his excellent book complete by itself.

Latent Tuberculosis.

La tuberculose pulmonaire latente. By Prof. J. Rieux. Paris: Gaston and Co. Pp. 247 and plates. Fr.27.

The author has written this book out of the rich fullness of 35 years' experience as Médicin-Inspecteur of the French Army. During this long period he has had ample opportunity of studying the question of latent tuberculosis in the young adult male population of France as it passes into the ranks of the Army. Many terms have been devised to express this condition in French military parlance—"pré-tuberculose, imminence tuberculose, bronchite suspecte, bronchite de sommets, sclérose de sommets"—but the author rejects them all as unsatisfactory and adheres to the term of latent tuberculosis. He lays down certain conditions for the definition. The esion should be manifest and accessible to investiation, its tuberculous nature should be proved, but the stage of its evolution should not be capable of recognition. Prof. Rieux devotes six chapters to an exposition of his subject, including symptomatology, radiology, and clinical pathology. At the end of the volume a number of illustrative cases are cited and a collection of radiograms, which last appear to have suffered a little in the process of reproduction. No strikingly new work is described—there is, indeed, none to describe—but the book is comprehensively written and forms a lucid presentation of the subject.

Rules for Recovery from Pulmonary Tuberculosis.

Fifth edition, thoroughly revised. By Lawrason Brown, M.D. Philadelphia and New York: Lea and Febiger. 1928. Pp. 244. $1.50.

Dr. Lawrason Brown believes that in pulmonary tuberculosis the physician must not only be prepared to do what is right himself, but also to make the patient, the attendants, and externals coöperate. The well-tried book before us is therefore intended to supplement the care of the physician which can only carry the phthisical patient a short distance on the way to recovery. The physician of to-day must, the author recognises, *teach* in order to serve most intelligently, and his own teaching in this little book has saved countless lives of a type which are peculiarly worth saving. Not dramatically, as a surgeon saves lives, but with precept upon precept, line upon line, chosen for effect. The book is not intended for skimming but to be gone over chapter by chapter day by day, for, as the author remarks, with increasing knowledge new and important facts may be discovered in many of its paragraphs. The present edition lacks the illustrations of the earlier editions, but the reader is referred to the *Journal of the Outdoor Life*, where they may be found.

The Surgery of the Skin.

Chirurgie der Haut und des Unterhautzellgewebes. By Dr. F. R. Ascher. Being an instalment of *Die Chirurgie*, by Prof. Dr. M. Kirschner and Prof. Dr. O. Nordmann. Berlin and Vienna: Urban and Schwarzenberg. 1928. With 46 illustrations and 29 coloured plates. Pp. 263. M.22.

This production on the surgery of the skin and subcutaneous tissues forms a small part of a new text-book on surgery, both general and special, by numerous writers. It cannot be purchased separately. After a short historical and anatomical introduction, the subjects discussed include nævi and other congenital conditions, such as v. Recklinghausen's disease, the various types of skin wounds, including gunshot and caustic wounds, and dog-bites, with the lines of treatment specified. Damage of the skin by heat, light, and X rays, electricity, lightening, and radium are next considered, and then follow the surgical aspects of furunculosis, erysipelas, tuberculosis, actinomycosis, anthrax, &c. The circulatory disturbances of the Raynaud type, gangrene, erythromelagia, and ulcers of the leg are fully discussed, and also neoplasms, benign and malignant. The volume has been written by a surgeon for surgeons, and with such a title should, we think, contain a chapter on the plastic surgery of the skin and the modern methods of skin-grafting.

In other respects the work is satisfying. The style is simple and succinct, and the publishers have been generous with a number of excellent illustrations.

Health and Cleanliness.

By W. A. Muir, M.D., D.P.H., Medical Officer of Health for Gillingham, Kent; and George H. Green, B.Sc., B.Litt., M.A., Ph.D., Lecturer in Education, University of Wales. London: The Health and Cleanliness Council. 1928. Pp. 63. Gratis.

This little text-book for teachers is still a further manifestation of the remarkable activity of the Health and Cleanliness Council, which seems to suffer from no shortage of funds for the free issue of educational material. After a brief foreword by Dr. George F. Buchan, M.O.H. of Willesden, and a concise introduction, it deals in nine lessons with the teaching of children about cleanliness of the person, of the home (especially the kitchen), of food, of personal and bed-clothing, and about the special problems of cleanliness while in camp or at picnics. The book is illustrated with reproductions of the now well-known posters of the Council, and is a model of its kind. How valuable this cleanliness propaganda would have been 50 or 100 years ago, when the dirt-diseases were really a serious menace! There is just a little danger now that too much stress on this one aspect of public health education may create an ill-balanced conception of the whole problem in the child-mind.

AIDS TO EMBRYOLOGY.

By RICHARD H. HUNTER, M.D., M.Ch., Lecturer in Anatomy, Queen's University, Belfast. London: Baillière, Tindall and Cox. 1928. Pp. 160. 3*s.* 6*d.*

THIS little book contains a good deal of information, given, of course, in a much abbreviated form. We do not believe in the utility, for the student of medicine, of accounts of development shorn of their details, so that, from this point of view, we consider the chapters which deal with general theories to be the best in the book; but for students who merely look on embryology as an examination necessity this little work will prove an admirable aid. It is only fair to say, however, that in some matters Dr. Hunter does not adopt the descriptions of parts undergoing development which are usually found in most English textbooks.

PERCIVAL'S MEDICAL ETHICS.

Baltimore: The Williams and Wilkins Company. 1927. Pp. 291. 13*s.* 6*d.*

Thomas Percival was born in Warrington in 1740, and entered the University of Edinburgh at what was then the rather advanced age of 21. From boyhood he had been a student and when he settled in practice in Manchester he became associated with the founding of the Manchester Literary and Philosophical Society, a distinguished body which fostered among others Dalton and Joule. Percival must have been a man of striking personal characteristics, for he was elected a Fellow of the Royal Society before he had made any public mark, and even in the eighteenth century, when the favours of private interest were bestowed with particular cynicism, his election seems to have caused surprise. However, in this event it was justified, for his public work in Manchester, where he lived all his life, led to the formation of proper sanitary standards in the city, and laid the foundation for factory legislation in the whole country. His work on medical ethics, which has now been edited by Prof. Chauncey D. Leake, the well-known pharmacologist of Wisconsin, was written for the guidance of his son, a medical student. It is entitled "A Code of Institutes and Precepts Adapted to the Professional Conduct of Physicians and Surgeons," and it was very thorough in its scope, taking regard of the medical position in hospitals, in private practice, and also in public situations—indeed, in its inception it was a work of medical jurisprudence. It may be thoroughly recommended for perusal by those who wish to understand what were in the eighteenth century the essential matters to be regarded for the formation of proper relations between medicine and the public, and it is interesting to note that in the twentieth century the main lessons are perfectly apposite, though in detail so many circumstances have changed. Both the editor and the publishers are to be thanked for an interesting volume. The London agents for the publication are Messrs. Baillière, Tindall and Cox.

THE YOUNG MAN AND MEDICINE.

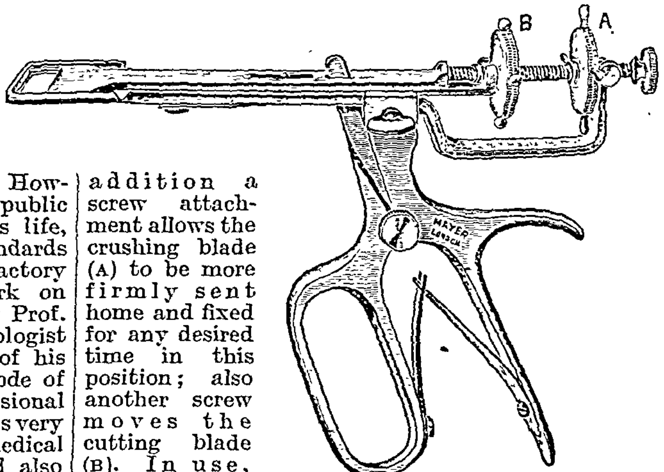
By LLEWELLYS F. BARKER, M.D., LL.D., The Macmillan Company. 1928. Pp. 202. 10*s.* 6*d.*

Dr. Barker is Professor Emeritus of Medicine in Johns Hopkins University, New York, and it is, consequently, out of large experience that he addresses his book "to the young men in medicine with whom I have had the privilege of association in Canada and in the United States." His purpose, in the first instance, has been to help those who have not reached any final decision as to what they want to do in life. The question is one which he thinks should be decided by themselves, but for this purpose guidance should be supplied out of the experience of leaders in various professions and callings. This small book is one of a series, termed the "Vocational Series," in which, for the information of the young man, the various things which he has to consider before deciding to be a lawyer, a clergyman, a doctor, a journalist, and the rest, are set out. The medical track is well charted, though some of the advice given is more suitable to one who is on the journey than one who has not yet made up his mind to start.

New Inventions.

THE LA FORCE GUILLOTINE.

IT is now nearly 12 months since an American visitor demonstrated the La Force guillotine to me. I have used the instrument many times and feel that its employment should be much more general in this country. As far as I know it is rarely used. The instrument is built on the pattern of the Ballenger guillotine, but with two sliding parts, the upper (or outer, when considered as in use on the tonsil) which is slightly roughened and clamps the tissue between tonsillar capsule and constrictor muscle, and the inner or cutting blade. Both are worked from a scissor or forceps handle as in the Ballenger pattern, but in addition a screw attachment allows the crushing blade (A) to be more firmly sent home and fixed for any desired time in this position; also another screw moves the cutting blade (B). In use, under general and complete anæsthesia to produce relaxation, the tonsil is engaged and dealt with as in any other enucleation operation with the guillotine, but after the crushing or hæmostatic blade has reached the bottom of the fenestrum it is still more firmly forced down and held in position by the screw. The cutting blade is then forced down by turning the second screw and withdrawn by reverse action of this screw, and the tonsil now freed from its bed lifted out with suitable forceps, such as Luc's, or with a sponge-holder. The hæmostatic blade is allowed to remain on for five minutes or more, when it is released by unscrewing, and the guillotine removed. In favourable cases there will be no bleeding at all, or at most only a slight tinging of the mucus in the pharynx; in the majority of cases there has been no need to use a single swab. There is singularly little pain or discomfort in the 48 hours following operation and in this, the method contrasts very favourably with other guillotine enucleations or with dissection. The instrument is not so easy to use as the O'Malley, and a slightly larger percentage of failures to enucleate the tonsil cleanly will result. I have no hesitation in stating that when successful the method is ideal, but like all others the La Force occasionally fails.



The instrument is made by Messrs. Mayer and Phelps, New Cavendish-street, London.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 15, 1928.

EPILEPSY AS A SOCIAL PROBLEM.

ALTHOUGH there are probably few diseases which have been recognised for a longer time and about which more has been written than epilepsy, it has to be admitted that as a social problem it has hitherto received comparatively little, and certainly quite inadequate, consideration. For this reason the two articles which we publish in the present number, the one (p. 568) on the results of a census made in Surrey and the other (p. 545) on the subsequent history of a number of children who have passed through a residential school, are worthy of careful attention. To those who are unaware how scanty are our statistics of disease which does not concern the sanitary or the burying authorities it may come as a surprise to learn that there are no reliable figures as to the incidence of epilepsy. Moreover, in view of the wide differences in the frequency of attacks, the great variations in type and severity which undoubtedly result in many cases being unrecognised, and the fact that epileptic attacks not uncommonly occur as a complication or symptom of some even graver and more urgent condition, it may safely be said that it would be impossible to obtain any complete and reliable statistics regarding the incidence of the disease. The Permanent Committee on Epileptics did not attempt the impossible. They limited their census to a definite area—namely, the county of Surrey—and to such persons as were chargeable to public authorities. They found that in the area examined the proportion of such epileptics amounted to 0·65 per 1000 of the general population, and, if this may be accepted as a fair sample of the country as a whole, they estimate that in England and Wales there are 25,000 persons affected by this disease who are a public charge. Of this number rather more than one-third—again judging from Surrey experience—are mentally normal, whilst the remainder are either insane or mentally defective. It is clear, therefore, that from the point of view of incidence alone the problem of the rate-supported epileptic is a serious one. It becomes the more so in view of the facts ascertained by the Committee that one-quarter of the total number of educable epileptic children are attending no school or institution, and that of those who come within the scope of, and should be dealt with under, the Mental Deficiency Acts, less than one-fifth are in fact so dealt with.

No doubt when epilepsy is complicated by, or has induced, serious mental defect or deterioration there is little likelihood of the sufferer being rendered economically useful; but there are many young mentally normal epileptics who drift into chronic unemployability for want of proper education and training, and there is every reason to believe that the absence of such care is also an important factor in bringing about mental deterioration in a number of cases. Dr. J. TYLOR FOX, medical superintendent of Lingfield Epileptic Colony, in his account of the after-history of 332 children who passed through the colony in a period of eight years, shows the benefits which may result from training in a suitable residential school. Although the children admitted to Lingfield are a worse than average group, inasmuch as they suffer from attacks which are too severe to allow of them attending ordinary schools, their subsequent history shows that 28 per cent. of the total have become partly or entirely self-supporting. When the unpromising nature of the raw material is borne in mind this result must be considered as very satisfactory and as demonstrating the value of the treatment and training received. Unfortunately, the accommodation at present existing for cases of this kind is so inadequate that these advantages are only available for a relatively small number. Dr. Fox estimates that the proportion of "educable" epileptic children who are accommodated in residential special schools is only about one-fifth of the total in existence, the remainder either drift into poor-law or other institutions or they are allowed to remain at home. In any event it may safely be said that the great majority of them receive little if anything in the nature of skilled treatment and training. In addition to this, as we have already mentioned, the accommodation available for those in whom the epilepsy is accompanied by mental defect is equally unsatisfactory. A careful study of the facts presented points conclusively to the serious nature of the problem, and to the utter inadequacy of the existing accommodation for the epileptic, whether mentally normal or abnormal. It may be that some of these matters will be dealt with by the Board of Education Committee on Mental Deficiency now sitting, whose report, we understand, will be published before the end of the year. It may also be that some attention will be given to the problem in the alterations to the poor-law system which are imminent. In any case, however, it cannot be doubted that epilepsy constitutes an important social problem, and that the time has arrived when it should receive serious consideration from this aspect.

◆

THE FALLING BIRTH-RATE.

THE birth-rate for 1927 turns out to have been the lowest recorded in this country since the establishment of civil registration, and responsible citizens hold up their hands in horror, wondering what the young people are coming to. A sane view of the situation suggests that there is nothing to be horrified at except the spectacle of human beings responding to their environment in the same way as any other live thing, animal or plant. Large and increasing populations have been welcome in the past for two reasons. In the first place, they provided larger armies—a consideration which was perhaps natural in Old Testament times and was artificially flogged into prominence in Europe as late as the nineteenth century; it has now, we hope, gone for good. And in the second place, rulers and governors realised that large numbers are more likely than small ones to comprise those extreme variants in qualities of body, mind, and spirit on which leadership depends so much. We have, too, in the last 150 years become so accustomed to seeing the population of this country progressively growing larger and larger, and to hearing continually that there is a shortage of houses that we find it difficult to realise the possibility—indeed, as far as can be foreseen, the certainty—that our numbers will very soon cease to increase and that the population will return to the stationary position which it had, at a much lower absolute level, in the sixteenth and seventeenth centuries. Even the town-planner and the speculative builder do not seem to have appreciated the position.

If people really believed in evolution, they would have more constantly in mind the thought that man is the product of his ancestry and that he is likely in matters of large temporal importance to behave in ways analogous to theirs. The numbers of any animal or plant which are alive in any given area at any moment are the maximum which conditions allow. Breeding is actually or potentially profuse enough to keep the place as full of a particular species as it will hold; with plants it is generally a question of space, with animals of food. And so long as conditions remain unaltered this optimum population persists at the level which allows the greatest number of individuals to exist at a fairly high level of perfection; natural populations of animals and plants do not consist of starvelings but of individuals which are well grown, healthy, and reproductive. There is, in short, no striking evidence in the survivors that there is any injurious overcrowding. But if conditions alter, the optimum population changes too; the dandelion and other weeds of bare soil exist on the minor catastrophes of the earth's surface and the rat population varies directly with the available food-supply. Man needs space and, being animal, especially food, and under any given set of conditions he multiplies till the number of human beings is the largest which can obtain the return from life which they are prepared to accept as adequate. In comparison with smaller animals he reproduces slowly, but given time he will fill up any conditions in which he finds himself. He differs, of course, from animals in that he can to some extent make his own environment—though animals are not wholly without that capacity—and to that extent he can control his own optimum population. It is here apparently that anthropoid apes fall short. With, at any rate in the orang and gorilla, exceptional physical powers they lack the mentality to alter the circumstances of their life in such a way that they can be numerous. They are, in fact, all sparse; it was, we think, Sir Harry Johnston who estimated that there were not more than 10,000 chimpanzees in equatorial Africa and the larger ones are fewer still. We may guess that early man was hardly abundant by modern standards; conditions of life must have been very hard, and it was perhaps just a lucky chance that enabled him to multiply enough to reach the stage where by numbers and herd action he could have the mastery over other beasts. And it is most interesting to note, as Prof. Carr-Saunders has pointed out, how primitive man always regulates his numbers to the available food; profuse procreation seems to have come in with the Christian era and among savages the production of children is, as a rule, severely restrained, partly by rules and customs, partly by a sheer lack of fertility to which attention has often been drawn lately in the South Sea Islanders. As man's control over his circumstances developed and increased, so larger populations became possible and where and when possible they were automatically achieved. The flood of new people which flowed in this country all through the nineteenth century was the product of the changes known as the industrial revolution; the flood has slackened some time since and will soon come to a standstill unless some undreamed-of expansion in the facilities of life is discovered. Theoretically, a further growth of population might occur if the standard of living required were reduced. But it is very doubtful whether this factor is really capable of any deliberate control. The indefinable "adequate return" is not luxurious physical ease but the state in which a man can do best with his mind and body; "motor-cars *versus* babies" applies only to a negligibly small part of the population; the ordinary run of men have derived from their animal ancestors a far finer sense of coöperative life.

It follows, as Dr. F. A. E. Crew pointed out in his thoughtful address at the British Medical Association at Cardiff (reported at some length in our issue of Sept. 1st, p. 463), that we must look much further than the boom in frank contraception for our explanation of the diminishing birth-rate. The birth-rate in England began to fall 50 years ago in obedience to the principles of populative growth which, as Pearl has pointed out, apply to yeast cells and the fly *Drosophila* as well as to Spaniards and Dutchmen and Frenchmen and any live thing else. It has continued to fall along the predicted lines and, whether we like it or not, in the absence of some paroxysm of civilisation our numbers will soon cease to increase any further. Deliberate birth restriction may be having a good deal of effect in these, the later, stages of the process, but the main explanation is in man's unconscious or subconscious adjustment to his environment, in his animal response to circumstances. Those will view the Registrar-General's figures with the greatest calm who believe with the authors of the Bridgewater Treatises that the world is constructed in the best possible way.

◆

COMPENSATION FOR SILICOSIS.

Compensation for the occupational disease silicosis is more complicated than for other diseases on account of the long latency and chronicity of the complaint. It has so far only been granted in Great Britain and some of the overseas Dominions. South Africa, with regard to the Rand gold mines, was the first to act, and there prevention and compensation are closely interlocked. Thus any miner who develops ordinary pulmonary tuberculosis is suspended from employment in order to exclude infection from the other miners, and is compensated. In England action was taken first on somewhat similar lines in 1918 under a scheme applied to the small refractories industries. Thenceforward use of the legislative powers taken was delayed until 1927 when compensation was granted to metal grinders, but the somewhat complicated procedure adopted in the refractories' scheme was then abandoned. At the same time a scheme for the pottery industry is in preparation. Action on these lines, however, is proving wearisomely protracted; and every year men are succumbing to this acceptedly occupational hazard in such important industries as stonemasonry, granite-cutting, quarrying, and metalliferous mining, without any compensation. The Home Office has now abruptly altered its policy of proceeding industry by industry, and has just issued a comprehensive draft scheme for granting compensation for death and total disablement in practically every occupation in which the silica risk exists. Even men in coal-mines driving hard headings or sinking shafts through sandstone rocks are to be included, also millstone builders and abrasive soap-makers, as well as the crafts named above. The plan of insisting upon periodical medical examinations, and upon suspension with compensation of those showing early signs, is abandoned. Compensation is only to be granted for total disablement or death. At the same time, while proposing thus to award compensation which is clearly overdue, the Ministry announces the intention to examine in due course each industry affected in order to link up preventive procedure with compensation awards. This procedure is likely to lead rapidly to limitation of the silica hazard. It will have an indirect economic effect, even where large operations, such as the construction of the Liverpool Cathedral with a dangerous stone, have reached an advanced stage, for the cost of completion must be greatly enhanced. Indeed, the use of sandstones for building purposes is likely to cease; since, however, bricks, cement, and limestone are all home products, no unemployment will be caused thereby. When the proposed scheme has been ratified in whole or in part England will have resumed her usual lead in matters of industrial hygiene. At present, besides South Africa, New South Wales, in relation to the county of Cumberland and to the Broken Hill mines, is ahead of us; and so also are the Canadian provinces of Alberta and Ontario. In several American States, where in the Compensation Acts the word "injury" is defined to include diseases arising out of employment, silicosis is covered with other occupational diseases. In continental countries, on the other hand, no compensation has yet been granted; but in Germany, at any rate, researches already published by L. TELEKY and in progress by F. KOELSCH, must before long result in the granting of compensation. Silicosis is one of the most widespread and fatal of all occupational risks. It has already demanded the attention of the expert advisers of the International Labour Office at Geneva, due mainly to British representation; and is likely soon to be placed on the list of compensable diseases for international adoption.

PSYCHOLOGY IN THE MEDICAL CURRICULUM.

AT the meeting of the British Association the committee appointed to consider the place of normal psychology in the medical curriculum presented its final report. The committee consisted of the following members: Dr. W. BROWN (chairman), Dr. R. D. GILLESPIE (secretary), Dr. C. H. BOND, Prof. E. P. CATHCART, Dr. H. DEVINE, Dr. J. A. HADFIELD, Dr. BERNARD HART, Dr. D. K. HENDERSON, Colonel J. R. LORD, Dr. C. S. MYERS, Prof. G. M. ROBERTSON, Dr. T. A. ROSS, and Prof. T. H. PEAR. They find that of 26 medical schools of the British Isles, 13 offer no courses whatever in normal psychology, while 8 offer optional courses and 5 compulsory ones, but since the report was prepared Edinburgh University has decided to make attendance at a course of lectures in normal psychology compulsory. Most of the medical schools in the Dominions offer courses in the subject. The committee report that they have received official replies in favour of the provision and value of such courses, while the deans of most of the medical schools have responded to their inquiry. After carefully examining existing conditions, the committee recommend that in every medical school a compulsory course of instruction in normal psychology, of not less than 10 and of not more than 20 lectures, should be given during the pre-clinical years—preferably in the second year; and that, whenever possible, it should be supplemented by a course of about ten two-hour meetings in experimental psychology. The committee further recommend that such instruction should be so planned as to serve as a foundation for subsequent lectures in the pathology of the mind given during the clinical years of the medical course, and it need hardly be said that from the point of view of the bulk of medical practitioners this is a most important proposal, as it is in this way that proper correlation of academic instruction with clinical procedure may be obtained.

Thus psychology and physiology would be taught at the same stage of the medical curriculum, and this combination is from every point of view desirable. It is usual to consider the two subjects as parallel, dealing respectively with the normal functions of the human mind and of the human body. Prof. W. MCDOUGALL[1] claims a much wider field for psychology, proposing the distinction between the two sciences that physiology studies the processes of organs and tissues, whereas psychology studies the total activities of the organism. To admit this view without reserve would be to confess that the medical curriculum which contains no course in psychology is absurdly inadequate, and indeed future generations are likely to take this attitude. Meanwhile all will agree that just as physiology provides the necessary basis for subsequent instruction in pathology, so a simultaneous course in normal and experimental psychology would be an excellent preparation for the lectures in morbid psychology which belong to the clinical years. There can be little doubt as to the wisdom of the committee's recommendations. Psychological medicine was at one time almost confined to the study of insanity; to-day it is recognised that the disorders of the mind and of the nervous system embrace a far wider field, and that the ability to recognise them immediately and to treat them effectively are of enormous importance in the everyday practice of the family doctor. We now know that there is not an organ in the body whose disorderly function may not be due to neurotic conditions. The origin and spread of the exaggerated claims of certain schools of psychotherapy have been largely due to the lack of previous systematic training in normal psychology. The same ignorance has been responsible for the equally untenable position adopted by opposite extremists who believe that functional disorders are merely "imaginary" and therefore demand merely "imaginary" remedies, that medical instruction should be confined to the study of living matter and of material remedies, and that a knowledge of the workings and influence of the mind is of no concern to the ordinary medical student. However congested be the present curriculum, there can be no doubt that by general demand the recommendations of the British Association Committee must soon be carried into effect.

FACTORY INSPECTION.—The Home Secretary has appointed a Committee to consider and report what addition to the Factory Inspectorate is required, whether any changes in its organisation are desirable, and what other measures, if any, can be taken to enable the Factory Department to discharge adequately its duties now and in the future. The members of the Committee are:—Sir Vivian Henderson (chairman), Sir Gerald Bellhouse, Mr. R. R. Bannatyne, Mr. Kenneth Lee, Miss H. Martindale, and Mrs. C. D. Rackam. The secretary of the Committee is Mr. L. N. Blake Odgers, of the Home Office.

GERMAN MEDICAL JOURNEY TO EGYPT.—On the occasion of the centenary celebration of the University of Cairo, the Vienna Committee for Medical Tours Abroad has arranged a visit to Egypt covering the period Dec. 14th, 1928, to Jan. 4th, 1929, the journey out being made by Venice, Brindisi, and Alexandria, returning by Rhodes, Athens, and Corfu. The visit coincides with a Congress of Tropical Medicine and Hygiene in Cairo, and the usual winter international exhibition of medical arts and sciences. Programme and information from Dr. F. Barach, Vienna I., Biberstrasse 11.

Annotations.

"Ne quid nimis."

THE YEAR'S WORK AT THE MINISTRY OF HEALTH

ALTHOUGH we still await the Report of the Chief Medical Officer for last year much interesting information is, as usual, conveyed in the Annual Report of the Ministry of Health (1927–28).[1] Its summary of general health questions rightly gives prominence to the amendment of our mental deficiency legislation at the end of last year. The old restriction which confined the application of the Mental Deficiency Act to persons whose mental defect had existed "from birth to early age" has at last disappeared and the new definition of "mental defectiveness" is "a condition of arrested or incomplete development of mind existing before the age of 18 years, whether arising from inherent causes or induced by disease or injury." One advantage of this enlargement of the statutory definition is that it will now be possible to take suitable steps to provide care and treatment for persons suffering from the sequelæ of encephalitis lethargica. Another important piece of legislation which became operative in the past year is the Therapeutic Substances Act, 1925, which is designed to regulate the manufacture, sale, and importation of vaccines, sera, and other therapeutic substances whereof the purity and potency cannot adequately be tested by chemical means. The Act and Regulations, it is stated, have been brought into force without friction. One of the medical officers of the Ministry, in conjunction with a representative of the Medical Research Council, has inspected manufacturers' premises both in this country and on the continent. At the end of last March 36 licences to manufacture had been issued, 43 licences to import, and 11 licences to import for the purposes of research. Other matters summarised in the Report include the winding up of the Voluntary Hospitals Commission. Here, it seems, the Ministry considers that there is no further scope at the moment. "In view of the improved financial position of the voluntary hospitals and the fact that the Government had found themselves unable to make any grant-in-aid of the capital cost of hospital extensions," the Commission has been encouraged to bring its labours to a close by the presentation of its Final Report. Mention is also made of the work of the Committee on Post-Graduate Medical Education. The Committee unanimously decided that the establishment of a new centre with the 300 or 400 beds requisite for providing adequate clinical material was impracticable on the ground of the expense of initial capital cost and annual maintenance. The alternative was the conversion of an existing hospital, and the report gives the reasons for the selection of the West London Hospital at Hammersmith, where there is already a long tradition of post-graduate teaching. The carrying out of the scheme is still delayed by lack of the capital wherewith to make the desired structural alterations. National health insurance practitioners will read with interest the section of the Ministry's report which deals with medical benefit, its cost, scope and administration, the investigation of excessive prescribing, and the revision of the disciplinary procedure. On the whole the Report gives the impression of a general improvement in health standards and facilities. Historically there has been a fusion of public health and local government administration in England. It is satisfactory to find that, when the Minister's hands are so full with changes in the rating system and the poor-law, the claims of public health are not overlooked.

CHRONIC PYELITIS IN CHILDREN.

MUCH attention has been devoted in recent years to the chronic infections of the urinary tract in children. The occasional occurrence of a valve in the posterior urethra of boys, for example, which has been noted by many observers, suggests that congenital abnormalities should be looked for in chronic cases resisting treatment. In a recent article[1] P. György mentions that this particular deformity was described by Englisch in 1875, a fact which appears to have been ignored by recent writers. György goes on to discuss the causation of chronic pyelitis, quoting cases which have confirmed his view that chronic pyelitis is a serious disease and, if untreated, may well lead to severe affection of the kidney and even uræmia. In nearly all resistant cases some congenital abnormality or interference with the neuromuscular mechanism of the ureters, bladder, or urethra with their sphincters is present. Just as in cases of enlarged prostate in adults deficient renal function may be restored to normal after removal of the cause of obstruction, so treatment of an obvious deformity in the urinary tract in the chronic pyelitis of children is well worth while, even if evidence of impairment of renal function is present. The five cases described by György, however, must be regarded as due to defective neuromuscular mechanism since no congenital deformity could be found to account for the dilatation of the ureters. That many of the older theories with regard to the ætiology of pyelitis can no longer be accepted is brought out by I. Robertson in a plea[2] for further investigation of the pyelitis of infancy. He points out that the theories of infection by upward spread, by the general circulation, or by direct spread from the bowel are none of them satisfactory from the pathological standpoint. The belief that pyelitis is much more common in girls than in boys is not, according to Robertson, altogether borne out by evidence from post-mortem figures, but since pyelitis tends to be more serious in boys than in girls, autopsies may not give a fair indication of sex incidence. In infancy, however, the mortality among girls is certainly not lower than that among boys. Of 105 cases of pyelitis in infants at the Harriet Lane Home, the death-rate is given as 60 per cent. girls and 40 per cent. boys. Dr. Robertson is inclined to believe that the symptoms of many cases of pyelitis are due to a focal suppurative nephritis. The subject needs more attention, for the association between pyelitis and inflammation of other sections of the urinary tract remains obscure. A large series of pyelograms might help to throw some light on the ætiology of the condition, and since they also may provide some guidance to treatment, they should be taken in all intractable cases of chronic pyelitis.

THE WHEATLEY MEMORIAL.

James Wheatley had a vivid and noble conception of the health service, and his recent death was a loss to public medicine which it may be hard to make good. He was frankly concerned less with the care of sick and abnormal persons than with work which tends to improve the vitality of the ordinary individual. Open-air schools for subnormal children were to Wheatley just the prelude to open-air methods for the school population. The risk of a few accidents should not, he held, interfere with the health and vigorous development in body and mind of the people as a whole, and when he watched German children swimming in the Rhine he thought of the resulting improvement in their health and physique and not of the casualty list of accidentally drowned. Indoor swimming-baths he looked upon simply as places for teaching swimming and for amusement; in the utilisation of our rivers for bathing and open-air swimming he saw a great forward movement in public hygiene. It is therefore peculiarly fitting for his colleagues in the public health service to perpetuate Wheatley's memory by the provision of a floating swimming-bath on the river Severn near to the town of Shrewsbury, whose health was his lifelong care. From the further side of the raft swimmers will have direct access to the river, while on the hither side there will be, pace Wheatley's gospel of living dangerously, a safe and sheltered bath for non-swimmers and children, with two screened lawns on the adjoining shore where men and women respectively can enjoy sun-bathing before and after entering the water. No charge will be made for admission to the lawns or dressing sheds, but a special pavilion is to be provided for those who can afford to make payment towards the upkeep of the bath. It is hoped by the promoters of the Wheatley Memorial that this bathing-place may become a model of its kind and extend further the influence of this great sanitarian in bettering the health of the people. The estimated cost is £2000, of which an anonymous donor has given £250; contributions may be sent to Dr. A. D. Symons, at 74, Wyle Cop, Shrewsbury.

INVESTIGATIONS ON PUERPERAL FEVER.

THE annual report of the Metropolitan Asylums Board for 1927–28 contains a valuable section on the investigations carried out on cases of puerperal fever admitted to their hospitals. The pathological side of this work is under the care of Dr. Leonard Colebrook. His report is in agreement with the views now generally held with regard to the causative organism of this disease—i.e., that nearly all severe cases of puerperal fever are due to infection by a hæmolytic streptococcus. In every fatal case investigated by him this organism was found and appeared to be the cause of death. A technique has been evolved by which the number of organisms present in the circulating blood can be estimated quantitatively. In fatal cases the number of streptococci per c.cm. of blood was found to increase in a more or less regular fashion until death, the number of organisms found in the blood varying between 5 and 5000 per c.cm. Only one patient survived in whom the number of streptococci exceeded 30; of those in whom the number was below 30, one-quarter lived. Contrary to the general views on the causation of rigors, the blood was often found to be sterile when rigors occur, repeated blood cultures proving negative. At the present time much attention is being directed to the association between the streptococcus of scarlet fever and the streptococcus of puerperal fever. Dr. Colebrook points out that there is one great difference between these two diseases. In scarlet fever the symptoms are the result of the action of an exo-toxin, whereas in puerperal fever the cause of the symptoms is the presence and proliferation of streptococci in the tissues and in the blood. He considers, therefore, that treatment of the two diseases should be on fundamentally different lines. In scarlet fever an antitoxin is required, whilst in puerperal fever antibacterial measures are called for. Post-mortem examinations revealed the fact that in most fatal cases gross septic foci were to be found in the uterine wall, broad ligaments, or pelvic cellular tissues, as well as infected clots in veins. It is difficult to see how any drug could reach such sites in sufficient concentration to be effective. Hope for the future appears to rest in early treatment by some efficient bactericidal agent. Four lines of treatment have been investigated: immuno-transfusion, passive immunisation by serums, intravenous administration of mercurochrome, and intravenous administration of organic arsenical preparations. In some of the patients who survived no specific treatment was carried out. Immuno-transfusion is now performed with whole blood. A preliminary leucocytosis is induced in the donor by the injection of nuclein. On the whole, the results have not been as good as had been hoped. If a high degree of immunity can be induced in the donor against the specific organism, better results may ensue. Various samples of serum from different laboratories have been tested. The result of this work is largely negative; very little increase in the bactericidal properties of human blood against hæmolytic streptococci was found. Mercurochrome was found to have no effect on the bactericidal power of the blood.

Arsenical drugs cause a marked increase in the bactericidal powers of the blood, and Dr. Colebrook considers this to be a most hopeful line for further investigation. Unfortunately the results obtained clinically do not confirm this optimism, since elsewhere in the report Mr. James Wyatt declares that the various organic arsenical preparations have had little or no effect on the course of the disease in cases of septicæmia. It is interesting to note that in 6 out of 22 cases operated upon for general peritonitis no vaginal examination had been made.

OBVIOUS AND OBSCURE INFECTIONS OF THE CENTRAL NERVOUS SYSTEM.

THE existence of epidemic diseases of the central nervous system is now well established, and the epidemic incidence of cerebro-spinal fever, poliomyelitis, and encephalitis has been memorable in the records of the first quarter of the twentieth century. In the George M. Kober Lecture, delivered on March 27th, 1928, at Georgetown University, Washington,[1] Dr. Simon Flexner reviews the history of these diseases and offers interesting comments on their ætiology and epidemiology. The large epidemic wave of cerebro-spinal fever which broke over Europe and America in 1904–05 and culminated in the pandemic of the war-period, appears to have spent its force and since 1920 the incidence of the disease has been endemic rather than epidemic. It is possible that emigrants from Germany and Austria conveyed the infection to the United States. The origin of epidemic poliomyelitis may be traced to north-western Europe—especially Sweden and Norway—and here again Dr. Flexner believes immigration to be responsible for the conveyance of infection. The first two outbreaks of poliomyelitis in the United States occurred on the eastern coast and in the States adjoining Minnesota, the western homeland of the Scandinavian emigrants. The outlook for this disease is less favourable than for epidemic meningitis. It arose in pandemic form in 1906–07; with many fluctuations epidemics have since recurred in Europe and the United States in late summer and autumn. In 1916 an unprecedented wave of poliomyelitis swept over New York State in which more than 20,000 cases were reported and many more cases, paralytic and non-paralytic, probably occurred. In 1926 outbreaks of some magnitude occurred in England and France, and in 1927 German Saxony, Roumania, and the United States were attacked. Epidemic encephalitis, the third disease which has reached epidemic proportions in the present century, can be traced back to two relatively small outbreaks during the war, one at Bar le Duc, in France, in 1916, the other in Vienna in 1917, which was well described by Economo. The extension of the disease was rapid. It appeared in England and Wales in 1918 and affected much of Europe. In 1919 cases were seen in the United States, and by 1920 the disease had become pandemic, whether permanently or not, Dr. Flexner is unprepared to say. He inclines to the view that epidemic encephalitis is of recent origin. The theory that it was confused in the past with other maladies does not appeal to him, not only because the clinical manifestations are very impressive, but because he considers that the after-effects are too severe and serious to have escaped incorporation into medical history. Dr. Flexner holds that meningitis and poliomyelitis may be dismissed from connexion with influenza since their epidemics arose independently. The epidemics of influenza and encephalitis certainly overlapped, but the height of the wave of encephalitis came several years after that of the influenza wave. He points out also that clinical cases of encephalitis were absent from the records of the pandemic of influenza of 1889–92. As to ætiology cerebro-spinal fever is due to the meningococcus, and the researches of Dr. Flexner and his collaborators at the Rockefeller Institute have demonstrated that poliomyelitis is due to a filter-passing virus. Epidemic encephalitis is probably due to a similar virus. Dr. Flexner reviews the work on the herpes virus and concludes that it is unlikely that simple herpes and epidemic encephalitis have a common ætiology. Accumulated evidence indicates that all these nervous epidemics are man-borne infections spread chiefly by way of the respiratory tract. Dr. Flexner expresses no definite opinion on post-vaccinal encephalitis, holding that its exact ætiology is still obscure.

PURER RIVERS.

THE first report of the Joint Advisory Committee on River Pollution is a businesslike and unanimous document. The law, it seems, is not inadequate to prevent contamination, but the law is not enforced. Serious and avoidable pollution exists, says the Committee, partly because the jurisdiction of the various administrative authorities is confined to a particular area only, partly because the bodies which ought to enforce the law have a number of other more pressing duties to discharge, and partly because the game-keepers are also poachers. The prevention of pollution should be in the hands of an authority exercising jurisdiction over the river as a whole (including its tributaries) at any rate so far as non-tidal waters are concerned. The creation of rivers boards or joint committees for this purpose is already possible under the existing law. Under Section 14 of the Local Government Act of 1888, the Ministry of Health can set up such bodies by Provisional Order on the application of the county councils and county borough councils concerned. The report recommends that this existing provision be specially brought to the notice of all these councils. There is reason to believe that the necessary applications to the Ministry of Health would then in many cases be made, and an important step would have been taken towards the ideal of purer rivers. The rivers Thames and Lee are controlled by special statutory Conservancy Boards with which the report does not propose to interfere. The powers of these two bodies, so vital to the water-supply of the metropolis, are already greater than the ordinary powers given by the River Pollution Acts. Indeed the methods employed by the Metropolitan Water Board for treating Thames water have, both in respect of finance and purification, been so successful as to encourage recourse to river water for domestic supply, and have been officially praised in the recent annual report of the Ministry of Health. Elsewhere, it is recommended, the Rivers Board areas should be big enough to make sure that skilled officers can be employed, and not so big as to make it impossible for the chief officers to keep themselves thoroughly informed of the existence of any pollution and the best means of prevention. Since effluents and local conditions vary, the problem is best dealt with by local effort, though central research must be pressed forward and results made generally available. The report is evidently impressed by the efficiency and economy of the three group-bodies which are already at work—the Ribble Joint Committee, the Mersey and Irwell Joint Committee, and the West Riding of Yorkshire Rivers Board. Though these bodies have power to take legal proceedings against offenders, legal process apparently is resorted to only in extreme cases. In most instances, advice and persuasion are found effective, and it seems to be happily the fact that the relations between the Rivers Boards, fishery boards, local authorities, and manufacturers are cordial and mutually helpful. It is obvious that this is not the time when Parliament can be asked to pass fresh legislation which may place further burdens upon industry. The figures of cost for efficient treatment of sewage in particular districts are sometimes extraordinarily high. Nevertheless, it is reassuring to find that much can be done under the existing law, that needless, wilful, and remediable pollution can be prevented without interfering with hard-pressed industries, and that there is evidence of a keener popular interest in the purity of our rivers than heretofore. Wider changes in the law and a more closely coördinated study of the problems of river purity, land drainage, and water power resources may come some day. Meanwhile the Joint Advisory Committee makes some simple proposals which can be tackled forthwith. As appointed by the Ministries of Health and of Agriculture and Fisheries, the Committee is fully representative of local authorities, water and rivers boards, and the manufacturing, fishing, and agricultural interests. Its report carries the greater weight on this account, especially as it has achieved unanimity.

THE PATHOGENY OF ANGINA PECTORIS.

ANGINA has always been somewhat of a stumbling block to the morbid anatomist, the autopsy findings are so varied and at times so inadequate. A number of distinguished physicians, including Allbutt in this country, Vaquez in France, and Wenckebach in Vienna, have found in aortitis an explanation of the symptoms, but aortitis could only act by producing a temporary rise in blood pressure during the attack—an assumption which is by no means proved. Mackenzie's theory that the pain is attributable to exhaustion of the heart muscle is also unsatisfactory. Anatomical evidence in many cases is in favour of coronary disease being the determining factor, but this is not invariably present, and in recent years there has been a tendency to abandon the anatomical in favour of a physiological explanation which will account for the varied post-mortem findings. The evidence in support of the physiological hypothesis that angina is due to anoxæmia of the heart muscle is well presented in a recent paper by C. S. Keefer and W. H. Reznik,* who, following Heberden's original description, define angina as a condition characterised by pain of a paroxysmal nature provoked by an increase and relieved by a diminution in the demand made upon the heart. They add that the diagnosis of angina should always imply the likelihood of sudden death. The similarity of the pain in angina to that in intermittent claudication, as well as the experimental evidence that voluntary muscles which are made to contract when their blood-supply is defective are easily fatigued, and that the contraction is accompanied by pain, strongly supports this hypothesis. Further, it is well known that anoxæmia is an important predisposing cause of ventricular fibrillation. This fact will account for the frequency with which sudden death is liable to occur in these cases. In affording an explanation of the persistence of the pain in coronary thrombosis the physiological hypothesis is equally satisfactory; for in that condition, unless the anastomoses be sufficient to compensate for the occluded artery, the anoxæmia is permanent and leads to infarction.

THE PARATHYROIDS AND BONE UNION.

MUCH attention has been paid of late to the significance of the parathyroids in metabolism, but experimental work has not yet thrown much light on clinical application. The work of Collip [1] and others has demonstrated that an extract can be obtained from these glands which can overcome the syndrome of tetania parathyreopriva with its attendant low blood calcium. The injection of active parathyroid extracts may in animals even lead to fatal results accompanied by very high blood-calcium values. The older observation of Koch [2] that methylguanidine appears in the urine of parathyroidectomised dogs, and of Paton [3] and his co-workers that the injection of guanidine and methyl-guanidine in animals leads to tetany-like symptoms gave rise to the theory that the parathyroids formed a part of the detoxicating mechanism of the body. The view more generally held to-day is that the parathyroids exert some at present unknown influence on calcium metabolism. Efforts have consequently been made to work out their relationship to bone metabolism, particularly from the clinical aspect of the healing of fractures. It was as long ago as 1907 that Erdheim [4] first reported experiments on rats which showed that, as a result of parathyroidectomy, the teeth lost their yellow transparent appearance, and became white and opaque. He noted also that there was a diminished and delayed deposition of calcium in the dentine, and that the enamel was decreased or thin or lacking. Hohlbaum [5] and others confirmed these results as well as Erdheim's further contention that reimplantation of the glands restored the teeth to normal. Other observations of Erdheim's,[6] however, to the effect that parathyroidectomy caused delay in the healing of fractures were not substantiated by Hohlbaum, or by Jovane and Vaglio,[7] or by Korenchewsky.[8] The latter pointed out that Erdheim's experiments were vitiated by lack of dietary control. Other workers, however, have supported Erdheim's conclusions. Ogawa,[9] for instance, investigated the relation of these glands to the healing of fractures, and reported that union was slower after their removal. Dieterich [10] also found that this operation delayed callus formation, though X ray and histological examination proved that otherwise the process was normal in every respect. Morel [11] found in cats a marked retardation in the formation of callus after parathyroidectomy, but only in young animals and not in adults.

---

* Arch. Intern. Med., 1928, xli., 770.

More recent work has, however, called in question some of the older experiments. Gates and Grant (1927)[12] have demonstrated fairly conclusively that subtotal removal of the parathyroids creates a deficiency which is rapidly compensated by hypertrophy of the remaining tissue, and that the blood calcium is restored to normal in a week to ten days. Anything short of complete removal therefore is not a reliable test of under-function of the tissue after this period of time. Until recently few observations have been made as to the effect of parathyroid extracts on the metabolism of bone, apart from scattered statements in the literature referring to its use in abnormal cases. There is some doubt, however, as to the activity of the extracts employed in these cases, for it is only since Collip isolated the active principle of the gland that definitely active preparations have been available. Morel, however, in 1909, claimed that subcutaneous injections of a parathyroid extract in young animals produced bones of twice the thickness of those in controls, regardless of the amount of calcium in the food. Recent experiments with Collip's extract do not support his work. Fine and Brown, working at Harvard, have published [13] the results of their experiments on bone repair under the influence of the extract, and their conclusions are in startling contrast to Morel's. They conclude that the clinical use of the extract for delayed bone union is not based on any sound principle, can do little if any good, and in fact may do harm. The number of their experiments, however, was small. The whole question of the relationship of the parathyroids to bone metabolism is still sub judice, and requires more extensive research before any definite conclusions can be arrived at.

STANDARDS OF ATMOSPHERIC POLLUTION.

IN the thirteenth report of the Advisory Committee on Atmospheric Pollution, to which reference has already been made, there is an interesting suggestion of the possibility of setting up limits or standards of permissible pollution. In the report the cities have been classified according to a scale of increasing pollution into four classes—A, B, C, and D. A table for the years 1914–15 to 1926–27 indicates a tendency towards improvement in many places, but unfortunately this improvement, as we have pointed out, is rather in the moderately clean than in the very dirty cities, which show little change. The important point is, however, that a step has been taken towards setting up some standard of clean air. The places classified *A* may be called clean, while the *D's* are certainly dirty. With the information now becoming available it should shortly be possible to take a most important step from a public health point of view—namely, to set up a standard of clean air, a condition of the air of a city which is to be aimed at and is reasonably attainable. So far only a standard for deposited impurity has been suggested; the limits of permissible suspended dust still remain to be fixed. Those who are engaged with these standards would find their work simplified if reliable information could be obtained as to the minimum requirements of sunlight, and especially of ultra-violet light, for healthy living. This would be a first step towards fixing limits of smoke pollution which could not be exceeded without detriment to the health of a city.

DARWIN'S KENTISH HOME.

AN announcement made at a meeting of the General Committee of the British Association in Glasgow in respect of the destination of Down House, Darwin's home in the county of Kent, is of real interest to the medical profession, when we remember the fundamental revolution in our philosophy and endeavour that has followed upon Darwin's work. Mr. Buckston Browne having acquired the property from Prof. Charles Galton Darwin, F.R.S., grandson of the great naturalist, has transferred its possession to the British Association under the most liberal conditions, and with an endowment for its maintenance and preservation. Mr. Buckston Browne's public spirit and generosity which have before now obtained publicity in spite of his retiring manner of doing good, are marked, as on the previous occasions, by conditions which are calculated to extract from his open-handed action the fullest benefit. He has assured the Council that he will make himself immediately responsible for the whole gift, and that while a committee will have to consider the details, he will also furnish an endowment fund, bringing his donation up to the splendid sum of from £12,000 to £15,000. Sir Arthur Keith, President of the General Committee of the Association, has suggested that out of the endowment fund money should be expended upon the foundation of a prize to be given every second year for the best contribution to biological knowledge, to be awarded by the Council, and to be known as the "George Buckston Browne Prize." For the moment Down House serves as a private school, but as soon as the property can become an effective gift to the nation Mr. Buckston Browne desires the house to be open every day of the week between the hours of 10 and 6 without charge, while the grounds of the house, which are of considerable extent, he intends should be employed for the benefit of science. Further, certain of the rooms in the house, particularly that in which so much of the "Origin of Species" was written, he proposes should be furnished as nearly as possible in accordance with their old appearance, and already this project is in process of fulfilment through the cordial help of the Darwin family, without which, it should be said, the new ownership of the property could not have been obtained. Charles Darwin's study chair and his machine for the weighing of letters and parcels have already been given by the late Mrs. Litchfield, a daughter of Charles Darwin, and the British Association is desirous of securing, for the transformation of the house into a veritable Darwin memorial, any articles known to have been in the possession formerly of Charles Darwin or to be associated with his literary work. Mr. Buckston Browne has commissioned the Hon. John Collier to paint replicas of the well-known portraits of Darwin and Huxley, and when the shelves of the old study are filled with all the editions of Darwin's works and the collections of original documents pertaining to these works, Down House will become a centre of research into the origin and development of the greatest intellectual movement the world has ever seen. The association of Down House with Charles Darwin and his family is extremely close. The property was presented to him by his father in 1842, three years after his marriage. His two elder children were born before the arrival at Down, but Mrs. Litchfield, and the four distinguished sons, George, Francis, Leonard, and Horace, were born at Down House. Charles Darwin died exactly 40 years after taking up his residence, in the seventy-fourth year of his age. There has probably never been one house associated with such a record of live and permanent work, brilliant in its scientific aspect and limitless in its power for good.

SAFETY AND HEALTH IN INDUSTRY.

Several points of interest to safety and health are presented in the latest annual report of the Chief Inspector of Factories.[1] First, reference is made to the opening of the Home Office Museum in Westminster where examples of good practice in safety appliances and hygienic environment are displayed. Next stress is laid on efforts to extend safety-first organisations throughout factories with workmen's committees and safety supervisors. Examples are given of excellent results attained and much expense on account of accident compensation saved. Attention in the section devoted to purely medical matters is directed to the Lead Paint (Protection against Poisoning) Act, 1926, under which the house painter is now protected. Information was received of 98 cases of lead poisoning among these painters with 21 deaths, as compared with 249 cases in all other industries with 14 deaths. Clearly the case fatality is much higher among painters. The long fight in the potteries against plumbism is being rewarded; last year only 14 cases with six fatalities occurred, compared with 78 cases in 1910 with 11 deaths. The extended use of low solubility glaze is held to be largely responsible; among 554 workers using this glaze, not one was found with signs of lead poisoning. But lead is being replaced as an occupational risk by skin troubles and particularly by epitheliomata which again accounted for 49 deaths. Pitch and tar are great offenders and caused 48 cases with 6 deaths; here periodical medical examinations to detect warts early are of the utmost value; one surgeon gives all early cases radium and only one case out of 56 has so resisted treatment as to require excision. But the chief instigator has been mineral oil which claimed 101 cases among mule-spinners with 31 deaths; preventive measures among these men have not been in force sufficiently long to be effective. Dermatitis of all kinds continues to demand attention; 525 cases were referred for inquiry. Of these, 13·7 per cent. were due to alkalies; 11·2 were due to oil, chiefly oil acne among engineers; dyes, acids, sugars, and turpentines each accounted for over 6 per cent.; french polish and paraffin each claimed over 5 per cent.; bakers' dough 4 per cent.; and accelerators of rubber 3·6 per cent. Another rival for first place among occupational risks is dust; here that composed of silica attracts particular attention on account of its slow, but specific, toxic action. Fortunately in the metal grinding industry, abrasive wheels, made of carborundum, are replacing sandstones; this change is being accelerated by granting to grinders compensation for silicosis. An inquiry among 1011 cotton weavers disclosed 6·7 per cent. had noise deafness, and 19·4 per cent. of those who had worked for 21 years and over. An important first-aid order was made prescribing a grade or quality for all materials for dressings used in factories. Reviewing the report as a whole it displays throughout a greatly improved and still improving hygienic environment throughout our industries.

HYPERTONIC SALT SOLUTION FOR GLAUCOMA.

In recent years much stress has been laid on osmosis occurring between the capillaries and the aqueous humour as a factor in the maintenance of normal intraocular pressure and in the pathogenesis of glaucoma. In 1926 W. S. Duke-Elder published experiments proving that intraocular tension can be temporarily lowered by the slow intravenous injection of a hypertonic solution of salt into the general circulation, and advocated this procedure in certain cases of glaucoma as a temporary measure to reduce tension prior to operation. This method had already been tried with success in four cases at Moorfield's Hospital. In the report of the Madras Government Ophthalmic Hospital for 1927, edited by Lieut.-Colonel R. E. Wright,[1] there is further evidence bearing on the subject. A series of 20 cases of glaucoma patients were taken without selection, so far as the variety of glaucoma was concerned. Their body-weight, blood pressure, intraocular tension, and a sample of blood were taken before saline injection, and again at intervals afterwards. The hypertonic solution was injected slowly into a vein of the arm—30 g. per 100 c.cm. of sodium chloride, the dose given being in most cases 20 c.cm., which worked out to an average of 0·134 g. of sodium chloride per kilogram of body-weight. Within 15 minutes of giving the injection the average fall of intraocular tension was from 46·7 to 34·2, and this fall was maintained with slight variations for 24 hours. The writer concludes that therapeutically the injection of strong sodium chloride solution is a valuable means of lowering the intraocular tension, effective in the great majority of cases, and especially valuable as a preoperative procedure; but cautiously adds that it remains to be shown whether the fall in intraocular tension is more closely connected with the osmotic pressure or with other changes in the constitution of the blood. Lieut.-Colonel Wright's conclusions are much the same as Mr. Duke-Elder's.[2] The main danger, according to the latter authority, is a sudden fall in the blood pressure which may occur during the injection, but this is obviated if the injection is made slowly and regularly, with a patient in the recumbent position.

The Clinical Congress of the American College of Surgeons is held in Boston this year from Oct. 8th to Oct. 12th. The Hunterian Oration of the College will be delivered by the Editor of The Lancet, Sir Squire Sprigge, upon whom the Honorary Fellowship of the College will be conferred.

University College Hospital.—The annual dinner of past and present students in this the centenary year of the Medical School will be held at the Hotel Cecil, London, W.C., on Oct. 12th, at 7 P.M. The chair will be taken by Surgeon Vice-Admiral Gaskell, Medical Director-General of the Navy. Tickets may be had on application to the hon. secs. at the Medical School.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

III.—REPORTS ON SWABS FROM THE THROAT AND NASAL PASSAGES.

By J. E. McCartney, M.D., Ch.B., D.Sc.,
DIRECTOR OF RESEARCH AND PATHOLOGICAL SERVICES, METROPOLITAN ASYLUMS BOARD.

(2) Cases not Suspected of Diphtheria.

Spirochætes and Fusiform Bacilli.

The examination of a direct smear of the swab after staining with dilute carbol-fuchsin or methyl-violet will determine or negative the presence of Vincent's angina. Microscopically, numerous large fusiform bacilli with pointed ends, together with spirochætes aving wide irregular coils, may be found, and this is ufficient for a diagnosis. It must be remembered hat Vincent's angina and true diphtheria may occur gether and that an immediate report of Vincent's ngina does not exclude the possibility that diphtheria may be present as well. In the laboratory all throat swabs are cultured and examined for diphtheria bacilli as a routine, irrespective of the direct examination, so there is no danger of the more serious disease of diphtheria being overlooked.

Hæmolytic Streptococci.

Throat swabs are sometimes sent to the laboratory to ascertain if hæmolytic streptococci are present in cases of convalescent scarlet fever patients ready for discharge. Although the hæmolytic streptococcus plays an important part in scarlet fever, the presence of these organisms does not mean that the patient is capable of transmitting the disease, or that the streptococci found are necessarily the cause of the illness. Over one-half of convalescent scarlet fever patients still harbour hæmolytic streptococci on discharge. Although certain strains of hæmolytic streptococci isolated from early cases of scarlet fever do fall into certain serological types, yet the whole group of hæmolytic streptococci are so closely interrelated that it is not possible to identify any one type or types as the cause of scarlet fever. Therefore a positive report of hæmolytic streptococci present in scarlet fever does not have the same significance as a positive report of diphtheria bacilli in convalescent diphtheria, and does not mean that the patient is necessarily infective or that he must be kept isolated. The release from quarantine of recovered scarlet fever cases must be determined solely from the consideration of the patient by the physician and not with reference to the laboratory report, although, of course, a negative result in such cases is of great assistance in arriving at a decision.

Meningococci.

In the usual examination of a throat swab, meningococci are not specially looked for. If, however, there s an epidemic, or cases of meningitis are occurring at he time, the bacteriologist will pay special attention to the Gram-negative group of cocci found in the nasopharynx and throat, and will usually determine or exclude the presence of meningococci without being definitely asked to do so. Special laboratory tests extending over several days are necessary to isolate meningococci; if they are found to be present the patient must be regarded as a meningococcus carrier and treated accordingly.

In examining for meningococcus carriers it is not advisable for the practitioner to take a throat or postnasal swab and send it to the laboratory; the bacteriologist should be asked to take the swab himself. In the first place special postnasal swabs such as West's swabs should be employed, and secondly, owing to the feeble vitality of the organism outside the body, it is necessary to inoculate the appropriate medium immediately, and to incubate it without delay, or to keep it warm until it can be placed in the incubator. Unless these precautions are taken no reliance can be placed on a negative report. Three successive negative reports are necessary before a known carrier can be considered free of infection.

The Normal and Pathological Flora of the Tonsils and Upper Respiratory Tract.

When considering the organisms present in cases of catarrh or other inflammatory conditions of the throat the normal flora must first be considered. In normal healthy children the commonest throat organisms are the "viridans" type of streptococcus, and Gram-negative cocci of the *Micrococcus catarrhalis* group, which are almost constantly met with. In addition, a few colonies of both α and β hæmolytic streptococci, together with some colonies of staphylococcus albus, are usually present. Occasionally Friedländer's bacillus and the pneumococcus are noted. In inflammatory conditions of the throat, however, the flora becomes very much more numerous, and certain organisms, rarely or never met with normally, such as pneumococci, *Staphylococcus aureus*, hæmophylic bacteria of the *B. influenzæ* type, and diphtheroids may predominate, while hæmolytic streptococci may be very abundant.

In cultures from the throat of the healthy child the growth of organisms is not great, and the number of bacteria present in the throat secretion is comparatively small. In his report the bacteriologist will indicate the predominating organism and the relative frequency. Reports such as the following indicate that there is an abnormal change in the flora of the throat, and that the condition requires attention by the practitioner.

(*a*) "Cultures show an abundant growth of an almost pure culture of pneumococci."

While pneumonia is usually due to the pneumococcus, such a report does not necessarily indicate that the patient either has, or will develop pneumonia. A pneumococcal infection of the throat or trachea ma be present, but in young children the possibility pneumonia must not be overlooked. Careful attentio should be directed towards the chest, and the possibl spread of infection down the respiratory tract must be kept in mind.

(*b*) "Very numerous colonies of hæmolytic streptococci present."

Here attention should be paid to the tonsils as the likely site of the infection.

(*c*) "Numerous colonies of *B. influenzæ* developed on blood-agar."

This report does not necessarily mean that the case is true influenza, since the precise cause of epidemic influenza has not yet been determined. *B. influenzæ* is met with in catarrhal conditions of the respiratory tract apart altogether from this condition.

(*d*) "Cultures show an abundant growth of organisms comprising hæmolytic streptococci, pneumococci, *M. catarrhalis*, and *Staphylococcus aureus*."

These findings are usually noted in cases of sore-throat and "colds."

On the other hand, a report such as—

"In direct films very few organisms could be found. In cultures a few colonies of *M. catarrhalis* and *Staphylococcus albus*, together with an occasional colony of *Streptococcus viridans* developed"

indicates that the flora is normal and that the throat is healthy.

Septic Foci in the Rheumatic Diseases.

Chronic Catarrhal Conditions of the Nose and Throat.—In these cases, particularly if involvement of the sinuses is suspected, swabs should be taken from the nose as well as from the throat, while a swab from the nasopharynx should also be forwarded if possible. This latter may be obtained by bending the wire of the swab at an angle and passing the end of the swab behind the soft palate into the naso-pharynx. The operation is facilitated if the patient be asked to phonate during the process. Vaccines are often of use in these conditions, particularly when one type of organism predominates. but failures are not uncommon.

Septic Tonsils.—Swabs from the tonsil are sometimes sent to the laboratory with a request for information as to whether the tonsils should be removed or not. Such a problem as this is outside the domain of the bacteriologist. He can state what organisms are present and their relative abundance in the material submitted; he may indicate whether such findings are abnormal, but beyond that he can give no help. He does not know how the swab was taken—whether from the surface of the tonsils or from the crypts. The report of the bacteriologist may assist the practitioner in arriving at a decision for or against tonsillectomy, but this must be reached mainly on clinical grounds.

The laboratory worker is frequently asked to give information regarding certain clinical conditions merely from the bacteriological examination of a throat swab, and it is opportune here to indicate the limitations of the information which can be supplied.

Acute Rheumatism.—Clinical experience suggests a connexion between rheumatic conditions in children and an abnormal state of the tonsils. At present it is not possible to state definitely what the causal organism of rheumatism is. A non-hæmolytic streptococcus has been thought by some observers to be responsible, but the isolation of such an organism from the tonsils has no special significance, since non-hæmolytic streptococci are almost invariably present in all throats, and, moreover, the non-hæmolytic cocci from rheumatic cases are indistinguishable by ordinary methods from similar organisms obtained from non-rheumatic conditions or healthy individuals.

Chronic Rheumatism and Rheumatoid Arthritis.—On the assumption that these conditions are due to a septic focus, often in the nose or throat, swabs are sometimes sent to the bacteriologist in order that he may isolate the offending organism and prepare a vaccine. Here again no one organism can be said to be responsible, and while some workers claim that certain types of streptococci are the cause of these conditions, nothing is definitely proved. A vaccine prepared from a certain organism may be beneficial to the patient, while the same organism may be present in a second case, and a similar vaccine be of no value. Some cases of chronic rheumatism do respond to vaccine treatment, but there are many others, apparently similar clinically, in which no benefit can be derived, even after a course of vaccines prepared from a number of organisms isolated from the nose, throat, or teeth. The practitioner therefore should realise: (*a*) that there is no one organism responsible for chronic rheumatism, or rheumatoid joint conditions; (*b*) that a vaccine or succession of vaccines prepared from cultures of a throat swab may fail to benefit the condition.

CONCLUSION.

In conclusion, it is urged that a greater coöperation should be maintained between the physician and the bacteriologist. The latter should be afforded full information as to the nature and source of the material submitted, and in turn he will be able to give the clinician more assistance in the diagnosis and conduct of the case.

GOLDEN-SQUARE, THROAT, NOSE AND EAR HOSPITAL. This hospital, which is within easy reach of Piccadilly-circus, is about to open 20 pay beds. These will be available at a moderate weekly charge, plus a fee to the surgeon, for those patients who are not eligible for admission to the general wards, but who are nevertheless unable to meet the expenses of a nursing home. A prospectus relating to the private rooms will be sent on application to the Secretary-Superintendent.

Special Articles.

AN OUTBREAK OF BACTERIAL FOOD POISONING.

BY JOHN McGARRITY, M.D. EDIN., D.P.H.,
MEDICAL SUPERINTENDENT, ISOLATION HOSPITAL, CARDIFF;
C. J. McSWEENEY, M.B. N.U.I., D.P.H.,
DEPUTY MEDICAL OFFICER OF HEALTH, CARDIFF;
AND
JOHN H. SUGDEN, M.Sc., F.I.C.,
CHEMIST AND BACTERIOLOGIST, CARDIFF AND COUNTY PUBLIC HEALTH LABORATORY.

DURING the night of Tuesday, August 16th, 1927, and throughout the 17th and 18th, 12 nurses, 1 maid, and 25 patients in a hospital were suddenly seized with vomiting, abdominal pain, and diarrhœa, usually accompanied by fever and preceded in many cases by headache, shivering, and aching pains throughout the body. The symptoms were in all respects typical of food poisoning, and in most cases lasted for three or four days, gradually abating. In a few instances the green stools persisted for about ten days. Onset occurred in the case of the nurses during the night and early morning of August 16th–17th and of the patients during the 17th and 18th. The sudden and simultaneous sickening of several people with these symptoms made a diagnosis of food poisoning almost certain.

The Infecting Agent.

The Particular Food Implicated and the General Distribution of the Outbreak.—On investigation it was found that the only item of food common to all those affected was minced meat—cooked meat minced and cooked a second time. Most of the nurses and maids in the hospital, who, it should be noted, have no food in the wards, had partaken of this minced meat for supper on Monday evening, August 15th, in the form of shepherd's pie. Of the 18 day nurses 12 were affected and three of the six who were unaffected did not have mince. Only one maid had mild symptoms. The sisters had no mince and escaped. Of the 56 patients in the wards 25 were affected; 21 of them had the same mince on Monday, August 15th, and Tuesday, the 16th, at the midday meal, while four had gravy from the same meat. Only one ward inmate who consumed the mince and two who took the gravy escaped. In all cases where symptoms arose the food had been last taken within about 24 to 36 hours previously. The meat, as originally cooked and served hot, was consumed by almost all the hospital staff without untoward effect. Also, no effects followed the eating of the same meat served cold. It was not until this meat was served in the form of mince or gravy that symptoms of food poisoning followed. The high percentage of infection of the ward inmates and day nurses will be noted, in contrast with the immunity of the night nurses and maids.

Composition of the Mince.—Unfortunately none of the mince was available for bacteriological examination when the outbreak was discovered. The utensils which had contained it had also been cleaned more than once. The chief constituent of the minced meat was beef brought to the hospital on Saturday, August 13th. There was also some lamb and salted beef. The beef and lamb were first roasted, and a portion of each consumed hot; a portion was also eaten cold later. The portions that remained were minced, a few scraps of salt beef being added during the mincing, and the mince, so constituted, was served with gravy to the children at midday on Monday, August 15th. The same mince was eaten by the nurses and maids that night for supper. Some of the mince was again served with gravy to some of the children on Tuesday. So far as was known no old scraps of meat of any kind were incorporated in the mince by the cooks.

Contamination of the Meat.—The beef, from which the mince was almost entirely derived, was traced back to a live beast reared at a local farm. The beast was healthy, and its flesh gave no sign of disease post m[illegible] in the public abattoir, conveya[illegible] butcher's premises, and in the [illegible] handling and preparation generally were carried out under conditions unfavourable to casual contamination. Other portions of the carcass were sold retail to the public without causing any illness which could be traced by the most careful inquiry. It must be remembered, however, that odd scraps of mutton and salted beef were thrown into the mincer and their varied origins were untraceable.

Possibilities of Infection in the Hospital from Human Sources.

J. M., a porter, had diarrhœa during the night of August 11th–12th. This continued for several days, but was not sufficient to cause him to go off duty. He lived in the lodge with his wife and had his meals there. His meat-supply was from a different source. This man was supposed not to get any food from the hospital supply, but he visited the kitchen precincts to help to carry the food to the wards. He had not eaten any of the mince, and, in any case, this was not made until some days after he was taken ill. The porter's symptoms started before the meat—making up the bulk of the mince—was actually delivered to the hospital, and they occurred some days previous to the outbreak among the staff and patients. The bacterial and serological findings in his connexion will be discussed later.

O. M., a nurse, was warded on August 4th as a suspected case of influenza or typhoid fever. She had symptoms closely resembling those observed in the outbreak. The fæces and blood, however, were subsequently found negative to all tests.

W. F., a nurse, was warded on August 14th. She had similar symptoms, which began with vomiting on Saturday evening, August 13th. She had not eaten any of the suspect mince and yet her blood showed a weakly positive reaction to *Bacillus aertrycke.*

Laboratory Investigation.

Epidemiologically and clinically the symptoms were in favour of an infection rather than an intoxication, and seemed to point to one of the Salmonella group of organisms. Specimens of fæces and vomited material were collected from several of the patients for examination at the Public Health Laboratory and similar samples were also sent to Dr. W. M. Scott at the laboratories of the Ministry of Health.

Laboratory Examinations at Cardiff.—On August 18th samples of stools were sent to the laboratory, collected from three of the patients—viz., A (M. P.), B (E. H.) and C (E. C.). Samples of vomit from three other patients—viz., D (M. C.), E (S. P.), and F (C. E.), were also submitted for examination. The only samples of food available which might possibly be regarded as associated with the outbreak were: (1) beef dripping, and (2) fish dripping. A bacteriological examination of these food samples for food-poisoning organisms gave negative results.

Examination of the Vomit.—Chemical examinations for preservatives and for arsenic or other poisonous metals gave negative results. From samples D and F a series of lactose bile-salt agar plate cultures gave non-lactose fermenting colonies in practically pure cultures. The fermentation characters and also the morphological and staining characters of several colonies from each of the samples were tested, and all conformed to those for food-poisoning organisms of the Salmonella group. Agglutination tests made with 24-hour agar cultures gave strong agglutination to a high dilution of *B. aertrycke* [illegible] approximating to t[illegible] *B. a*[illegible] (Mutton) used as a control. Negative results were given by cultures from both samples with standard *Bacillus enteritidis* Gaertner serum of an agglutinating titre of 100 units. The failure to isolate any food-poisoning organisms from sample E is probably to be attributed to the marked acidity of this sample.

Examination of Stools.—Samples A and B gave non-lactose fermenters, more numerous on plates after incubation with brilliant-green broth. Sample C gave negative results. A number of colonies isolated from samples A and B were fully examined, as in the case of samples D and F. The fermentation characters and also the agglutinating tests were identical with those obtained above. No absorption tests for specific organisms were made, but the results indicated a strong probability that the organism was of the *B. aertrycke* type.

Serological Tests.—On August 26th, allowing a period of ten days from the acute stage of the outbreak, a number of specimens of blood serum were collected from patients and staff. Specimens A, B, D, and F were from the patients M. P., E. H., M.C., and C. E. respectively, from whom a food-poisoning organism had previously been isolated. The sera were tested for agglutinating titre against the specific organisms and also with *B. aertrycke* (Mutton). The following were the highest dilutions showing marked agglutination:—

Serum.	Specific organism.	*B. aertrycke* (Mutton).
A	+1 in 500	+1 in 500
B	+1 in 500	+1 in 500
D	+1 in 1000	+1 in 500
F	+1 in 1000	+1 in 500

Samples of sera from two members of the staff gave weak reactions, but from three others negative results were obtained as follows:—

Serum.	Organism F.	*B. aertrycke* (Mutton).
No. 1 (J. M.), porter	+1 in 20	+1 in 20
No. 2 (W. F.), nurse	+1 in 100	+1 in 100
No. 3 (O. M.), "	−1 in 20	−1 in 20
No. 4 (E. F.), cook	−1 in 20	−1 in 20
No. 5 (E. W.), "	−1 in 20	−1 in 20

No absorption tests were made locally, but most of the above sera were examined at the laboratory of the Ministry of Health, and none showed any specific paratyphoid B agglutinin. The organisms isolated by us from cases A, B, D, and F, and also a culture of *B. aertrycke* (Mutton), were each tested for agglutination with a paratyphoid B serum up to a dilution of 1 in 1000. Organism A showed definite agglutination to 1 in 250, whilst organisms B, D, and F, and *B. aertrycke* agglutinated to 1 in 500 dilution.

Theories of Infection.

This outbreak is a good example of the difficulty often arising in tracing the origin of food poisoning even in what might appear at first sight to be the most favourable conditions. While it was possible to isolate the organism causing the infection, and to conclude from circumstantial evidence that the article of diet involved was minced meat, yet how the original meat or the mince became infected could not be determined. It is possible that the porter (J. M.) was infected from some outside source and casually contaminated the meat or mince, although no action of his could be traced which might account for the extensive contamination both of staff and patients' diets. His stools, examined rather late, were negative, but his blood was very weakly positive to *B. aertrycke.* The conduct of the institution made fly-contamination of the meat from the porter's stools or any other source unlikely, and inquiries in the district failed to reveal any cases in the households of persons supplied with the same meat as this porter. On the whole, he must be considered a very unlikely source of contamination. An interesting feature of the outbreak was that the maids of the hospital all had mince, but only one was affected, and that very slightly; neither did any of the night nurses suffer, and yet they all had the same minced meat as the day nurses. The suspect mince, however infected, was, of course, not served from one, but from several dishes. There was one dish for the day nurses, several small dishes for the night nurses, and one larger dish for the maids —all containing the mince in the form of shepherd's pie—while each ward had its own numbered dish containing ordinary minced meat and gravy. The mince may have become contaminated during mincing by the inclusion of infected portions of meat, these portions being localised in the dishes set apart for the day nurses and patients in the wards. The fact that scraps of salt beef and mutton were mixed with the wire of the swab at an angle and passing the end of the swab behind the soft palate into the naso-pharynx. The operation is facilitated if the patient be asked to phonate during the process. Vaccines are often of use in these conditions, particularly when one type of organism predominates, but failures are not uncommon.

Septic Tonsils.—Swabs from the tonsil are sometimes sent to the laboratory with a request for information as to whether the tonsils should be removed or not. Such a problem as this is outside the domain of the bacteriologist. He can state what organisms are present and their relative abundance in the material submitted; he may indicate whether such findings are abnormal, but beyond that he can give no help. He does not know how the swab was taken—whether from the surface of the tonsils or from the crypts. The report of the bacteriologist may assist the practitioner in arriving at a decision for or against tonsillectomy, but this must be reached mainly on clinical grounds.

The laboratory worker is frequently asked to give information regarding certain clinical conditions merely from the bacteriological examination of a throat swab, and it is opportune here to indicate the limitations of the information which can be supplied.

Acute Rheumatism.—Clinical experience suggests a connexion between rheumatic conditions in children and an abnormal state of the tonsils. At present it is not possible to state definitely what the causal organism of rheumatism is. A non-hæmolytic streptococcus has been thought by some observers to be responsible, but the isolation of such an organism from the tonsils has no special significance, since non-hæmolytic streptococci are almost invariably present in all throats, and, moreover, the non-hæmolytic cocci from rheumatic cases are indistinguishable by ordinary methods from similar organisms obtained from non-rheumatic conditions or healthy individuals.

Chronic Rheumatism and Rheumatoid Arthritis.—On the assumption that these conditions are due to a septic focus, often in the nose or throat, swabs are sometimes sent to the bacteriologist in order that he may isolate the offending organism and prepare a vaccine. Here again no one organism can be said to be responsible, and while some workers claim that certain types of streptococci are the cause of these conditions, nothing is definitely proved. A vaccine prepared from a certain organism may be beneficial to the patient, while the same organism may be present in a second case, and a similar vaccine be of no value. Some cases of chronic rheumatism do respond to vaccine treatment, but there are many others, apparently similar clinically, in which no benefit can be derived, even after a course of vaccines prepared from a number of organisms isolated from the nose, throat, or teeth. The practitioner therefore should realise: (*a*) that there is no one organism responsible for chronic rheumatism, or rheumatoid joint conditions; (*b*) that a vaccine or succession of vaccines prepared from cultures of a throat swab may fail to benefit the condition.

CONCLUSION.

In conclusion, it is urged that a greater coöperation should be maintained between the physician and the bacteriologist. The latter should be afforded full information as to the nature and source of the material submitted, and in turn he will be able to give the clinician more assistance in the diagnosis and conduct of the case.

GOLDEN-SQUARE, THROAT, NOSE AND EAR HOSPITAL. This hospital, which is within easy reach of Piccadilly-circus, is about to open 20 pay beds. These will be available at a moderate weekly charge, plus a fee to the surgeon, for those patients who are not eligible for admission to the general wards, but who are nevertheless unable to meet the expenses of a nursing home. A prospectus relating to the private rooms will be sent on application to the Secretary-Superintendent.

AN OUTBREAK OF BACTERIAL FOOD POISONING.

BY JOHN McGARRITY, M.D. EDIN., D.P.H.,
MEDICAL SUPERINTENDENT, ISOLATION HOSPITAL, CARDIFF;
C. J. McSWEENEY, M.B. N.U.I., D.P.H.,
DEPUTY MEDICAL OFFICER OF HEALTH, CARDIFF;
AND
JOHN H. SUGDEN, M.Sc., F.I.C.,
CHEMIST AND BACTERIOLOGIST, CARDIFF AND COUNTY PUBLIC HEALTH LABORATORY.

DURING the night of Tuesday, August 16th, 1927, and throughout the 17th and 18th, 12 nurses, 1 maid, and 25 patients in a hospital were suddenly seized with vomiting, abdominal pain, and diarrhœa, usually accompanied by fever and preceded in many cases by headache, shivering, and aching pains throughout the body. The symptoms were in all respects typical of food poisoning, and in most cases lasted for three or four days, gradually abating. In a few instances the green stools persisted for about ten days. Onset occurred in the case of the nurses during the night and early morning of August 16th–17th and of the patients during the 17th and 18th. The sudden and simultaneous sickening of several people with these symptoms made a diagnosis of food poisoning almost certain.

The Infecting Agent.

The Particular Food Implicated and the General Distribution of the Outbreak.—On investigation it was found that the only item of food common to all those affected was minced meat—cooked meat minced and cooked a second time. Most of the nurses and maids in the hospital, who, it should be noted, have no food in the wards, had partaken of this minced meat for supper on Monday evening, August 15th, in the form of shepherd's pie. Of the 18 day nurses 12 were affected and three of the six who were unaffected did not have mince. Only one maid had mild symptoms. The sisters had no mince and escaped. Of the 56 patients in the wards 25 were affected; 21 of them had the same mince on Monday, August 15th, and Tuesday, the 16th, at the midday meal, while four had gravy from the same meat. Only one ward inmate who consumed the mince and two who took the gravy escaped. In all cases where symptoms arose the food had been last taken within about 24 to 36 hours previously. The meat, as originally cooked and served hot, was consumed by almost all the hospital staff without untoward effect. Also, no effects followed the eating of the same meat served cold. It was not until this meat was served in the form of mince or gravy that symptoms of food poisoning followed. The high percentage of infection of the ward inmates and day nurses will be noted, in contrast with the immunity of the night nurses and maids.

Composition of the Mince.—Unfortunately none of the mince was available for bacteriological examination when the outbreak was discovered. The utensils which had contained it had also been cleaned more than once. The chief constituent of the minced meat was beef brought to the hospital on Saturday, August 13th. There was also some lamb and salted beef. The beef and lamb were first roasted, and a portion of each consumed hot; a portion was also eaten cold later. The portions that remained were minced, a few scraps of salt beef being added during the mincing, and the mince, so constituted, was served with gravy to the children at midday on Monday, August 15th. The same mince was eaten by the nurses and maids that night for supper. Some of the mince was again served with gravy to some of the children on Tuesday. So far as was known no old a better chance of maintaining themselves, and thus keeping out of the scope of the inquiry, but even so the number of old people is rather surprising. Table II., however, makes it clear that the proportion of the insane among the older epileptics is very much higher. Nearly half of those over 50 are insane, while the incidence of insanity in the whole group is less than one-quarter.

The Authorities Concerned.

Feeble-minded children between the ages of 5 and 16 come under the care of local education authorities; feeble-minded persons of 16 or over and all imbeciles or idiots of whatever age should come under the care of mental deficiency authorities. It appears therefore from Table II. that the mental deficiency authorities have, or should have, the responsibility for 271 or 37·3 per cent. of the total number, while the corresponding figure for authorities acting under the Lunacy Acts is 162, or 22·3 per cent. The remaining 293, or 40·4 per cent. of the whole, are independent of either of these authorities. In other words, nearly one-half of all the epileptics known to the public authorities are quite outside the provisions of the Mental Deficiency or Lunacy Acts. Of these 293 epileptics, 96 are children between the ages of 5 and 16. These should be dealt with by the local education authority, and educated, as the circumstances demand, at public elementary schools, day special schools, or residential special schools. For the remaining 197 the only authority competent to give assistance or treatment would appear to be the poor-law authority.

It has been stated above that the mental deficiency authorities have, or should have, the care of 271 of the series of epileptics, or 37·3 per cent. of the total number. As a matter of fact it is found that only 49 cases are under their care, of whom 19 are in institutions and 30 not in institutions. Of all patients certified under the Mental Deficiency Acts it is probable that epileptics stand more in need of institutional treatment than any other class, and it is remarkable that three-fifths of even this small group are allowed to remain at home. Three of the 49, being feeble-minded children of school age, should really come under the local education authority, leaving a balance of 46. Where and under whose care are the remaining 225 out of the total of 271? 112 of them, all imbeciles or idiots, are in public mental hospitals, where they constitute, indeed, nearly half of the epileptic population; 108 of them are maintained by poor-law authorities, 4 are returned by maternity and child welfare committees, and 1 over school age is reported as known to a local education authority. The 108 maintained by poor-law authorities are distributed as follows:—

In epileptic institutions	47
In poor-law institutions	24
In other institutions	15
On outdoor relief	18
Boarded out	4

It will be clear, therefore, that less than one-fifth of the epileptics who should come under the mental deficiency authorities are in fact dealt with by them; the remainder are maintained in approximately equal numbers either in lunatic asylums or by poor-law authorities. It is useless to expect any alteration in this state of affairs unless and until there is very substantial increase in residential accommodation provided by the mental deficiency authorities. There are 19 epileptic imbeciles or idiots of various ages and 30 feeble-minded epileptics above school age who are not in institutions. It is probable that there are few households that can cope adequately with mentally deficient epileptics, especially those of the lower grades.

It appears that 62 epileptics of varying mental grades are dealt with in general poor-law institutions or infirmaries. Where these institutions are large and a special ward can be allotted to epileptics the arrangement may be open to little objection. But in smaller institutions, where these patients have to share wards with other inmates, it would be more desirable from their own point of view and certainly from the point of view of others that other accommodation should be provided for them, either in appropriate hospitals under the lunacy or mental deficiency authorities, or in epileptic colonies.

Children of School Age.

There are 124 children of school age in the series, of whom 67 are reported as mentally normal, 27 as feeble-minded, and 30 as of still lower grade of mental defect. Table III. shows the authorities who are dealing with these children and beside it a table showing how the children should be apportioned between the local education authority and mental deficiency authority.

TABLE III.

	Distribution.	
	Present	Suggested.
Local education authority	86	94
Mental deficiency authority	16	30
Mental hospitals	9	—
Poor-law authority	13	—

Of the 94 children who should be attending school there are:—

At elementary schools	46 (48·9 %)
At residential schools for epileptics	19 (20·2 %)
In other institutions	5 (5·3 %)
Boarded out	1 (1·1 %)
At no school or institution	23 (24·5 %)

(Of the 23 children at no school or institution 14 are mentally normal and 9 are feeble-minded.)

Conclusions.

It has been stated above that, including war pensioners, it is estimated that there are 781 epileptics known to public authorities in Surrey. If from this total of 781 we deduct 154 epileptics who are not in institutions and not in receipt of outdoor relief the balance of 627 should represent the number who are chargeable in one form or another to public authorities. This total of 627 is equivalent to 0·65 per 1000 of the population of Surrey (including Croydon).

Assuming the incidence of epilepsy to be the same throughout the country a ratio of 0·65 per 1000 of the population would give an approximate total of 25,000 epileptics chargeable to the public authorities of England and Wales. On the basis of Table II. above the age-groups and mental condition of these 25,000 would be as follows (Table IV.).

TABLE IV.

Mental condition.	Age-groups.			
	0–5	6–15	16–70 and over.	Total.
Mentally normal	277	2,498	6,475	9,250
Mentally defective or feeble-minded	90	990	3,420	4,500
Imbecile or idiot	172	1,035	4,543	5,750
Insane	—	—	5,500	5,500
Total	539	4,523	19,938	25,000

It may be suggested that the survey was made in an area in which the public authorities are unusually active and progressive, and that the figures for the whole country, could they be ascertained on similar lines, would be smaller. It is certainly true that within the county area there are three special institutions for epileptics—viz., one at Woodmansterne maintained by the Surrey Joint Poor-law Committee for sane female epileptics, a general epileptic colony at Lingfield, and the Meath Home for women and girls at Godalming. There is, however, no evidence that the incidence of epilepsy is likely to vary in different parts of the country, or that it bears any relation to industrial or economic conditions or to density of population. It is considered fair, therefore, to state that on the basis of the figures obtained by this inquiry, the number of epileptics chargeable to the meat during mincing confuses the picture. These portions may have carried the infection and accounted for its random distribution. None of these had done any damage when consumed in the freshly cooked state. As they were the surplus of several days' diet, salted and kept in the larder, it was impossible to trace them to their source.

Summary.

In an outbreak of food poisoning in a hospital affecting 12 day nurses, 1 maid, and 25 patients, an organism of the Salmonella group was isolated from the fæces and vomit of a number of cases. Direct agglutination tests indicated that the organism was a member of the group having type agglutinins for *B. aertrycke* and *B. paratyphosus* B. The absence of specific agglutinins for *B. paratyphosus* B ruled out this organism as a causal agent, apart from the clinical evidence. The organism isolated from the vomited material and stools of several patients was agglutinated by the blood sera of these patients in high dilution. These sera also agglutinated *B. aertrycke*, but failed to agglutinate other organisms, including those of the enteric group. The conclusion from laboratory investigations conducted at Cardiff, confirmed by the bacteriologist to the Ministry of Health, is that the outbreak was due to a food-poisoning organism of the *B. aertrycke* type. The infection was contained in twice-cooked meat served either as mince or gravy, but how it gained access to the meat could not be ascertained.

We are indebted to Dr. R. M. F. Picken, medical officer of health, Cardiff, for kindly permitting us to publish these notes.

A CENSUS OF EPILEPTICS IN SURREY.

THE Permanent Committee on Epileptics, a body representative of the various voluntary agencies dealing with epilepsy, has recently reported on the number of epileptics known to the public authorities in the county of Surrey. Copies of the full report, containing various classification tables, are available on application to the Secretary of the Committee, 296, Vauxhall Bridge-road, London, S.W. 1. The following is an abstract of the report.

The usual estimate of the incidence of epilepsy, as given in the text-books, is 2 per 1000 of the population. This would mean that at the present time there are some 76,000 epileptics in England and Wales, but no one can say that this is even approximately correct; still less is it possible to give with any exactness the proportion of the sexes, the ages, or the mental conditions of these epileptics.

This lack of any exact knowledge is a serious obstacle in any attempt to deal with the problem of the epileptic. It is obviously impossible to take a census of the epileptics in the general community of even a small section of the country. It occurred, however, to the Permanent Committee that it would serve a useful purpose to endeavour to ascertain the numbers of epileptics known to the public authorities of one county area, and to obtain details of their age, sex, and mental condition. It is thought that from the figures thus obtained it should be possible to form some more or less reliable estimate of the numbers and types of epileptics who come under the care of the public authorities of the country as a whole.

The area chosen by the Committee is that of the administrative county of Surrey together with the county borough of Croydon. Questionaires have been addressed to all public authorities in that area, and replies have been received from all with the exception of the maternity and child welfare committees of three of the smaller districts. It may be claimed, therefore, that the figures are practically complete for the area covered by the inquiry. So far as possible overlapping between the various authorities in the supply of information has been avoided.

The Gross Numbers.

Table I. is a summary of the cases returned by the respective authorities:—

TABLE I.

Authority.	M.	F.	Total.
Mental hospitals	127	144	271
Poor-law guardians	135	126	261
Local education authorities	65	67	132
Mental deficiency authorities	27	22	49
Maternity and child welfare authorities..	6	7	13
Totals	360	366	726

It had been hoped to include the figures of epileptic war pensioners in this census, but on inquiry it was found that it was impossible to separate the Surrey figures from those of the much larger area in which the county is included for statistical purposes by the Ministry of Pensions. It is understood, however, that there are now approximately 3000 officers and men in receipt of pensions and allowances in respect of epilepsy. The population of Surrey (including Croydon) is slightly under 2 per cent. of that of Great Britain and Ireland, and it has been assumed therefore that 55 may be taken as an approximate estimate of the epileptic pensioners in the former area.

The 726 cases of epilepsy included in the above table are equivalent to 0·75 per 1000 of the population of Surrey (including Croydon). If the 55 war pensioners, as estimated above, are added, the total of 781 is equivalent to 0·81 per 1000 of the population of that area.

Age and Mental Condition.

Table II. gives the age and mental condition of the 726 epileptics returned by the various authorities.

TABLE II.

Age-group.	Mentally normal.	Mentally deficient or feeble-minded.	Imbecile or idiot.	Insane.	Totals and percentage.
—* ..	3	—	—	—	3 (0·4)

56–60 ..	16	4	3	17	40 (5·5)
61–65 ..	3	4	4	8	19 (2·6)
66–70 ..	3	2	1	17	23 (3·2)
Over 70	8	3	3	6	20 (2·8)
Total ..	265 (36·5 %)	130 (17·9 %)	169 (23·3 %)	162 (22·3 %)	726

* Age not stated.

Of the 726 cases 515 (or 70·9 per cent.) are in institutions, the remaining 211 living at home. Fourteen cases are said to be blind as well as epileptic, 6 are dumb, 4 deaf, and 6 both deaf and dumb. Sixty-four cases are returned as crippled or paralysed, but these terms are so vague that the figure is of doubtful value.

It will be seen from Table I. that the number of male and female epileptics known to the various authorities is almost exactly equal. Sex seems to play no part in the incidence of the disease.

While youth and early middle life are most strongly represented, it is remarkable how the numbers of sufferers from epilepsy are maintained well into old age. If the generally accepted dictum be true that 80 per cent. of epileptics show manifestation of their disease before the age of 20, it would appear from this table that the expectation of life is greater than is supposed. Younger epileptics, of course, would have

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING AT CARDIFF.

(Continued from p. 525.)

SECTION OF DISEASES OF CHILDREN.

UNDER the presidency of Dr. ALFRED HOWELL (Cardiff) a discussion on

CHRONIC SPLENOMEGALY IN CHILDHOOD,

its Diagnosis and Treatment, was introduced by Dr. ROBERT HUTCHISON (London), who said that before proceeding to the differential diagnosis of the various splenomegalies of childhood it was advisable to make sure that the abdominal tumour in question really was an enlarged spleen. Usually this was easy enough, but sometimes there was a doubt, especially as to the possibility of the tumour being an enlarged left kidney or suprarenal. Having settled that the tumour was really an enlarged spleen it was necessary to have some sort of classification of the different varieties of splenomegaly met with in childhood. An ætiological classification was the only satisfactory one, but was impossible in the present state of our knowledge and, therefore, for purposes of discussion, he proposed to consider the subject under certain broad groups.

Tumours were very rare and for practical purposes undiagnosable.

Chronic Infections.—In tuberculosis splenomegaly was unlikely to be the "presenting sign." The relation of congenital syphilis to splenomegaly was very important, but he suggested for the purpose of discussion that its frequency as a factor in causing that condition was exaggerated. In pre-Wassermann days the tendency was to ascribe every splenomegaly of doubtful origin to syphilis. It had been suggested by Dr. Parkes Weber and others that an inherited taint might form a basis on which enlargement of the spleen—though not primarily due to syphilis—might develop more easily than in a normal child. Such a view appeared very speculative. In cases of syphilitic splenomegaly in which vigorous antisyphilitic treatment did not produce any diminution in the size of the spleen splenectomy was indicated. Lymphadenoma as a cause of enlargement of the spleen without any evidence of the disease in the glands was very rare, and he did not see how it could be diagnosed with certainty. Chronic sepsis had been put forward as a cause of splenomegaly as of most things. That splenomegaly might be the presenting sign in cases of very chronic infective endocarditis (endocarditis lenta) was certain, but he doubted if cases of that very chronic type were ever met with in childhood.

Tropical splenomegalies such as malaria and kala-azar presented no difference from the adult form.

Splenomegaly in Metabolic Disease.—The part played by rickets in causing enlargement of the spleen had been as much exaggerated as the rôle of syphilis. Severe rickets certainly led to some enlargement of the spleen, but in some cases the organ was not so much enlarged as pushed down by the deformity of the ribs.

Gaucher's disease was rare, although not so rare as usually believed. Opinions as to the value of splenectomy were divided. The operation could not be regarded as a cure because the disease affected the whole of the reticulo-endothelial system, but if the tumour was causing discomfort its removal appeared to be justified.

Splenomegaly in Diseases of the Blood.—This group included the leukæmias, splenic anæmia of infancy (von Jaksch's disease), acholuric jaundice, purpura, and erythræmia. Splenic anæmia of infancy used to be relatively common, but had become rare in recent years. In considering its treatment it must be remembered that the disease tended to spontaneous recovery given suitable hygienic measures, and he did not consider that splenectomy was ever called for. Acholuric jaundice was now recognised to be of not uncommon occurrence; its diagnosis could be established with certainty and splenectomy was the only effective method of treatment.

Splenomegaly associated with Cirrhosis of the Liver.—Excluding Banti's disease three forms could be distinguished. First, an idiopathic, non-alcoholic progressive cirrhosis (Parkes Weber) of unknown cause which resembled the ordinary portal cirrhosis of adults, ran a fairly rapid course, and often terminated in hæmatemesis. There was always some enlargement of the spleen, but in some cases this was the "presenting" sign, and such cases had been spoken of as cirrhosis with "splenic predominance." The diagnosis from Banti's disease was not easy, and some writers—J. H. Thursfield, for example—maintained that splenectomy was almost invariably fatal, but he was not at all sure that such a view was correct. Secondly, a syphilitic cirrhosis with splenomegaly was met with in later childhood and did not always give a positive Wassermann reaction. Splenectomy might be justified if antisyphilitic treatment failed. And thirdly, splenomegaly with biliary cirrhosis (Gilbert and Fournier), believed to be the form which Hanot's cirrhosis took in the child. He was very sceptical as to the occurrence of Hanot's cirrhosis at all, and still more sceptical as to its occurrence in childhood.

Splenomegaly the Result of Splenic Thrombosis.—Wallgren had drawn attention to thrombosis of the splenic vein as a cause of splenomegaly in childhood, and believed that it was commoner than supposed, but was usually confused with Banti's disease. The leading features of the syndrome were splenomegaly, anæmia with leucopenia, and slight ascites. Sooner or later hæmatemesis set in, and after a bleeding the volume of the spleen shrank and a temporary leucocytosis occurred. The liver in all the cases which came to autopsy was found to be normal. The prognosis of these cases was bad unless splenectomy was performed.

Splenic anæmia of adult type and *Banti's disease* were to some extent diagnostic rag-bags. Seeing that the splenic anæmia of adults was a very prolonged disease, the final stage of which was only reached after some years, it followed that the full syndrome was not likely to be met with whilst the patient was still a child, but in spite of this he thought the diagnosis in childhood of Banti's disease was sometimes justified. The difficulty was to distinguish this disease from cases of idiopathic cirrhosis "with splenic predominance," and this could only be done if the history showed that the spleen had been enlarged for some years before signs of cirrhosis supervened. It was sometimes asserted that the presence of leucopenia put a case in the category of splenic anæmia rather than of idiopathic cirrhosis, but with this statement he could not agree because in his view leucopenia tended to be a feature of most chronic splenomegalies. The treatment for splenic anæmia of the adult type was splenectomy, but it was a matter for discussion as to whether the operation was worth doing after cirrhosis had supervened.

With regard to treatment, debate, said Dr. Hutchison, must chiefly centre round the question of splenectomy. He agreed with Parsons that the cases suitable for operation were those which showed a negative Wassermann reaction, no enlargement of the lymph glands and no characteristic leucocytic picture, but in which there was some degree of anæmia, associated with (1) leucopenia, or (2) increased fragility of the red cells, or (3) hæmatemesis. There might, however, be differences of opinion as to the advisability of splenectomy in Gaucher's disease and in cases of cirrhosis of the liver whether of the idiopathic or Banti variety, even although these fell within the limits of the above criteria.

Discussion.

Mr. L. E. BARRINGTON-WARD (London) said that from the surgical standpoint enlargements of the spleen fell into two categories. In the one group removal of the spleen cured the disease or produced a definite amelioration of symptoms; in the other splenectomy offered some hope of improvement, but without any prospect of producing a real cure. In the first class could be placed acholuric jaundice and public authorities of England and Wales approximates, or *should* approximate, 25,000.

Salient Points.

1. The sex incidence in the series of cases is equal.
2. The proportion of the insane rises rapidly in later years.
3. Only 60 per cent. of the epileptics who come under the notice of public authorities can be dealt with under the Mental Deficiency or Lunacy Acts; the remainder are "mentally normal."
4. The mental deficiency authorities deal with less than one-fifth of the cases coming within the scope of the Mental Deficiency Acts, the remainder being divided equally between the mental hospitals and the poor-law authorities. There appears to be a need for considerably more residential accommodation for epileptics certified and certifiable under the Mental Deficiency Acts.
5. 24·5 per cent. of educable children are at no school or institution.
6. It would appear that there are something like 25,000 epileptics chargeable to public authorities in England and Wales. The problem is, therefore, a large one, and it is submitted that the points that have arisen in connexion with this survey merit careful consideration.

BUCHAREST.

(FROM OUR OWN CORRESPONDENT.)

The Educational Treatment of Neurasthenia.

AT a recent meeting of the Medical Society of Bucharest Dr. Ramniceanu expressed the opinion that cases of neurasthenia were rapidly increasing in number. He showed that a definite percentage of the symptoms of a neurasthenic were illusory or hallucinatory in character, and claimed that practically every phase had one symptom, complaint, apprehension, or fear, which predominated over all the others. This one predominating symptom he called the chief obsession, and stated that when this was overcome or removed either by education, by medicinal treatment, or by psycho-analysis, all lesser symptoms were either abated or were entirely relieved. He cited a number of cases of neurasthenia from his own practice, giving the chief obsession in each case, and the educational or other means used to remove it. Reference was made to the use of some modern drugs in these cases; in Dr. Ramniceanu's view the majority of patients were made worse by their administration. It was essential to get hold of the mentality of each patient and to treat the mind rather than the body.

Poisoning by Wood Alcohol.

Dr. Olteanu describes in the *Spitalul* the case of a man of 34 who presented himself at the Central Hospital suffering from acute total blindness. Investigation of the history showed that the loss of sight had come on during the second day after taking about 50 c.cm. of corn brandy, which subsequent analysis showed to contain some 15 per cent. of wood alcohol. Symptoms which had accompanied the development of the eye condition included nausea, vomiting, weakness, cold extremities, and sensations of chilliness. On ophthalmoscopic examination the optic nerves presented the picture of a neuro-retinitis of moderate intensity, and in the macular regions were disposed numerous yellowish shining spots similar to those described as occurring in choroiditis guttata. Good food, warm baths, and large doses of potassium iodide were prescribed; four months later one eye showed complete recovery of function, and the other eye presented moderate concentric contraction of the field, considerable diminution of central vision, and impairment of colour vision.

Typhoid Fever in Children.

The differences between typhoid fever in children and in adults were recently reviewed by Dr. M. Edelmann in a communication to the Oradea Medical Society. Many of the 180 cases discussed showed the relation between vomiting and hæmorrhage first observed by Butler in the United States, especially those in whom vomiting had started at the onset of the illness and had been repeated. The appearance of the stools in very young children was not so characteristic as in adults, though in older children pea-soup stools often occurred. A preliminary constipation was shown to have no evil significance. Rose spots occurred in 52 per cent. of all cases, and herpes in three cases, two of which had complications. The average duration of the fever was 18 days, a much shorter period than is customary in adults. The usual parallelism between the pulse and the temperature was not present in very young children. Leucopenia was mostly present and the Widal test was positive in nearly all cases where it was performed. Relapses were more frequent than in adults, especially in girls. The mortality in the series of cases was 7 per cent., and was twice as high in relapses as in original attacks.

The Improvement of School Hygiene.

A movement is on foot for a great extension of the present methods of medical school inspection. It is championed by Dr. A. M. Marinescu who suggests the establishment of national, State, and local boards of school hygiene under the direction of specially qualified medical officers. Most of the bad conditions now existing he ascribed to the ignorance of school boards, of parents, and the children themselves. The functions of a national board would be to provide plans for sanitary school buildings and school furnishings, to conduct civil service examinations for school physicians, and to publish leaflets of instruction from time to time. The State boards should have the power to choose proper sites for schools, to frame and enforce laws governing school hygiene, to close insanitary school buildings, to ensure the exclusion of degenerate or criminal children from State schools, and to keep records of the progress and development of school-children of the State. The local board should consist of business men and physicians, should keep records, and should keep in touch with the national and State boards from time to time. Under this scheme every child in each school would undergo a complete physical examination. The functions of the board would also include the distribution of literature bearing on hygiene and also the instruction of parents as to the needs of each child, based on its physical examination.

RADIUM AT THE LONDON HOSPITAL.—At the quarterly court of governors last week it was reported that in response to urgent representations from the medical and surgical staff, the purchase of 210 mg. of radium for the treatment of cancer had been authorised, in addition to the 121 mg. already possessed. This amount, with the containers, will cost £2854. Last year more than 800 cancer cases were treated as in-patients and very many more as out-patients. Disappointment was expressed at the result of the quinquennial appeal, which has, so far, produced only £95,000. Last year 10,271 patients were admitted from London boroughs, and about 6000 from other parts of the country, including the Channel Islands.

ST. THOMAS'S HOSPITAL.—In his annual report, the treasurer, Sir Arthur Stanley, states that the number of in-patients last year was 11,510, who stayed, on the average, 18 days at a cost per head of £11 11s. 9*d*. New out-patients numbered 92,325, of whom 57,047 were casualty patients. They made 580,356 attendances and cost a fraction under 12*s*. 2*d*. each. The income was £190,000, of which investments produced £69,000, and the expenditure £183,000. Referring to the suggested coöperation of the voluntary hospitals with the public authorities in providing a medical service adequate to the needs of the community, Sir Arthur Stanley expresses the hope that nothing may be done that will interfere in any way with the autonomy of the voluntary hospital "which has proved of such immense value in furthering improvement in general methods of treatment, in research, in nursing, and in social service."

from each other very widely and were best considered as separate diseases. These were: (*a*) chronic interstitial nephritis; (*b*) chronic parenchymatous nephritis, including nephrosis; and (*c*) chronic ascending pyelonephritis. It was true that the latter was not a primary disease of the kidney, but it impaired the renal function in the same way as chronic interstitial nephritis and so was likely to be mistaken for it. Chronic hæmorrhagic nephritis was not included because such cases were probably recurrent attacks of slight acute glomerular nephritis.

Chronic interstitial nephritis was at one time regarded as a great clinical rarity and Leonard Guthrie, in 1896, could only collect seven cases under the age of 14; since 1911, however, when Fletcher, Parsons, and Miller drew attention to the fact that the disease might result in peculiar bony changes and dwarfism, a great number of cases had been recognised. He believed that there were three clinical types of this condition in children. There were, however, certain symptoms common to them all. The symptoms might arise from infancy onwards, but usually advice was not sought for several years, and then a history of thirst, polyuria, anæmia, and arrested development could be obtained. On the other hand, an attack of uræmia might be the first warning of the condition. In well-established cases the patients were usually emaciated, with coarse, dry, and pigmented skins, and were liable to repeated attacks of uræmic vomiting and headaches. There was no mental defect. If dwarfism and bone changes were present they might be of an extreme degree. Bone changes were not likely to appear in those cases which ran a rapid course towards a terminal uræmia, but only in those which ran a long course and in which the renal function was much impaired. Polyuria was a prominent symptom. The amount of albumin was variable and often so slight as to be overlooked. Casts, leucocytes, and red cells were to be found in the urine. The blood pressure might be normal throughout, high throughout, or become so during the course of the disease. Renal retinitis might be absent throughout, even although the patient died in uræmia. Renal function tests demonstrated great loss of function in all cases of "renal dwarfism" and "renal rickets." It was on certain combinations of these symptoms and signs hat he proposed to divide cases of chronic interstitial ephritis into three types.

Type 1.—A primary renal type without history of acute ephritis, or preceding sepsis. The chief features of this pe were that the onset of the disease was unrecognisable, at it had a slow course, and that renal dwarfism developed. ere was marked azotæmic nephritis, the blood pressure ally remained normal, and retinitis was not present. acks of tetany might occur, and the terminal uræmia that described as true azotæmic nephritis, an undramatic picture of muscular twitchings, vomiting, and coma.

Type 2.—A primary renal type with a history of acute glomerular nephritis, or prolonged sepsis. In these cases within a few years of the initial illness there was found a high blood pressure (150 to 200 mm.), cardiac hypertrophy, albuminuria, with numbers of red cells in the urine, azotæmia, and retinitis. The course of the disease in these cases was usually a rapid one.

Type 3.—A primary arterio-sclerotic type with secondary contraction of the kidneys. Cases in this group showed a preliminary stage of high blood pressure which was often found to be over 200 mm. when the patient was first seen. The blood urea was, however, normal and there was only a mere trace of albumin in the urine. Later there was cardiac hypertrophy, retinitis, and a tendency to "uræmia of the cerebral type," with transient amaurosis, monoplegia, and convulsions. Later still albuminuria and some azotæmia developed, and death occurred from heart failure or apoplexy.

Renal rickets and tetany in chronic nephritis were the result of a metabolic disturbance which accompanied azotæmic nephritis, but which did not yield to the usual antirachitic remedies; indeed, one of his cases was thrown into uræmia after exposure to ultra-violet ray treatment. Frank tetany was not common, but in many cases latent tetany could be demonstrated by the presence of Chvostek's sign. In azotæmic nephritis there was a retention of phosphorus and often a fall in the calcium of the blood, but in some cases of renal rickets the fall in blood calcium did not occur. It was reasonable to believe that the bony changes and the tetany which might be present were dependent on the disturbance of the phosphorus-calcium ratio of the blood and tissue fluids.

Chronic parenchymatous nephritis or nephrosis was the commonest form of chronic nephritis. Müller coined the term "nephrosis" in 1905, maintaining that the kidney lesion was a degeneration and not an inflammation. Now it appeared that the disease was not primarily a kidney disease at all, but a general disease with "an abnormal permeability of the cutaneous and renal vessels for albumins and lipoids referable to changes of metabolism," so the most recent fashion was to call it "lipoid dystrophy of the kidneys." The only evidence that the clinical condition was due to a disease of the kidneys was the occurrence of albuminuria and casts in the urine, but there were cases on record in which the œdema preceded the urinary findings. Some held that the œdema was due to the retention of chloride, but de Wesselow had shown that the kidneys were quite capable of passing and concentrating the chlorides if they were given the opportunity. These cases rarely ran an uncomplicated course and were peculiarly liable to secondary infections, and at such times a glomerulitis with hæmaturia and nitrogen retention were superimposed. With regard to treatment, Marriott maintained that the disease was due to a toxin which damaged the tissue cells, causing them to absorb more chloride from the blood, so producing œdema. The toxin was usually the result of a staphylococcal infection of the mastoid or paranasal sinuses, and therefore this writer advised a very thorough examination and exploration of these sites and reported rapid cures after sinus drainage. Osman had revived the using of large doses of alkalis as a method of treatment, and this should be tried in obstinate cases, but it should be remembered that it often produced severe vomiting and tetany. The disease was so liable to fluctuations that it was difficult to assess the value of any particular form of treatment, but it was commonly agreed that a high protein diet was beneficial, that decapsulation of the kidney was useless, and that it was imperative that every patient with nephrosis should be guarded rigidly against the development of intercurrent infections in case an acute hæmorrhagic nephritis developed.

Chronic Ascending Pyelonephritis.—Most cases of acute pyelitis, if promptly diagnosed and treated, made a satisfactory recovery, but there were more chronic cases which remained in ill-health and were liable to recurrences of fever and pyuria. In a few of the latter a permanent damage of the kidney resulted and the failure in renal function showed itself as an advancing azotæmic nephritis ending in uræmia. If the condition was sufficiently prolonged these patients developed renal dwarfism. In such instances the question as to whether there was some chronic obstruction or deformity of the urinary tract which was the cause of the infection must be considered. One of the most striking examples of ascending pyelonephritis was due to a valvular obstruction in the posterior urethra of male children, of which quite a considerable number of cases had now been diagnosed and successfully treated.

Discussion.

Dr. NORMAN B. CAPON (Liverpool) said he wished to lay down two propositions. First, that in any particular case of nephritis the lesions were diffuse; and, secondly, that the renal efficiency tests were not of very great assistance and were of little real value in treatment. Every case of chronic nephritis represented a kidney which was the seat of repeated acute attacks. Emerson had pointed out that chronic nephritis was not the result of one, but of a thousand and one acute attacks. The treatment of chronic nephritis in general was a dismal thing, but in the treatment of chronic hæmorrhagic nephritis—the commonest form of nephritis—there was a little more ground for hope. Effective treatment of tonsils, teeth, or any other infective focus did more to allay-thrombo-cytopenic purpura. The second class was made up of more debatable material, but he advocated early splenectomy in Banti's disease before ascites developed. In Gaucher's disease if the spleen were large and producing abdominal discomfort he thought removal should be practised. Splenomegaly due to thrombosis of the splenic vein was difficult to diagnose and could only be recognised with certainty at operation or autopsy. The difficulties of splenectomy in this condition were very great. With regard to the operation of splenectomy blood transfusion was essential both before and after operation. He had not had any experience of preliminary irradiation of the spleen in children, but this procedure had been well spoken of in leukæmia by W. S. Mayo. Gas and oxygen was the anæsthetic of choice. Happily the common conditions, for which removal of the spleen was required in children, presented no great difficulties.

Prof. **Leonard Findlay** (Glasgow) pointed out that it was only possible to estimate the palpability and not the size of the spleen, because conditions such as hypernephroma, retroperitoneal sarcoma, enlargement of the liver, or a deformed chest would displace an enlarged spleen. He agreed with the opener that there was not any enlargement of the spleen in rickets unless that disease was complicated by tuberculosis, syphilis, or severe thoracic deformity. He had on one occasion found a palpable spleen as the only evidence of tuberculosis, but the diagnosis was only made as the result of splenic puncture, and he had also seen a case of lymphadenoma in which, except for anæmia, splenomegaly was the only manifestation of the disease, the diagnosis being made at autopsy. Whilst he agreed that the incidence of congenital syphilis had been overestimated yet in the presence of anæmia and splenomegaly that disease must be eliminated by a negative Wassermann reaction. Splenectomy did not interfere with the course of von Jaksch's anæmia, but after splenectomy in that disease the number of leucocytes diminished whereas they increased after splenectomy for other conditions. Of the two cases quoted by Dr. Hutchison as examples of cirrhosis of the liver with splenic predominance and Banti's disease respectively, he thought that either case might do for either condition. There was a great deal of confusion about Banti's disease, but Banti himself had stated specifically that cirrhosis of the liver was present in the early stages of the disease; there should, however, be no confusion as to the methods of arriving at the diagnosis of the cause of an enlarged spleen, which were: a complete blood count, an estimation of the fragility of the red cells, a Wassermann reaction, and splenic puncture. Without splenic puncture it was impossible to separate Banti's from Gaucher's or Hodgkin's disease, tuberculosis, &c.

Dr. C. P. **Lapage** (Manchester) in his remarks dealt chiefly with cases of Jaksch's anæmia which had been under his care. The frequency of this disease, which occurred chiefly in the artisan classes, had diminished considerably but was now increasing again. Two cases had occurred in one child of each of two pairs of twins. Many had suffered from digestive disorders and many showed signs of rickets. He did not consider the latter a causal factor nor was there anything to suggest that the disease was due to syphilis. The blood showed a secondary anæmia which varied from time to time. He had been able to follow up some of his cases and all of those examined were in ordinary health, the blood and spleen being normal. He hesitated to recommend splenectomy and thought that in all cases arsenic, benzene, and, perhaps, liver extract should be tried first, but if the child was not very ill and the course of the disease a protracted one, splenectomy was advisable.

Dr. J. **Wilkie Scott** (Nottingham) said that in cases with splenomegaly and hæmatemesis he found it difficult to differentiate splenic thrombosis from cirrhosis of the liver. He had recently seen two patients who when apparently healthy had an acute hæmatemesis followed by a rise of temperature and slight ascites. In both instances splenectomy was performed with successful results. Thrombosis of the splenic vein was not found at operation, and he thought the hæmatemesis was due to an active and not a passive hyperæmia, possibly caused by a perisplenitis.

Dr. **Hilda Stoessiger** (London) described a case of Banti's disease occurring in a boy aged 14. The patient had suffered from abdominal discomfort due to the presence of an enlarged spleen for some months; there was slight anæmia with leucopenia and the Wassermann reaction was negative. A lævulose tolerance test showed marked hepatic insufficiency. Splenectomy was performed and at operation the liver was noted to be cirrhosed. Two years later the patient was well, but the onset of puberty was delayed. The liver was enlarged and still showed marked inefficiency.

Dr. **Leonard G. Parsons** (Birmingham) agreed that the diagnosis of an enlarged spleen might be difficult and quoted a case in which a mass of tuberculous glands presented under the left costal margin and showed typical splenic notches. He had listened with great interest to Dr. Hutchison's remarks on the differentiation of Banti's diseases from cirrhosis of the liver with splenic predominance, and he agreed with Prof. Findlay's criticism of the cases quoted. As far as he (Dr. Parsons) could judge the only point of difference between the two conditions was that the cases of "splenic predominance" ran a more rapid course than those of Banti's disease. Splenomegaly with thrombosis of the splenic vein described by Walgren was not mentioned as a cause of enlarged spleen in the discussion on this subject at the Royal Society of Medicine in 1925, but two of the cases described by him (the speaker) as instances of Banti's disease had been claimed as examples of the Walgren type. He asked whether Mr. Barrington-Ward recommended the removal of spleniculi if found during the operation of splenectomy in acholuric jaundice and if the gall-bladder should be examined for gall-stones, as recommended by Sir Berkeley Moynihan.

Dr. E. A. **Cockayne** (London) pointed out that although removal of the spleen for acholuric jaundice cured the symptoms, yet it did not cure the disease. He asked if irradiation of the spleen had any curative effect on this disease, and also if this method of treatment produced adhesions and thereby rendered any subsequent operation more dangerous. Splenic anæmia of the adult type, if diagnosed, should be treated by removal of the spleen because it was a primary splenic disease, but there was no method of accurately diagnosing the condition. Some cases of cirrhosis of the liver ran a very protracted course and this, he thought, accounted for some of the supposed cures of hepatic cirrhosis after splenectomy. Since hepatic cirrhosis was a primary liver disease a cure could not be expected by performing splenectomy.

The **President** said that occasionally patients suffering from acholuric jaundice showed a normal red-cell fragility. He also referred to the occurrence of pigmentary concretions in the gall-bladder in this disease, pointing out that Mayo had found these in three out of five cases.

Reply.

Dr. **Hutchison** said he quite realised the difficulty in deciding into which category a case should be put, but if the splenic enlargement had been known to be present for some years before cirrhosis of the liver developed the case should not be classed as one of idiopathic cirrhosis.

CHRONIC NEPHRITIS IN CHILDHOOD.

The subject was opened by Dr. J. C. **Spence** (Newcastle-on-Tyne), who said that from the standpoint of morbid anatomy there were no forms of chronic nephritis which were peculiar to childhood, but there were certain clinical features about the disease in children which deserved attention and which might throw some light on some of the obscure problems of the subject. For the purposes of description and discussion it was necessary to attempt some form of classification. Three main groups of the condition occurred in childhood, and these differed to the action on the disease directly, but to an action on the skin, and only indirectly on the disease. In the various lamps employed for the artificial production of ultra-violet rays the spectral distribution varies greatly. Sunlight at sea-level contains less than 2 per cent. ultra-violet rays, but in a water-cooled mercury-vapour lamp the ultra-violet rays may rise to 50 per cent., and the spectral quality is different from that of the sun in that it contains a large proportion of the short and more physiologically active waves, so that with such an artificial source the skin is subjected to rays of a quality foreign to natural sunshine. In his opinion the carbon arc was the nearest approach to the natural sun. Sunlight, ultra-violet rays, and infra-red rays all cause the skin to turn red at first, and if the dose is repeated or prolonged to become pigmented later. Pigmentation rom lamps is more superficial and transient than that roduced by sunshine. Apart from its action on the in, ultra-violet radiation gives a feeling of well- ing and vigour. Many other effects on metabolism re been ascribed to ultra-violet rays, but he did believe they were specific. The skins of patients r in their reactions towards light, due probably he presence of a sensitiser. But quite apart from this natural sensitiveness the condition can be acquired. The application of powerful ultra-violet rays alter the proteins of the skin. These abnormal proteins are absorbed, and an allergic condition arises in which the skin becomes intolerant to light. Thus, the importance of correct dosage cannot be overexaggerated, since burns may lead to light allergy. Much of the literature in the advertisements on lamps leaves the impression that they are a panacea for all disease. In reality, very many patients are not benefited by this treatment, and some may suffer injury. The radiations from ultra-violet lamps, which emit rays of shorter wave-length than those found in the solar spectrum, when applied to the skin, are just as foreign to the body as to be comparable with the administration of a poisonous drug; either may be beneficial in a suitable subject but iarmful in an unsuitable. Few of us would dare to ave a prescription containing poisons dispensed y an untrained person, but the dispensers of rays are uncontrolled, unregistered, and may be unqualified. At the present time all kinds of rays are used by charlatans in Europe and America to impose on the public. Sun ray institutes are becoming the fashion, and the public is buying machines and indulging in self-treatment. Already action has been taken in France and America, and an endeavour is being made to control this form of treatment and prevent its indiscriminate use, and he thought it was obviously right that the public in this country should be given such information as will enable them to distinguish etween those who have been properly educated to ispense rays, and others.

"I have endeavoured," said Prof. Dixon, "to show that treatment by radiation may be either beneficial or harmful; that its employment by unskilled people may cause serious ill-effects to the patient, and that the time has come when some sort of protection must be extended to the public."

Dr. C. B. HEALD (London) said there was ample evidence that electrical treatments could do harm; and he commended the resolution passed by the Representative Body a few days previously.[1] He instanced cases where fatalities had occurred with much lower voltages than those in general therapeutic use. With regard to the ignorant applications of X rays and radium, it was not necessary for him to dwell on the dangers both to patient and operator. But he pointed out that special courses and diplomas in radiology and electrotherapeutics for medical men had been instituted, and the possession of such a diploma was essential in many hospitals for the appointment of radiologist. Coming to ultra-violet light, he said an argument sometimes advanced is: "Control X rays, radium, and obviously dangerous things like that if you like, but surely no one can do much harm with an ultra-violet lamp. At the worst, all that can happen is an uncomfortable sunburn." That idea he most strongly condemned. Prof. Dixon had shown the dangers of ultra-violet radiation, and public interest demanded imperatively that it should only be used by trained and experienced persons. He had examined the evidence of damage by ultra-violet light treatment from the contributions of many writers. He mentioned three of the ailments that had been adversely affected—quiescent phthisis, arterio-sclerosis, and chronic nephritis—and asked how the unqualified therapist was to recognise these conditions. Many of the contra-indications to ultra-violet treatment are such that the qualified doctor finds it hard to detect their presence, and there was certainly not the least hope of the unqualified detecting them before damage was done. He thought the formation of a roll or register of persons regarded by a competent authority as suitably qualified to administer medical electricity as a matter of urgency. It would enable those of the public who cared for their own safety to be sure of their therapist. It would also be of great value to doctors who would thus be able to select a suitable assistant to whom to send their cases. The duly qualified among the medical electricians would welcome it, if for no other reason than that it would protect them from the unfair competition, backed by advertisement, of those who have spent neither time nor money in acquiring skill and experience and who are not bound by any ethical rule of modesty or truthfulness.

Discussion.

Dr. OWEN L. RHYS (Cardiff), who presided, thought the most striking point brought out by the introducers was that here was an agent with potentialities of danger still largely unknown.

Dr. A. J. H. ILES (Taunton) said that a penal clause regarding unqualified practice should certainly be imposed and that it should be also made illegal for a registered electrotherapeutist to employ people who themselves were not qualified. It should also be made clear that if a medical practitioner sent his cases to an unqualified electrotherapeutist he would be responsible if any damage resulted.

Dr. MARIA ARMSTRONG (Ballymena) asked how far responsibility rested with the prescribing physician. In a cottage hospital with which she was connected, "artificial sunlight" lamps had been instituted, and the committee had thought that the treatment might be in the hands of the masseuse, who, by her own admission, knew nothing about light treatment and was not even qualified in electricity. The doctors, however, had refused to allow the treatment to be placed in the hands of this woman, or to be responsible for mistakes made by her.

Dr. P. W. HAMOND (Croydon) said that this matter had been discussed in the Representative Meeting, and the conclusion arrived at was that no absolute rule could be laid down, and that if legal proceedings resulted, each case would have to be decided according to the circumstances.

Dr. GARFIELD EVANS (Cardiff) considered that there should be a definite course of training undertaken by the people who were going to administer light treatment, and that a register should be set up.

Dr. T. MARLIN (London) said that he had refused to instal a mercury-vapour lamp (although it was very convenient for treatment) because he felt that this was an agent of which so little was known.

In reply to a question as to whether the proposed registrants would be required to be medical men or qualified physicists, Dr. HEALD said that, in his view, a registrant should be required to produce some evidence of qualification such as the B.Sc. in physics, and should undertake that he would not act except under medical guidance as to treatment.

Prof. DIXON agreed with Dr. Heald. It was the function of the physician, he said, to diagnose and then to prescribe treatment, but in a number of cases the treatment required was of a very special kind.

---

[1] See THE LANCET, July 28th, p. 194.

the course of the disease and limit the number of recurrences than any other method.

Dr. COCKAYNE, who was in the chair, stressed the importance of discussing treatment because if, for instance, nephrosis was due to infection it obviously could be effectively treated.

Dr. PARSONS pointed out that in one type of renal rickets—the "stippled" type—primary optic atrophy was not uncommon and was probably the result of pinching of the optic nerve in the foramen. With regard to the suggestion that the parathyroids might be connected with the bone changes and the absence of tetany, the Section might be interested to know that he had given parathyroid hormone for some time to a child suffering from "renal rickets" with the result that her blood calcium was raised to a higher level, and in the radiogram the rickets appeared to be increased. Owing to the normal variations of the disease, however, it was not possible to say whether this was cause and effect. It was, however, clear that the hormone should not be used in the treatment of tetany in renal rickets, and it was also important to avoid making use of acid sodium phosphate because this drug was likely to produce an attack of tetany in these children.

Dr. HUTCHISON said that Dr. Spence was particularly well fitted to open the discussion because he was a biochemist as well as a physician. The difficulty in discussing the subject was the question of classification because the more chronic was the case the more likely were the lesions to be diffuse. He wondered whether the primary renal type was a true renal disease. Might not the renal changes and the rickets be both manifestations of a metabolic disorder? He had never seen the primary arterio-sclerotic type in a child, and he doubted whether the condition was, as generally stated, a primary vascular disease with secondary renal changes, and he suggested that the glomeruli at least were affected. He noticed that the opener had not said much about casts in the urine, and he asked if any importance was to be attached to these because he himself thought that granular and blood casts were of great importance. He did not believe that staphylococcal infections were the cause of chronic parenchymatous nephritis, nor had he ever known decapsulation of the kidneys do any good. Quite dramatic results, however, sometimes occurred in that disorder as a result of tapping if the œdema was very marked. In many cases after treatment by dieting and diuretics had failed, tapping not only removed the fluid but a spontaneous diuresis had occurred and the dropsy did not return.

Dr. WILKIE SCOTT said he had recently had two cases of the arterio-sclerotic type which threw some light on the cause of that condition. Both cases had retinal changes and normal blood urea, and both at the onset had hæmaturia, a fact which suggested that this type was the result of an acute, perhaps slight, hæmorrhagic nephritis. He had been impressed with the number of times a slight hæmaturia was found in patients who were in hospital for nasal disorders, and which was only discovered by routine examination. He also quoted another case in which there was marked œdema and ascites but no albuminuria until within a day or two of the child's death, and at the autopsy the kidney showed the lesion of a typical chronic parenchymatous nephritis.

Dr. LAPAGE was convinced of the septic origin of many cases of chronic nephritis, and that not enough attention was paid to dieting. Many cases were kept on too low a diet, thereby preventing recovery.

Dr. D. T. DAVIES (Cardiff) agreed that the study of uræmia in childhood was one that promised to be of great value. In the primary renal type there was a conspicuous absence of respiratory symptoms, and also for long periods of time the blood urea was high, even as high as 300 mg. per cent., without any symptoms of uræmia. When uræmia occurred vomiting was a marked symptom, and this was one method of excreting urea, for he had found as much as 600 to 800 mg. per cent. in the vomitus. Another point to remember was that osseous changes were not invariably present.

Dr. A. MONCRIEFF (London) said that there were two ætiological factors in chronic nephritis—the vascular and the infective. The vascular factor had been emphasised by Volhard, who said that the glomerular vessels were affected in exactly the same way as the vessels of the skin by chill. The vessels contracted, nutrition was cut off, and death and degeneration followed by fibrosis occurred. Infection caused kidney damage in one of two ways: streptococcal emboli might affect the glomeruli producing acute hæmorrhagic nephritis, or toxins might affect the tubules and produce a chronic parenchymatous nephritis. The vascular cases were difficult to treat, but it might be possible to do something for the infective ones. It should be remembered that in lipoid nephrosis the kidney was choked with fat, which interfered with filtration just as filter paper when soaked in fat delayed filtration; therefore it was essential to give a low fat diet in the treatment of this disease.

Dr. HOWELL quoted a case of the primary renal type which had recently been under his care and which had died from uræmia. This case was sent up to the orthopædic department for treatment of knock-knee and showed other evidence of renal rickets. The optic discs in this case were pale, although he could not say that there was any actual atrophy.

Dr. H. GAINSBOROUGH (London) said he disliked the term "lipoid nephrosis" because he did not know what a "lipoid" was. Nor did he see any reason for giving a fat-free diet in cases of this disorder, because cholesterol was not a fat.

SECTION OF RADIOLOGY AND PHYSIO-THERAPEUTICS.

ULTRA-VIOLET LIGHT AND THE GENERAL PUBLIC.

Prof. W. E. DIXON (Cambridge) outlined the nature of radiation and said the different rays so far as they have been mapped extended through 62 octaves. Visible sun rays occupy only one octave. Beyond the violet rays of visible light are five octaves of ultra-violet rays which are invisible. Solar radiation contains a few of these, something less than one octave. On the other side of the solar spectrum are the infra-red rays, about seven octaves, of which solar radiation contains three or four. Sun rays have been used in the treatment of disease for long ages, but during the last 30 years precise observations have been made of their action in disease. The proof is complete that they exert a curative action in cases of surgical tuberculosis, rickets, and in some cases of nerve disease, anæmia, and skin disease, but atmospheric conditions alter the action of sunshine to some extent. Thus, the presence of water vapour acts in much the same way as a fire screen which lets us see the fire but cuts out the heat.

It is generally believed, said Prof. Dixon, that it is the violet and longer ultra-violet rays that possess the greatest curative value, because these are especially prevalent in the sunshine of mountainous districts and near the sea where they become refracted and reflected by the sand and water. If the short ultra-violet rays were the most important, then the mercury-vapour lamp, in which they are very rich, ought to be the most effective treatment. Rollier, the pioneer of sunshine treatment, regards the light waves as the most important, and abundant pigmentation as a sign that the patient is deriving benefit. Others believe that the value of heliotherapy is the direct effect of the power of the rays to produce redness of the skin. All skin contains a substance called ergosterol; when this is acted on by ultra-violet rays it is changed chemically and the changed substance acts as a preventive and a cure for rickets. So that in this particular instance ultra-violet is all-important. Regarding general benefit, however, all we know for certain is that sunshine exerts a curative action in certain diseases, and that this is not due

After several questions Dr. **Barber**, in reply, pointed out that they had not claimed to have discovered the cause of urticaria, but had simply investigated the biochemistry of the allergic state. The causation was a much more complicated matter. Allergic symptoms were common in liver disease—prurigo and itching, for example. One of the functions of these allergic people was wrong, either from heredity or some other cause. Amino-acid estimations had been done in a very long list of other diseases. There was an initial acidosis in allergic states, and bicarbonate of soda might stop this. The calcium factor entered in relation to the vegetative nervous system; the irritability of the sympathetic largely depended on the calcium content. Protein therapy acted by desensitisation and preventing anaphylaxis. The liver was in some way responsible for anaphylactic shock, which could not be produced if the liver were cut out. He had used ephedrine and atropine, which undoubtedly acted through the parasympathetic system, on which the symptoms depended. Adrenalin acted on one phase only of the anaphylactic state. He thought it unjustifiable at present to speak of treatment.

Dr. **Hallam**, in reply, expressed sympathy with speakers who had asked for guidance in treatment, but said there was no other way than to go systematically through the possible causes. He had been disappointed in autohæmotherapy. Cases varied very much and often got well by themselves; he agreed that many were due to a *B. coli* leak through pelvic adhesions.

THE STEAM CAUTERY IN DERMATOLOGY.

This, said Dr. **Semon**, was a most valuable destructive agent, especially when associated with vigorous use of the sharp spoon. It was better than diathermy, because there was no fear of breakdown of the apparatus, which was portable, cheap, and independent of lighting circuits. The penetration of heat was very slow, about an inch a minute, and it was therefore possible to determine when normal tissue had been reached and save penetration of cartilage or mucous membrane. Open ether should be avoided because of the open flame, and local anæsthesia was the best. The only hitch he had encountered was locking by chalk deposits from the water; either istilled water should be used or the pipes should be leared periodically with a piece of wire. There was ever any charring, and a constant heat was well aintained and bleeding easily controlled, provided e apparatus was cleaned from time to time of the altered blood that crusted on to it. A striking feature was the absence of consecutive pain. The steam cautery was indicated for any accessible epithelioma, especially where cartilage and mucous surfaces were involved and X rays and radium therefore futile. It was useful for lupus verrucosus if the horny layer were previously macerated with salicylic acid plasters for a few days. The tuberculous nodule was blackened by the cautery and stood out against the white scar tissue. Soft chancres and chancroids were very amenable, and the steam cautery would probably prove the method of choice for them. Granuloma pyogenicum and intractable papillomatous leukoplakia of the tongue had been cured (THE LANCET, Oct. 8th, 1927). The tissue to be destroyed must be soft and free from horn, so that warts and unmacerated verrucose tumours were excluded. The coagulability of the tissue was important, therefore moles and fibromata were not amenable, but anthrax pustule and Delhi sore probably would be. The wound must be kept dry until the slough separated; ambrine was good for the raw stage and red lotion or scarlet red might be applied if the granulation were poor. There had been very few complications.

Dr. J. E. M. **Wigley** (London) suggested that electrical heating of the water would be more convenient, and mentioned the danger of local treatment of carcinomata, with which infected glands were so often associated.

Dr. **Semon**, in reply, pointed out the value of being independent of electrical circuits and agreed that only local growths should be treated locally. The steam cautery was better than the knife in that it closed channels rather than opening them.

THALLIUM DEPILATION FOR RINGWORM.

Dr. **Wigley** recorded the treatment of 50 outpatient cases of both sexes, aged between 18 months and 9 years. Depilation had been spontaneous only in 50 per cent., and growth had been much more rapid than after X rays. On checking the cures by Wood's glass inspection he had found that many macroscopically normal hairs showed fluorescence, and the microscope revealed infection along their length. Hairs infected with endothrix but with unbroken cuticle failed sometimes to fluoresce. X rays might fail but the failures were not deceptive, whereas those of thallium were. Moreover, it was impossible with out-patients to be certain of the vigorous local treatment essential during the depilation stage of thallium treatment. The older the child the more certain were the toxic symptoms. Physicians should be very chary of risking permanent damage to the growing organism for a treatment that was by no means a certain cure. There was great risk of reinfection of the growing hair, and he preferred X rays from every point of view.

Dr. **Barber** agreed that thallium was very dangerous for older children though useful for young ones, who were unsuitable for X rays.

Dr. **Haldin Davis** (London) doubted whether there remained any field for thallium; everyone agreed that it was dangerous to a child over 6, and younger children could be treated by X rays if given a 20-gr. dose of bromide the night before, the morning before, and half an hour before treatment. This was better for them than the "psychic trauma" of forcible restraint.

Dr. **Semon** did not agree. The results of bad X ray treatment were appalling, and he had never heard of a fatal case of thallium poisoning. Toxic phenomena were probably due to keeping the hygroscopic acetate too long.

Dr. **O'Donovan** had abandoned thallium. The occasional catastrophes were no more reason for abolishing X rays than anæsthetic deaths were for abolishing chloroform.

Dr. **Hallam** agreed with Dr. Semon, but thought both methods were bad. He had had 13 failures out of 42 out-patients treated with thallium, and seven had had severe toxic symptoms. Patients did much better if kept in bed throughout the treatment. The dosage ought always to be checked by a third person.

Dr. J. T. **Ingram** (London) had had only three failures in 48 cases treated with thallium and would continue to use the drug for selected cases. Only one child had had toxic symptoms, and she had been over 8 years of age. It was important to have the patient under careful supervision during the period of depilation.

The **Chairman** agreed that neither method was satisfactory, but still kept an open mind for thallium.

ILL-EFFECTS OF SALVARSAN.

Dr. **O'Donovan** said that there were no clear and recognised ill-effects of salvarsan therapy; ill-effects might follow small doses of any brand and might appear at any time. Alarming lists of untoward symptoms had been recorded, including headache, shivering, vomiting, dyspnœa, palpitation, fainting, cramps, diarrhœa, cardiac distress, jaundice, urticaria, and many other dermal reactions, Reynaud's syndrome, uterine hæmorrhage, epileptiform seizures, epistaxis, and hæmaturia. Many cases were lost sight of through dissociation of clinics from general hospitals and practitioners. Dr. O'Donovan then gave details of a case of post-salvarsan melanodermia, another of maculo-melanodermia with follicular hyperkeratosis in a French polisher, and a third of multiple subcutaneous abscesses associated with arsenical exfoliawhich the physician himself might not have the time, or perhaps the skill, to carry out. The physician did not make up prescriptions; they were made up by skilled people called chemists. If a medical man decided on ultra-violet light treatment he should put down on the prescription the light source, the area to be irradiated, the time, and so forth, and the administration of the treatment should be carried out by people trained in a particular way; that they should not be unskilled people was perfectly obvious.

SECTION OF DERMATOLOGY.

UNDER the presidency of Sir ROBERT BOLAM a discussion on

URTICARIA

was opened by Dr. R. HALLAM, who said that this complaint was both common and distressing. It served to impress on the dermatologist the fact that a change in the skin was often the expression of some pathological process in another part of the body, and that a knowledge of the latest advances in biology and physiology were necessary for its elucidation and treatment. Urticaria was not a disease but a symptom. Urticaria factitia or dermographism might or might not be accompanied by urticaria vulgaris but, curiously, did not irritate. Lewis had ascribed the wheals of both to the release of a histamine-like substance from the cells of the skin, though the cause of the exaggerated susceptibility of the patient with urticaria factitia was not clear. Its incidence was higher in epileptics and alcoholics, although it occurred in perfect health. Acute urticaria might follow some dietetic error and be accompanied by more or less severe constitutional symptoms. The chronic recurring form, however, was that which most exercised the skill and patience of the physician. True urticaria was not common in children, but papular urticaria, or lichen urticatus, was usually classified with it and was peculiar to childhood. A curious feature was that patients recovered directly they were admitted to hospital, even without treatment, and their rash recurred on discharge. Anaphylaxis did not always explain the reaction, and the term "sensitisation" had therefore to be used for the inexplicable predisposition to react to stimuli which had no effect on a normal individual. The antigen might be ingested, inhaled, or absorbed through the skin with identical results. The susceptibility apparently existed in the serum and was transmissible to offspring. When once sensitivity to one antigen was established, sensitiveness to others seemed to follow. The diversity of the causes of urticaria had long been recognised; Dr. Hallam thought that focal sepsis played a far greater rôle than food protein. Every case must be approached with the greatest circumspection and each system must be examined. Trauma might be an exciting cause. Should the offending antigen be detected, desensitisation might be attempted. Of empirical remedies, calcium salts were disappointing. If the exciting cause could not be discovered, thyroid extract was worth a trial.

Biochemical Investigation.

Dr. H. W. BARBER (London) discussed the biochemical investigations of Mr. G. H. Oriel and himself into allergy, which he characterised as the most important biological and medical problem that had ever existed. It represented the pathology of the reaction of man and the lower animals to their environment. It seemed clear that in the ichthyosis-asthma-hay-fever-eczema-prurigo-urticaria-migraine syndrome, in which there was almost invariably a strong family history, there must be some inborn metabolic kink predisposing the victim to become sensitised to various proteins. Dr. Oriel had discovered an "ether reaction" in the urine of certain cases of cardiac failure and also in urticarial subjects. The connexion between the two was probably some degree of hepatic insufficiency or some common factor concerned with the production of tissue œdema. The reaction was also positive in other allergic patients and in toxic jaundice; this supported the hepatic theory of its cause. The amino-acid content of the blood had therefore been estimated, and found to be high in untreated allergic patients, especially during attacks, but to return to normal when the condition remitted or was cured. Only a small number of estimations of urea, uric acid, and creatinine had been made, but these non-protein nitrogenous substances seemed also to be raised during the acute paroxysms. The rise in amino-acid might be partly accounted for by the presence of toxic amines of the histamine type, or might be merely an indication of the disturbance of endogenous protein metabolism. All allergic attacks were accompanied by almost complete suppression of chloride excretion, which became excessive immediately after recovery. The total blood chlorides were markedly diminished, whereas the serum chlorides might remain normal—i.e., there was a reduction in the corpuscle content of chloride. In simple urticaria the chloride reduction occurred during the attacks and was apt to return to normal in the intervals. Deposition of urates often occurred. This was not related to concentration or acidity but to the state of the urine colloids, and was always an indication (except after excessive sweating) of a temporary functional metabolic disturbance. To summarise the findings in the blood: just before and during the paroxysms there was a rise in amino-acid content, in uric acid, and creatinine, and a fall in total chloride—chiefly that of the corpuscles. In the urine there was a rise in free acidity; in ammonia excretion (the ratio of free acid to ammonia was altered); in specific gravity, owing to diminished water excretion; in excretion of amino-acid, creatinine, and uric acid. There was a retention of chlorides; urates often deposited on cooling; and ether reaction was strongly positive. After the subsidence of the paroxysm all these were reversed, diuresis occurred, and the urine often became alkaline.

Very large numbers of controls and of patients with all varieties of allergic disease had been tested and the results had been remarkably constant. It was probable that the increased ammonia excretion and the reaction of chlorides were protective mechanisms. These investigations suggested certain principles of treatment based on the idea that the central factor in allergy was hepatic insufficiency. These principles had proved successful clinically, and were of far wider application than at first appeared; it would enable us to prevent light sensitisation and the after-effects of treatment by deep X rays, arsenic, bismuth and gold, as well as the more strictly allergic conditions.

Discussion.

Dr. H. C. SEMON (London) asked why allergic phenomena did not occur more often in cases of undoubted hepatic insufficiency, and in what other diseases the investigations had been made. Certain cases of urticaria reacted very well to calcium injected intravenously; others to autohæmotherapy and protein shock, which was rather difficult to explain on Dr. Barber's hypothesis.

Dr. W. J. O'DONOVAN (London) pleaded for a more careful definition of "allergy" and of "hepatic insufficiency" than Dr. Barber had allowed. There were multitudinous ways of injuring the human system but few reactions, and he thought the way we reacted was Mendelian. There might be many causes for one disease which was a pattern reaction.

Dr. J. BEATTY (Cardiff) thought that liver insufficiency was too big a thing to have attributed to it one group of diseases alone. The liver was a microcosm of the body and would be disordered in any form of disease. Ephedrine might have an effect on intractable cases of urticaria, and atropine might be even better. Identical results would follow the prolonged administration of any kind of protoplasmic poison. It was a local skin weakness that determined the onset of urticaria rather than any other reaction to a protoplasmic poison released by hepatic inadequacy.

After several questions Dr. BARBER, in reply, pointed out that they had not claimed to have discovered the cause of urticaria, but had simply nvestigated the biochemistry of the allergic state. The causation was a much more complicated matter. llergic symptoms were common in liver disease—rurigo and itching, for example. One of the functions these allergic people was wrong, either from heredity r some other cause. Amino-acid estimations had been done in a very long list of other diseases. There was an initial acidosis in allergic states, and bicarbonate of soda might stop this. The calcium factor entered in relation to the vegetative nervous system; the irritability of the sympathetic largely depended on the calcium content. Protein therapy acted by desensitisation and preventing anaphylaxis. The liver was in some way responsible for anaphylaxis. The liver which could not be produced if the liver were cut out. He had used ephedrine and atropine, which undoubtedly acted through the parasympathetic system, on which the symptoms depended. Adrenalin acted on one phase only of the anaphylactic state. He thought it unjustifiable at present to speak of reatment.

Dr. HALLAM, in reply, expressed sympathy with peakers who had asked for guidance in treatment. t said there was no other way than to go stematically through the possible causes. He had en disappointed in autohæmotherapy. Cases varied y much and often got well by themselves; he eed that many were due to a *B. coli* leak through pelvic adhesions.

THE STEAM CAUTERY IN DERMATOLOGY.

This, said Dr. SEMON, was a most valuable destructive agent, especially when associated with vigorous use of the sharp spoon. It was better than diathermy, because there was no fear of breakdown of the apparatus, which was portable, cheap, and independent of lighting circuits. The penetration of heat was very slow, about an inch a minute, and it was therefore possible to determine when normal tissue had been reached and save penetration of cartilage or mucous membrane. Open ether should be avoided because of the open flame, and local anæsthesia was the best. The only hitch he had encountered was blocking by chalk deposits from the water; either distilled water should be used or the pipes should be cleared periodically with a piece of wire. There was never any charring, and a constant heat was well maintained and bleeding easily controlled, provided the apparatus was cleaned from time to time of the altered blood that crusted on to it. A striking feature was the absence of consecutive pain. The steam cautery was indicated for any accessible epithelioma, especially where cartilage and mucous surfaces were involved and X rays and radium therefore futile. It was useful for lupus verrucosus if the horny layer were previously macerated with salicylic acid plasters for a few days. The tuberculous nodule was blackened by the cautery and stood out against the white scar tissue. Soft chancres and chancroids were very menable, and the steam cautery would probably rove the method of choice for them. Granuloma yogenicum and intractable papillomatous leukolakia of the tongue had been cured (THE LANCET, ct. 8th, 1927). The tissue to be destroyed must be soft and free from horn, so that warts and unmacerated verrucose tumours were excluded. The coagulability of the tissue was important, therefore moles and fibromata were not amenable, but anthrax pustule and Delhi sore probably would be. The wound must be kept dry until the slough separated; ambrine was good for the raw stage and red lotion or scarlet red might be applied if the granulation were poor. There had been very few complications.

Dr. J. E. M. WIGLEY (London) suggested that electrical heating of the water would be more convenient, and mentioned the danger of local treatment of carcinomata, with which infected glands were so often associated.

Dr. SEMON, in reply, pointed out the value of being independent of electrical circuits and agreed that only local growths should be treated locally. The steam cautery was better than the knife in that it closed channels rather than opening them.

THALLIUM DEPILATION FOR RINGWORM.

Dr. WIGLEY recorded the treatment of 50 out-patient cases of both sexes, aged between 21 months and 9 years. Depilation had been spontaneous only in 50 per cent., and growth had been much more rapid than after X rays. On checking the cures by Wood's glass inspection he had found that many macroscopically normal hairs showed fluorescence, and the microscope revealed [illegible]. Hairs infected with endothrix [illegible] cuticle failed sometimes to fluoresce. [illegible] fail but the failures were not dangerous [illegible] of thallium were. Moreover, it was [illegible] out-patients to be certain of the [illegible] ment essential during the depilation stage [illegible] treatment. The older the child the more [illegible] the toxic symptoms. Physicians should be very chary of risking permanent damage to the growing organism for a treatment that was by no means a certain cure. There was great risk of reinfection of the growing hair, and he preferred X rays from every point of view.

Dr. BARBER agreed that thallium was very dangerous for older children though useful for young ones, who were unsuitable for X rays.

Dr. HALDIN DAVIS (London) doubted whether there remained any field for thallium; everyone agreed that it was dangerous to a child over 6, and younger children could be treated by X rays if given a 20-gr. dose of bromide the night before, the morning before, and half an hour before treatment. This was better for them than the psychic trauma of forcible restraint.

Dr. SEMON did not agree. The results of bad X ray treatment were appalling, and he had never heard of a fatal case of thallium poisoning. Toxic phenomena were probably due to keeping the hygroscopic acetate too long.

Dr. O'DONOVAN had abandoned thallium. The occasional catastrophes were no more reason for abolishing X rays than anæsthetic deaths were for abolishing chloroform.

Dr. HALLAM agreed with Dr. Semon, but thought both methods were bad. He had had 13 failures out of 42 out-patients treated with thallium, and seven had had severe toxic symptoms. Patients did much better if kept in bed throughout the treatment. The dosage ought always to be checked by a third person.

Dr. J. T. INGRAM (London) had had only three failures in 48 cases treated with thallium and would continue to use the drug for selected cases. Only one child had had toxic symptoms, and she had been over 8 years of age. It was important to have the patient under careful supervision during the period of depilation.

The CHAIRMAN agreed that neither method was satisfactory, but still kept an open mind for thallium.

ILL-EFFECTS OF SALVARSAN.

Dr. O'DONOVAN said that there were no [illegible] and recognised ill-effects of salvarsan therapy; ill-effects might follow small doses of any brand and might appear at any time. Alarming lists of untoward symptoms had been recorded, including headache, shivering, vomiting, dyspnœa, palpitation, fainting, cramps, diarrhœa, cardiac distress, jaundice, urticaria, and many other dermal reactions, Reynaud's syndrome, uterine hæmorrhage, epileptiform seizures, epistaxis, and hæmaturia. Many cases were lost sight of through dissociation of clinics from gen. and practitioners. Dr. O'Donovan then of a case of post-salvarsan melanode maculo-melanodermia with follicular in a French polisher, and a third of cutaneous abscesses associated with which the physician himself might not have the time, or perhaps the skill, to carry out. The physician did not make up prescriptions; they were made up by skilled people called chemists. If a medical man decided on ultra-violet light treatment he should put down on the prescription the light source, the area to be irradiated, the time, and so forth, and the administration of the treatment should be carried out by people trained in a particular way; that they should not be unskilled people was perfectly obvious.

SECTION OF DERMATOLOGY.

UNDER the presidency of Sir ROBERT BOLAM a discussion on

URTICARIA

was opened by Dr. R. HALLAM, who said that this complaint was both common and distressing. It served to impress on the dermatologist the fact that a change in the skin was often the expression of some pathological process in another part of the body, and that a knowledge of the latest advances in biology and physiology were necessary for its elucidation and treatment. Urticaria was not a disease but a symptom. Urticaria factitia or dermographism might or might not be accompanied by urticaria vulgaris but, curiously, did not irritate. Its incidence was higher in epileptics and alcoholics, although it occurred in perfect health. Acute urticaria might follow some dietetic error and be accompanied by more or less severe constitutional symptoms. The chronic recurring form, however, was that which most exercised the skill and patience of the physician. True urticaria was not common in children, but papular urticaria, or lichen urticatus, was usually classified with it and was peculiar to childhood. A curious feature was that patients recovered directly they were admitted to hospital, even without treatment, and their rash recurred on discharge. Anaphylaxis did not always explain the reaction, and the term "sensitisation" had therefore to be used for the inexplicable predisposition to react to stimuli which had no effect on a normal individual. The antigen might be ingested, inhaled, or absorbed through the skin with identical results. The susceptibility apparently existed in the serum and was transmissible to offspring. When once sensitivity to one antigen was established, sensitiveness to others seemed to follow. The diversity of the causes of urticaria had long been recognised; Dr. Hallam thought that focal sepsis played a far greater rôle than food protein. Every case must be approached with the greatest circumspection and each system must be examined. Trauma might be an exciting cause. Should the offending antigen be detected, desensitisation might be attempted. Of empirical remedies, calcium salts were disappointing. If the exciting cause could not be discovered, thyroid extract was worth a trial.

Biochemical Investigation.

Dr. H. W. BARBER (London) discussed the biochemical investigations of Mr. G. H. Oriel and himself into allergy, which he characterised as the most important biological and medical problem that had ever existed. It represented the pathology of the reaction of man and the lower animals to their environment. It seemed clear that in the ichthyosis-asthma-hay-fever-eczema-prurigo-urticaria-migraine syndrome, in which there was almost invariably a strong family history, there must be some inborn metabolic kink predisposing the victim to become sensitised to various proteins. Dr. Oriel had discovered an "ether reaction" in the urine of certain cases of cardiac failure and also in urticarial subjects. The connexion between the two was probably some degree of hepatic insufficiency or some common factor concerned with the production of tissue œdema. The reaction was also positive in other allergic patients and in toxic jaundice; this supported the hepatic theory of its cause. The amino-acid content of the blood had therefore been estimated, and found to be high in untreated allergic patients, especially during attacks, but to return to normal when the condition remitted or was cured. Only a small number of estimations of urea, uric acid, and creatinine had been made, but these non-protein nitrogenous substances seemed also to be raised during the acute paroxysms. The rise in amino-acid might be partly accounted for by the presence of toxic amines of the histamine type, or might be merely an indication of the disturbance of endogenous protein metabolism. All allergic attacks were accompanied by almost complete suppression of chloride excretion, which became excessive immediately after recovery. The total blood chlorides were markedly diminished, whereas the serum chlorides might remain normal—i.e., there was a reduction in the corpuscle content of chloride. In simple urticaria the chloride reduction occurred during the attacks and was apt to return to normal in the intervals. Deposition of urates often occurred. This was not related to concentration or acidity but to the state of the urine colloids, and was always an indication (except after excessive sweating) of a temporary functional metabolic disturbance. To summarise the findings in the blood: just before and during the paroxysms there was a rise in amino-acid content, in uric acid, and creatinine, and a fall in total chloride—chiefly that of the corpuscles. In the urine there was a rise in free acidity; in ammonia excretion (the ratio of free acid to ammonia was altered); in specific gravity, owing to diminished water excretion; in excretion of amino-acid, creatinine, and uric acid. There was a retention of chlorides; urates often deposited on cooling; and ether reaction was strongly positive. After the subsidence of the paroxysm all these were reversed, diuresis occurred, and the urine often became alkaline.

Very large numbers of controls and of patients with all varieties of allergic disease had been tested and the results had been remarkably constant. It was probable that the increased ammonia excretion and the reaction of chlorides were protective mechanisms. These investigations suggested certain principles of treatment based on the idea that the central factor in allergy was hepatic insufficiency. These principles had proved successful clinically, and were of far wider application than at first appeared; it would enable us to prevent light sensitisation and the after-effects of treatment by deep X rays, arsenic, bismuth and gold, as well as the more strictly allergic conditions.

Discussion.

Dr. H. C. SEMON (London) asked why allergic phenomena did not occur more often in cases of undoubted hepatic insufficiency, and in what other diseases the investigations had been made. Certain cases of urticaria reacted very well to calcium injected intravenously; others to autohæmotherapy and protein shock, which was rather difficult to explain on Dr. Barber's hypothesis.

Dr. W. J. O'DONOVAN (London) pleaded for a more careful definition of "allergy" and of "hepatic insufficiency" than Dr. Barber had allowed. There were multitudinous ways of injuring the human system but few reactions, and he thought the way we reacted was Mendelian. There might be many causes for one disease which was a pattern reaction.

Dr. J. BEATTY (Cardiff) thought that liver insufficiency was too big a thing to have attributed to it one group of diseases alone. The liver was a microcosm of the body and would be disordered in any form of disease. Ephedrine might have an effect on intractable cases of urticaria, and atropine might be even better. Identical results would follow the prolonged administration of any kind of protoplasmic poison. It was a local skin weakness that determined the onset of urticaria rather than any other reaction to a protoplasmic poison released by hepatic inadequacy.

was appointed medical officer to the Garw Valley Collieries, and remained connected with these collieries until 1916, when he resigned on grounds of ill-health. Dr. Parry was keenly interested in the welfare of miners and in the educational facilities available for their children, and did his utmost to improve conditions of hygiene in the mines. He was a J.P. of Glamorgan for many years, and at the time of his death was one of the senior magistrates in the county. During the war he acted as chairman of the Medical Recruiting Board for Glamorgan. He was a member of the first county council elected for Glamorgan and served on several other public bodies in the county.

Dr. HENRY WILLIAM JACOB died at Malvern on August 31st after a long illness. He had practised in Malvern since 1895, and of recent years had devoted much time to municipal affairs as chairman of the urban district council. Born in Dublin in 1866, Dr. Jacob studied science and then medicine at Trinity College, Dublin, taking his M.A. with a gold medal in natural science in 1890. He qualified M.D., B.Ch. and B.A. in the same year, and became a medical resident at the Adelaide Hospital, Dublin, and later house surgeon to the General Hospital, Birmingham. He practised at Taunton for a few years, when he acted as honorary physician to the Taunton and Somerset Hospital, and then moved to Malvern, where he soon became interested in the movement for developing the town and extending its amenities. His policy on the urban district council was progressive and vigorous, and the improvement in housing conditions and the provision of a public park and swimming baths in Malvern are largely due to his influence.

DONATIONS AND BEQUESTS.—Mrs. R. M. Bradshaw, of Mold, Flint, left £1000 to Liverpool Royal Infirmary for the endowment of a bed in memory of her late husband, Dr. Thomas Robert Bradshaw, consulting physician to the infirmary.—Mrs. F. W. L. Giles, Netherhall-gardens, Hampstead, left, subject to the life interest of her son, the ultimate residue of her property, about £10,000, to be applied for the general purposes of the mental hospital known as Cheadle Royal, Cheadle, Cheshire.—Miss E. M. Clauson-Thue, of Bournemouth, left the bulk of an estate of over £85,000 to charitable institutions. Amongst the bequests were £1000 to the Victoria Hospital, Bournemouth, for an "Edith Clauson-Thue bed"; £1000 to the Miller Hospital, Greenwich, to endow a "William Clauson-Thue bed" in memory of her father; £500 each to the London Homœopathic Hospital, the Royal Blind Pension Society, and the London Association for the Blind; £250 each to the British Home for Incurables, Streatham, and the Infant Orphan Asylum, Wanstead. After the death of a legatee the Hospital for Children, Great Ormond-street, the London Orphan Asylum, Watford, the Hospital for Consumption, Brompton, and the Evelina Hospital, Southwark, will each receive £720.—Mrs. A. Archer, Bournemouth, left £300 to the Royal Victoria and West Hants Hospital.—Mr. David McCausland, Belfast, left the residue of his property to his wife for life and then £1000 each to the Victoria Hospital, Belfast, the Ulster Hospital for Women and Children, the Children's Hospital, Queen-street, Belfast, the Incorporated Cripples' Institute, and Dr. Barnardo's Homes.—Dr. Frederick Durham left £100 each to the Royal Medical Benevolent Fund, the Royal Hospital and Home for Incurables, Putney, and the Northampton General Hospital.—Mr. William Foley, Birmingham, left £1000 to a legatee for life and then to be divided between the Birmingham General Hospital and Queen's Hospital, Birmingham. The residue to his wife for life and on her death, after other bequests, one-fifth each to the Royal Cripples' Hospital, Birmingham, the Birmingham and Midland Eye Hospital, Birmingham, the Birmingham and Midland Hospital for Women, the Birmingham General Dispensary, and one-fifth between the Birmingham General Hospital and Queen's Hospital, Birmingham.—Mr. Henry Charles Summers, of Forest Hill, London, left £500 to the London Hospital and £3000 to such charitable institution or institutions (and in such proportions) in England as the executors may select.—Sir William Forrest, of Leeds, left £1000 each to the Leeds General Infirmary and the Bradford Infirmary, and £500 to the Bradford Eye and Ear Hospital.—Mr. W. J. Boothroyd, chairman of the Board of Management of the Southport Infirmary, is contributing £1000 towards the cost of the extension of the institution.

EPIDEMIC (LETHARGIC) ENCEPHALITIS

To the Editor of THE LANCET.

SIR,—From your leading article of June 30t (p. 1333), and your annotation of Sept. 1st (p. 457 on the later manifestations of this disease, it is eviden that if we trace the after-histories of a group of patients who have suffered from an acute illness recognised as lethargic encephalitis, the conclusions we must come to are gloomy enough. The position, however, is even more serious than these analyses would suggest. If the relative numbers coming under my own observation are approximately those occurring over the whole country, there are a large number of cases who present no such history of initial illness and are, it seems, liable to escape timely recognition. They labour under some such diagnosis as "nervousness," "neurasthenia," "muscular weakness," or even, as in one case which came under my notice, "a puir cratur." Many of them are such a burden on their relatives that it is not to be wondered at if domestic sympathy is often strained to breaking point.

As you rightly point out, there are several different organisations under whose care these unfortunates may come and it is to be feared that each one, having other sheep to tend, may hope to see the unprofitable ones fed by another flockmaster. It is not inapposite to call these sufferers sheep, because their bearing suggests nothing else so much as that of a dumb animal. Indeed, they seem bereft of those very characteristics which have established man's supremacy in the animal kingdom. They even have difficulty in maintaining the erect posture. Here is a disease capable of taking frightful toll of its victims in mental deficiency and even criminal lunacy. It is notifiable and it is an undoubted fact that notification creates the impression that the body responsible for the care of a patient is the public health authority. That this is so in the acute stage, when the disease assumes epidemic proportions, is clear, but the real problem, and the lasting problem, is the care of the chronic encephalitic. When he is a certifiable lunatic, with or without criminal tendencies, he is comparatively easily disposed of. It is in the stage preceding this that he is so difficult to deal with and to the majority of these patients, I believe, benefit would accrue from institutional treatment. There is no occasion to put them in the infectious diseases' hospital; the voluntary hospitals are full and overflowing with patients of every description and the parochial hospitals do not carry either the atmosphere or the personnel to treat satisfactorily so highly specialised a condition. What is wanted is a hospital devoted to it alone.

The available accommodation under public authority at present is deplorably inadequate, and the matter is one of some urgency. In the last few months I have noted an instance of a girl standing in risk of her life in the middle of a crowded thoroughfare completely "mazed" who, when asked what she was doing, replied, "Would you show me the way to the infirmary?" Another case was that of a young man found wandering on the railway. Both of these are chronic encephalitics and I have no doubt such occurrences could be duplicated all over the country. It can scarcely be anticipated that effective prevention against this disease will appear for many years, and I would like to see the establishment at suitable points of encephalitic settlements. Scarcely a week passes but that some country house, whose owner feels the burden of existing rates too heavy, comes into the estate market. The acquisition and utilisation of such houses, each accommodating, say, 50 patients, would not, I think, be an insuperable difficulty. At tive dermatitis; over 40 "cold" abscesses had been opened and had yielded *Staphylococcus aureus*. Another patient had developed cutaneous and subcutaneous necroses, perforation of the nasal septum, and arsenical exfoliative dermatitis; his urine had contained *B. proteus*. Another man had had exfoliative dermatitis, had become very ill with fever and albuminuria, and his nasal septum had perforated. During convalescence he had had small boils and had then died of pulmonary embolism. Dr. O'Donovan felt it important that these uncommon ill-effects should be known, so that the practitioner learned not to use salvarsan unless there were facilities for transferring patients to hospital.

Dr. **Barber** asked if Dr. O'Donovan had tried preliminary large doses of glucose and alkali in sensitive cases; he believed this would prevent many toxic effects.

Dr. **Hallam** asked if sodium thiocyanate had been used for the dermatitis; he himself had not been quite satisfied with it.

The **Chairman** recalled extraordinary pigmentations after the dermatitis, and concluded that most of the dermatological troubles were due to too frequent doses of the drug.

Dr. **O'Donovan**, in reply, said he had no idea which patients were going to prove susceptible. It was not the poor, half-starved patients who proved sensitive. He had no confidence in sodium thiocyanate, though he continued to use it.

Corrigendum.—In the discussion on the Treatment of Diphtheria (The Lancet, Sept. 8th, p. 517) Dr. E. W. Goodall is reported as having tried antitoxin in doses up to 200,000 units. The figure should have been 100,000 units.

Obituary.

CRESSY LIVINGSTON WILBUR,

M.D. New York.

The death of Dr. Wilbur from pneumonia on August 9th has removed America's pioneer vital statistician. He was in his sixty-fourth year, having been born at Hillsdale, Michigan, the son of Rodney Wilbur and Frances Cressy. He studied medicine at the University of Michigan, qualifying from the Bellevue Hospital Medical College of New York in 1890, and from 1893 to 1905 he was in charge of the Division of Vital Statistics of the Michigan State Department of Health. It was Wilbur who drafted a model vital statistics law and helped to secure its adoption by several of the American States; he was also responsible for the standard death certificate now in general use. From 1906 to 1914 Wilbur was Chief Statistician of the Division of Vital Statistics of the U.S. Bureau of Census and it fell to his lot to edit two international manuals of causes of death. In 1914 Dr. Hermann Biggs, then newly appointed to the position he made so famous, secured the services of Wilbur for New York State, but failing health compelled him to resign this post two years later. Dr. Wilbur leaves many indelible impressions of his foresight and energy in the statistical legislation of the United States.

NANCY MABEL HIELD, M.B., B.S. Lond.

Dr. Nancy Hield, who died at her home in Highgate on Sept. 6th, was born in 1899, the younger daughter of the late John Heaton Hield and of Harriet Hield. She entered the London (Royal Free Hospital) School of Medicine for Women in 1917, and qualified M.B., B.S. Lond., in the spring of 1923, having also in this time passed the Primary Fellowship Examination. She was among the prize winners of her year, obtained a resident post at the Elizabeth Garrett Anderson Hospital immediately after qualification, and became successively house surgeon and casualty officer at the Royal Free Hospital, and house surgeon at the Cancer Hospital. She was later appointed clinical assistant to surgical out-patients at the Hospital for Sick Children, Great Ormond-street, and medical officer to the North Islington Welfare Centre. In 1925 she became M.R.C.S. Eng., L.R.C.P. Lond. She took a keen interest in her profession and particularly in the surgical side of it. It was while acting as surgical registrar at the Royal Free Hospital during the summer of 1927, and working for the Fellowship of the Royal College of Surgeons, that she became aware that her health was definitely impaired, and it was decided that she should undergo an operation for the removal of a thoracic growth. Later a definite diagnosis of lymphadenoma was possible. It was a cause of great distress to her that she should be compelled to relinquish any of her work, and in spite of considerable difficulties she continued part of it up to within a few weeks of her untimely death. A friend writes:—

"Though Dr. Nancy Hield was devoted to her profession, and an indefatigable worker, she had a zest for enjoyment, and shared fully in the diversions of her friends, whether at the hospital or in the home circle. She enjoyed dancing and tennis, and pleasant outings and pretty things, and of private theatricals she had an extensive experience. She was endeared to her many friends by a lively sense of humour, never more happily exercised than in describing experiences in the hospital casualty department. Responsibility put on her naturally impulsive and affectionate nature a certain reserve; but below that reserve lurked an unfailing sympathy with misfortune and suffering, and the warmest attachment to her chosen friends, among whom must be numbered a cocker spaniel, 'Mr. Brown,' acquired just before her last illness declared itself. Nancy Hield had strong opinions, especially on professional matters, and expressed herself with directness and force on such questions as the desirability of co-education in the medical schools. She was not tolerant of insincerity or false sentiment and apt to be impatient of obstructions. Perhaps for this reason even her closest friends were surprised by the stoic fortitude with which she faced a situation she knew must end fatally for herself. The nature of her illness could not be a mystery to her, but she bore with quiet dignity, through long distressing months, not only physical suffering but the knowledge of untimely closure of a career which had been full of promise and interest. She never let her courage or composure fail. It was as if she had resolved that her profession, which had no reason to be ashamed of her career, should also have no reason to be less than proud of her at its close."

John Davidson, M.B. Lond., whose death occurred last month at his home in Uxbridge, was born in 1858. He received his medical education at King's College Hospital, where he qualified M.R.C.S. Eng. and L.S.A. in 1879 and took his M.B. Lond. with honours in 1881. He served the hospital as resident accoucheur and also as house surgeon to Lord Lister. In 1882 he became a junior partner in a firm of practitioners at Uxbridge and in due course was appointed medical officer to the Uxbridge Joint Isolation Hospital and to the Hillingdon and Uxbridge Cottage Hospital, a post he held for 36 years. Dr. Davidson worked in Uxbridge for over 40 years, and on his retirement in 1925 a presentation was made to him by his patients and friends. His professional activities did not exclude other interests. He was an amateur actor and elocutionist of some merit and played cricket and bowls with enthusiasm and skill. He was a well-known climber and a member of the Alpine Club.

Dr. Edward John Parry, who died at his home in Dinas Powis on Sept. 3rd, aged 78, studied medicine in Edinburgh and qualified L.R.C.P., L.R.C.S. Edin. in 1879, becoming M.D. R.U.I. in 1881. On settling down to practice in his native country he was appointed medical officer to the Garw Valley Collieries, and remained connected with these collieries until 1916, when he resigned on grounds of ill-health. Dr. Parry was keenly interested in the welfare of miners and in the educational facilities available for their children, and did his utmost to nprove conditions of hygiene in the mines. He was J.P. of Glamorgan for many years, and at the time of his death was one of the senior magistrates in the county. During the war he acted as chairman of the Medical Recruiting Board for Glamorgan. He was a member of the first county council elected for Glamorgan and served on several other public bodies in the county.

Dr. HENRY WILLIAM JACOB died at Malvern on August 31st after a long illness. He had practised in Malvern since 1895, and of recent years had devoted much time to municipal affairs as chairman of the urban district council. Born in Dublin in 1866, Dr. Jacob studied science and then medicine at Trinity College, Dublin, taking his M.A. with a gold medal in natural science in 1890. He qualified M.D., B.Ch. and B.A. in the same year, and became a medical resident at the Adelaide Hospital, Dublin, and later house surgeon to the General Hospital, Birmingham. He practised at Taunton for a few years, when he acted as honorary physician to the Taunton and Somerset Hospital, and then moved to Malvern, where he soon became interested in the movement for developing the town and extending its amenities. His policy on the urban district council was progressive and vigorous, and the improvement in housing conditions and the provision of a public park and swimming baths in Malvern are largely due to his influence.

DONATIONS AND BEQUESTS.—Mrs. R. M. Bradshaw, f Mold, Flint, left £1000 to Liverpool Royal Infirmary for he endowment of a bed in memory of her late husband, r. Thomas Robert Bradshaw, consulting physician to e infirmary.—Mrs. F. W. L. Giles, Netherhall-gardens, mpstead, left, subject to the life interest of her son, the ultimate residue of her property, about £10,000, to be applied for the general purposes of the mental hospital known as Cheadle Royal, Cheadle, Cheshire.—Miss E. M. Clauson-Thue, of Bournemouth, left the bulk of an estate of over £85,000 to charitable institutions. Amongst the bequests were £1000 to the Victoria Hospital, Bournemouth, for an "Edith Clauson-Thue bed"; £1000 to the Miller Hospital, Greenwich, to endow a "William Clauson-Thue bed", in memory of her father; £500 each to the London Homœopathic Hospital, the Royal Blind Pension Society, and the London Association for the Blind; £250 each to the British Home for Incurables, Streatham, and the Infant Orphan Asylum, Wanstead. After the death of a legatee the Hospital for Children, Great Ormond-street, the London Orphan Asylum, Watford, the Hospital for Consumption, Brompton, and the Evelina Hospital, Southwark, will each receive £720.—Mrs. A. Archer, Bournemouth, left £300 to the Royal Victoria and West Hants Hospital.—Mr. David McCausland, Belfast, left the residue of his property to his wife for life and then £1000 each to the Victoria Hospital, Belfast, the Ulster Hospital for Women and Children, the Children's Hospital, Queen-street, Belfast, the Incorporated Cripples' Institute, and Dr. Barnardo's Homes.—Dr. Frederick Durham left £100 each to the Royal Medical Benevolent Fund, the Royal Hospital and Home for Incurables, Putney, and the Northampton General Hospital.—Mr. William Foley, Birmingham, left £1000 to a legatee for life and then to be divided between the Birmingham General Hospital and Queen's Hospital, Birmingham. The residue to his wife for life and on her death, after other bequests, one-fifth each to the Royal Cripples' Hospital, Birmingham, the Birmingham and Midland Eye Hospital, Birmingham, the Birmingham and Midland Hospital for Women, the Birmingham General Dispensary, and one-fifth between the Birmingham General Hospital and Queen's Hospital, Birmingham.—Mr. Henry Charles Summers, of Forest Hill, London, left £500 to the London Hospital and £3000 to such charitable institution or institutions (and in such proportions) in England as the executors may select.—Sir William Forrest, of Leeds, left £1000 each to the Leeds General Infirmary and the Bradford Infirmary, and £500 to the Bradford Eye and Ear Hospital.—Mr. W. J. Boothroyd, chairman of the Board of Management of the Southport Infirmary, is contributing £1000 towards the cost of the extension of the institution.

EPIDEMIC (LETHARGIC) ENCEPHALITIS.

To the Editor of THE LANCET.

SIR,—From your leading article of June 30th (p. 1333), and your annotation of Sept. 1st (p. 457) on the later manifestations of this disease, it is evident that if we trace the after-histories of a group of patients who have suffered from an acute illness recognised as lethargic encephalitis, the conclusions we must come to are gloomy enough. The position, however, is even more serious than these analyses would suggest. If the relative numbers coming under my own observation are approximately those occurring over the whole country, there are a large number of cases who present no such history of initial illness and are, it seems, liable to escape timely recognition. They labour under some such diagnosis as "nervousness," "neurasthenia," "muscular weakness," or even, as in one case which came under my notice, "a puir cratur." Many of them are such a burden on their relatives that it is not to be wondered at if domestic sympathy is often strained to breaking point.

As you rightly point out, there are several different organisations under whose care these unfortunates may come and it is to be feared that each one, having other sheep to tend, may hope to see the unprofitable ones fed by another flockmaster. It is not inapposite to call these sufferers sheep, because their bearing suggests nothing else so much as that of a dumb animal. Indeed, they seem bereft of those very characteristics which have established man's supremacy in the animal kingdom. They even have difficulty in maintaining the erect posture. Here is a disease capable of taking frightful toll of its victims in mental deficiency and even criminal lunacy. It is notifiable and it is an undoubted fact that notification creates the impression that the body responsible for the care of a patient is the public health authority. That this is so in the acute stage, when the disease assumes epidemic proportions, is clear, but the real problem, and the lasting problem, is the care of the chronic encephalitic. When he is a certifiable lunatic, with or without criminal tendencies, he is comparatively easily disposed of. It is in the stage preceding this that he is so difficult to deal with and to the majority of these patients, I believe, benefit would accrue from institutional treatment. There is no occasion to put them in the infectious diseases' hospital; the voluntary hospitals are full and overflowing with patients of every description and the parochial hospitals do not carry either the atmosphere or the personnel to treat satisfactorily so highly specialised a condition. What is wanted is a hospital devoted to it alone.

The available accommodation under public authority at present is deplorably inadequate, and the matter is one of some urgency. In the last few months I have noted an instance of a girl standing in risk of her life in the middle of a crowded thoroughfare completely "mazed," who, when asked what she was doing, replied, "Would you show me the way to the infirmary?" Another case was that of a young man found wandering on the railway. Both of these are chronic encephalitics and I have no doubt such occurrences could be duplicated all over the country. It can scarcely be anticipated that effective prevention against this disease will appear for many years, and I would like to see the establishment at suitable points of encephalitic settlements. Scarcely a week passes but that some country house, whose owner feels the burden of existing rates too heavy, comes into the estate market. The acquisition and utilisation of such houses, each accommodating, say, 50 patients, would not, I think, be an insuperable difficulty. At present it is impossible to do anything to restore the broken faculties of the encephalitic and any measures designed to prevent the onset of complete mental decrepitude in these sufferers are worthy of sympathetic study.

I am, Sir, yours faithfully,

Dundee, Sept. 7th, 1928. J. M. STALKER.

⁂ The situation is to some extent met in London where the Metropolitan Asylums Board has for the past three years allotted 100 beds at the Northern Hospital, Winchmore Hill, for children 3–16 years of age suffering from the after-effects of epidemic encephalitis. These beds, it seems, are now not fully occupied.—ED. L.

THE LATER RESULTS OF PARTIAL GASTRECTOMY FOR GASTRIC AND DUODENAL ULCER.

To the Editor of THE LANCET.

SIR,—In Mr. Flint's letter (p. 478) it is stated that no less an authority than Sir Berkeley Moynihan "has never seen an anastomotic ulcer develop after primary gastrectomy" for gastric ulcer. I have had one such case under my care.

A woman, aged 42, was operated upon by myself on May 23rd, 1923, for a gastric ulcer high up on the lesser curvature by the antero-Polya method. She remained perfectly well for two years. In June, 1925, she commenced having pain after food on the left side of her abdomen radiating round to the back. During these attacks, which lasted about three weeks, she vomited and thus relieved the pain. She vomited blood on two occasions. The intermissions between the attacks varied from four to six weeks. After admission to hospital X ray examination showed nothing very definite, but the history was so suggestive that on June 29th, 1926, a few days after blood transfusion, I operated upon her again. I found definite thickening of the anterior surface of the anastomosis in its lower third near the greater curvature of the stomach and extending into the jejunum. No definite ulcer could be felt, there was no narrowing of the orifice, there was no ulcer in the stump of the stomach. I excised the thickened portion and to the naked eye it appeared a typical anastomotic ulcer. It was examined at once by the pathologist, who reported that he thought a fragment of foreign body was present (? thread). Microscopically there was granulation tissue with many giant cells, but no definite ulceration was found. I reconstructed the anastomosis and made an entero-anastomosis between the entering and returning limb of the jejunum.

I have heard from this woman to-day stating, "since my operation in 1926 my health is generally much improved. I have had no pain or indigestion since." This is the only case that has come under my notice in a considerable number of gastrectomy cases for chronic gastric ulcer. Thread was used in this case for stitching the sero-muscular coats.

I am, Sir, yours faithfully,

Sheffield, Sept. 5th, 1928. ERNEST FINCH.

BLEPHARITIS SUCCESSFULLY TREATED BY AN AUTOGENOUS ANTIVIRUS.

To the Editor of THE LANCET.

SIR,—A woman sent to me for bacteriological treatment by one of the surgeons of the Central London Ophthalmic Hospital had been troubled with blepharitis for a number of years. For some time past the disease had been getting worse, so that when I first saw her it had reached a stage when it was seriously interfering with the ordinary routine of her life. Staphylococci were the only bacteria demonstrated in material taken repeatedly from the inflamed areas. Treatment was carried out by four distinct bacteriological methods, only one of which proved efficacious. The first method used was the administration of subcutaneous inoculations of stock polyvalent staphylococcus vaccine. This vaccine, having failed to produce any improvement in the condition, an autogenous vaccine was made and administered without any more favourable result. It was then determined to try the effect of Besredka's antivirus therapy. A stock antivirus was employed and handed over to the patient with the instructions as to its application. Although this particular batch of antivirus had given promising results in similar cases on former occasions, it failed to ameliorate the condition. At this stage the patient became sceptical as to the value of any treatment, and it was difficult to persuade her to continued efforts. However, she consented to have an autogenous antivirus prepared and applied, and within 24 hours of its first application in the form of a lotion to the affected parts improvement in signs and symptoms became manifest. Persistent treatment has led to what appears to be a cure of the condition.

In view of the intractable nature of the disease in question the case appears worthy of notice. It affords a near approach to a crucial experiment. The element of suggestion can certainly be eliminated, since the patient's faith had been reduced to a minimum or even to a negative quantity by a series of failures. The results obtained in this case, coupled with experience in other less dramatic cases, suggest that treatment by autogenous antivirus preparations should be tried in certain forms of eye disease.

I am, Sir, yours faithfully,

W. E. M. ARMSTRONG, M.D.

Weymouth-street, W., August 28th, 1928.

PAPWORTH COLONY AND SANATORIUM TREATMENT.

To the Editor of THE LANCET.

SIR,—Certain newspapers appear to have given the impression that in my address at Dublin I attacked sanatoria, but I can assure Dr. Walters that this was not the case. What I did say, and indeed have been saying for years, is that in a great number of cases the benefits of sanatorium treatment alone cannot be more than temporary and that the village settlement is an after-care scheme which meets all the requirements of the consumptive worker. Papworth exists entirely because it was found impossible for patients to follow the advice of the profession after they had had sanatorium treatment and returned to their homes. Public opinion and economic necessity are the principal enemies of the discharged sanatorium patient. At Papworth neither enemy is present, and consequently we are able to see what happens when the advice of the medical profession can be followed. That the results have been so entirely satisfactory is a welcome indication that the profession has made no mistake in this matter. The only difficulty is to convince people that to maintain sanatoria without village settlement is to put into practice only half the advice of the profession, and therefore to achieve results which cannot help being grossly disappointing.

I am, Sir, yours faithfully,

P. C. VARRIER-JONES,
Medical Director, Papworth Village Settlement.

Sept. 6th, 1928.

INSOLATION IN PULMONARY TUBERCLE.

To the Editor of THE LANCET.

SIR,—May I recall the attention of my colleagues to a point in the treatment of phthisis which seems to me in process of being overlooked—namely, that direct sunshine is a source of danger to patients who have not been warned to keep out of it? Doctors who only occasionally see cases of pulmonary tubercle do not get the opportunity of noting the deplorable results which may follow one "sun bath," and this in a patient who before was doing well in every way. Certainly, medical students do not recognise the danger, for they use the phrase "plenty of sunlight" when prescribing treatment, and the same idea is conveyed in some of the smaller text-books of medicine. As a patient in two sanatoria I have seen pyrexia, increased sputum, pleurisy, and hæmoptysis follow the first spell of fine summer weather, and I have observed in myself increased languor and malaise. Later on in summer, when the skin has become heavily pigmented, the risk of harm from the sun may be less, and for some reason harm s less likely to follow from walking in the sun than itting in it; but the danger to many patients is lways there, and those who have learned by experi- ice prefer to sit in the shade.

I am, Sir, yours faithfully,

August 30th, 1928.

M.R.C.S.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

THE following appointments are notified:—Surg. Comdrs. E. B. Kelley to *Champion*; W. P. Vicary to *Erebus*; and M. J. Aitken to *Calliope*. Surg. Lieut.-Comdrs. S. R. Johnston to *Caradoc* (on recommg.); S. G. Rainsford to *Centurion*; R. W. Nesbitt to *Victory*, for R.N. Hospital, Haslar, temp., and as medical Specialist; F. L. H. McDowel, T. N. D'Arcy, A. G. Bee, C. H. Savory, and G. G. Newman to *President*, for course of instruction; and T. Madill to *Victory*, for Royal Marine Infirmary, Portsmouth. Surg. Lieuts. E. V. Barnes to *Erebus*; A. A. Pomfret to *St. Vincent*; R. W. Mussen to *Danae*; E. J. K. Weeks to *Victory*, for R.N. Barracks, Portsmouth; H. W. Strong to *Fisgard*; W. J. Doody to *Calliope* and to *Cleopatra*; W. A. Hopkins to *Pembroke*, for R.N. Hospital, Chatham; D. M. Beaton to *Sutton*; P. H. Deeny to *Endeavour*, and on recommg.; D. R. Campbell to *Suffolk*; O. Watson to *Iroquois*; A. P. Anderson-Stuart to *Benbow*; and L. P. Sayers to *Godetia*.

Entries: M. A. Graham-Yooll has been entered as Surgn. Lieut., R.N., for Short Service, and apptd. to *Victory*, for R.N. Hospital, Haslar, for course of instruction, and R. E. G. Richmond has been entered as Surgn. Lieut., R.N., for Short Service, and apptd. to *Victory*, for R.N. Hospital, Haslar, for course of instruction.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Comdr. A. E. W. Hird, V.D., to *Victory*, for R.N. Hospital, Haslar, for training.

Proby. Surgn. Sub-Lieuts. R. M. B. Lewis and D. M. Craig to *Victory* for R.N. Hospital, Haslar, for training.

Surg. Lieut. H. G. Ungley, to *Victory*, for R.N. Hospital, Haslar, for training, and R. Russell to *Victory*, for R.N. Hospital, Haslar, for training, and to *Tiger*, to complete training.

ROYAL ARMY MEDICAL CORPS.

Maj. (Bt. Lt.-Col.) (temp. Col.) G. de la Cour, O.B.E., to be Lt.-Col., and to be supern. in that rank whilst holding the appt. of Consulting Surg. to the British Army.

Capt. A. H. Clarke, M.C., to be Maj. (Prov.).

The undermentioned to be temp. Lts.: G. F. Maher, A. R. Cowan.

General List: C. H. Wilson (late Surg. Sub-Lt., R.N.V.R.), to be Lt.

MILITIA.

Capt. L. A. B. Moore to be Maj.

ROYAL AIR FORCE.

The undermentioned Flying Officers are promoted to the rank of Flight Lt.: C. W. Coffey, J. Hutchieson.

Flight Lt. E. J. Mockler is granted a permanent commission in this rank.

INDIAN MEDICAL SERVICE.

Lt.-Col. S. H. Middleton-West, M.C., retires.

COLONIAL MEDICAL SERVICES.

H. R. Dive, Medical Officer, Federated Malay States, has been promoted to be Senior Medical Officer, Pahang.

The following appointments are notified: N. Chilton, Medical Officer, Tanganyika Territory; R. F. Pinson, W. Hunter, C. E. G. Nunns, Medical Officers, West African Medical Staff; F. J. Farr, Radiologist, Electrologist Medical Dept., Hong-Kong; A. J. McKinlay, Assist. Medical Supt., Lunatic Asylum, Barbados; A. W. Carleton, Colonial Surgeon, St. Helena.

ST. MARY'S HOSPITAL (PADDINGTON) RUBBISH COLLECTION FUND.—This fund, which was started on July 1st, 1927, had by the end of the year produced £380. The annual report asks the public to notify the hospital when old clothes, linen, &c., are available for collection.

Medical News.

UNIVERSITY OF LONDON.—The Connaught Hall of Residence at 14, Bedford-place, London, W.C. 1, recently presented to the University of London by the Duke of Connaught, will be ready for students of any of the colleges and schools of the University at the opening of the session in October. Mr. W. S. Angus has been appointed warden and Miss Burnett matron.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—At a meeting on Sept. 3rd, Sir Arthur Keith, F.R.S., was admitted to the Honorary Fellowship, and Dr. Samuel McMahon to the Fellowship, after examination.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.—The anniversary dinner will be held at the Hotel Victoria, Northumberland-avenue, at 7 P.M., on Wednesday, Oct. 3rd.

ROYAL DENTAL HOSPITAL OF LONDON.—The dinner of the past and present students will be held at the Trocadero Restaurant (Empire Rooms) on Oct. 20th, at 7 P.M. Mr. G. G. Campion will preside.

CHARING CROSS HOSPITAL MEDICAL SCHOOL.—Prizes will be distributed in the Out-patients' Hall of the hospital by Dr. T. Watts Eden on Thursday, Oct. 4th, at 3.30 P.M., to be followed by a reception at the school.

MIDDLESEX HOSPITAL MEDICAL SCHOOL.—The winter session will open on Tuesday, Oct. 2nd, when the introductory address will be delivered at 3 P.M. in the Queen's Hall by Mr. A. E. Webb-Johnson. Prizes will be distributed by Prince Arthur of Connaught, and Princess Arthur will present the Fardon Memorial Medals. The annual dinner will be held the same evening at 7.30 P.M., at the Savoy Hotel, when the chair will be taken by Prince Arthur.

THE first number of a new monthly journal, intended to keep members of the medical profession in touch with the latest developments in artificial sunlight therapy, medical radiology, and electrology, will be published on Oct. 1st. under the title, *The Actinic Practitioner and Electrotherapist*. Price 6*d*. Publishing offices at 139, High Holborn, London, W.C. 1.

MINERS' HOSPITAL, CAERPHILLY.—Extensions estimated to cost £40,000 are now being made to the Miners' Hospital, Caerphilly, South Wales. Accommodation for 50 new beds will be available when they are completed.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Four post-graduate courses are due to begin on Sept. 17th, each of them lasting for two weeks. Medicine, surgery, and the specialties will be dealt with at the Westminster Hospital, the whole of each day being occupied with lectures, demonstrations, and operations. The course in orthopædics to be held at the Royal National Orthopædic Hospital will also occupy the whole of each day, and that on diseases of children at the Queen's Hospital for Children, Bethnal Green. The course on diseases of the eye at the Royal Eye Hospital, St. George's-circus, London, S.E. 1, will be held each afternoon at 3 P.M.

A CANADIAN MEDICAL TOUR.—The members of the Canadian Tuberculosis Association, who are on a tour of European institutions, visited King Edward VII. Sanatorium on Sept. 7th, and were entertained to lunch, followed by a lantern demonstration by Sir StClair Thomson, who related his 17 years' experience as laryngologist to the institution. Dr. F. H. Pratten (London, Ontario), in proposing a vote of thanks, mentioned that the lead given by Midhurst had been followed practically throughout Canada, and that every sanatorium in Canada now had a laryngologist on the staff, the larynx in every case being systematically examined.

PIGMENTATION OF SKIN AND TUBERCULOSIS.—On Sept. 5th, at the Annual Congress of the National Veterinary Medical Association held at Newcastle-on-Tyne, the relative immunity from tuberculosis of the dark-skinned Jewish races compared with the blondes of Northern Europe was discussed. Mr. W. C. Miller, of Edinburgh, said that there was authority for the statement that certain races of cattle possessed of a light-coloured coat and hide contracted tuberculosis more easily than those with dark coats when they were put together in infected places. This contention was in accord with the statement of other authorities who had been compiling statistics of tuberculosis in the human race. The blonde individual with auburn, silky hair, and pale, freckled skin of fine texture, showed a greater degree of susceptibility to infection with tuberculosis than those of the Jewish race.

Bradford Mental Hospital.—A new mental hospital is to be erected at Bradford at a cost of £132,000, to house 400 patients.

Glasgow Refraction Hospital.—A refraction hospital, under the control of a committee of qualified opticians, is about to be opened in Glasgow. The principal object of the institution will be the provision of free sight-testing facilities, and the supply of glasses in necessitous cases, while classes will be conducted in connexion with the diplomas of the British Optical Association and the Spectacle Makers' Company. Patients found to be suffering from disease of the eye will be advised where to obtain professional treatment.

Appointments.

Anderson, J. S., has been appointed by the City Council of Leeds, as Medical Superintendent of Seacroft Hospitals.

Bebbington, Evelyn F., M.B., Ch.B. Liverp., D.P.H., Assistant Medical Officer for Maternity and Infant Welfare at Northampton.

Hancock, A. C., M.B. Lond., M.R.C.S. Eng., L.R.C.P. Lond., D.P.H., Medical Superintendent at Kent County Mental Hospital, Barming Heath, Maidstone.

Henderson, A., M.B., Ch.B. St. And., Assistant Medical Officer of Health for the county of Aberdeenshire.

Sheffield Royal Hospital: **Allott, E. N.**, M.B., Ch.B., B.Sc., full-time Assistant Physiologist; **Callcutt, J. Shirley**, M.B., Ch.B., Resident Surgical Officer; **Beattie, Wm.**, M.B., Ch.B., Senior Casualty Officer; **Maxwell, C. G.**, M.B., B.Ch., B.A.O., First Assistant Casualty Officer; **Patterson, W. J.**, M.B., B.Ch., B.A.O., Second Assistant Casualty Officer; **Rainsford, C.**, M.B., B.Ch., B.A.O., First House Physician; **Flint, A. O.**, M.B., Ch.B., Second House Physician; **Hynes, W.**, M.B., Ch.B., M.R.C.S., L.R.C.P., First House Surgeon; **Lynn, Alan**, M.B., B.Ch., B.A.O., Second House Surgeon; **Alcock, Wm.**, M.B., Ch.B., Ophthalmic House Surgeon; and **Marwood, V.**, M.B., Ch.B., Aural House Surgeon.

Vacancies.

For further information refer to the advertisement columns.

All Saint's Hospital (For Genito-Urinary Diseases), 49–55, Vauxhall Bridge-road, S.W.—H.S. At rate of £150.

Bath, Somerset and Wilts Central Children's Orthopædic Hospital, Combe Park.—Asst. Res. M.O. At rate of £120.

Birmingham and Midland Eye Hospital, Church-street.—H.S. £110.

Birmingham City.—Asst. M.O. £750.

Birmingham General Hospital.—Asst. S. £50.

Birmingham, Highbury Hospital.—Jun. M.O. £300.

Birmingham, Queen's Hospital Medical School.—Res. Anæsthetist. £70–£100.

[illegible] *Windlesham-road.*—H.S. £50.

[illegible] 2nd Asst. M.O. £200.

[illegible] *folk General Hospital.*—Res. H.S. £180.

Cairo, Egyptian University Faculty of Medicine, Dental School.—Lecturer in Dental Prosthesis, &c. £E480.

Cambridge, Addenbrooke's Hospital.—H.S. At rate of £130.

Chester, East Lancashire Tuberculosis Colony, Barrowmore Hall, Gt. Barrow.—Assist. M.O. £250.

Connaught Hospital, Orford-road, Walthamstow, E.—Sen. Res. H.S. At rate of £150. Also Jun. Res. H.S. and Res. H.P. Each at rate of £100.

Croydon, Mayday-road Hospital.—Res. Asst. M.O. £300.

Cyprus.—District M.O. £600.

Denbigh (near), North Wales Sanatorium.—Male Asst. Res. M.O. At rate of £200.

Derby, Derbyshire County Council.—Tuberculosis Officer. £750.

Evelina Hospital for Children, Southwark, S.E.—H.P. At rate of £120. Also Hon. Asst. Aural Surg.

Gloucestershire County Council.—M.O. for Maternity and Child Welfare. £750.

Gloucester, Gloucestershire Royal Infirmary, &c.—H.P. At rate of £150.

Hospital for Sick Children, Great Ormond-street, W.C.—H.S. Also H.P. Each at rate of £100. Also Part-Time Jun. Cas. O. At rate of £150.

Jersey General Hospital and Poor-law Infirmary.—Res. M.O. £200.

Leamington Spa, Warneford, Leamington and S. Warwickshire General Hospital.—Hon. Asst. S.

Leeds, St. James' Hospital.—H.P. and S. £200.

Liverpool, Liverpool Eye and Ear Infirmary.—Hon. Asst. Surgeon to Ear, Nose and Throat Department.

Liverpool Sanatorium, Delamere Forest, Frodsham.—Asst. to Med. Supt. £250.

London Lock Hosp., 91, Dean-st., W.—H.S. At rate of £200.

London Temperance Hospital, Hampstead-road, N.W.—Res M.O. At rate of £175. Cas. O. At rate of £120. Also H.P. At rate of £100.

Macclesfield, Parkside Mental Hospital.—Res. Clin. Asst. £75.

Manchester, Maternity and Child Welfare Centres.—M.O. £600.

Manchester, Monsall Hospital.—1st Asst. M.O. £600.

Manchester, Royal Infirmary.—Res. M.O. £200. Also Asst. M.O. and Asst. S.O. Each £35. Also Asst. Surg. O. for Central Branch £75.

Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Sen. Res. M.O. Also Asst. Cas. O. At rate of £140 and £100 respectively.

Miller General Hospital for South-east London, Greenwich-road, S.E.—[illegible]

National [illegible] .—Asst. P.

Newcastle [illegible] *rham, College of Medicine.* Asst. [illegible]

Nottingha [illegible] *d Infirmary.*—Res. Asst. M.O. [illegible]

Plymouth Homœopathic and General Hospital.—H.S. At rate of £150.

Plymouth, South Devon and East Cornwall Hospital.—Cas. H.S. At rate of £100.

Prince of Wales's General Hospital, Tottenham, N.—H.S., Special H.S., and H.P. Each at rate of £120. Also Jun. H.S. and Jun. H.P. Each at rate of £90.

Queen's Hospital for Children, Hackney-road, E.—H.P. Also Cas. O. Each at rate of £100. Also Physician-in-Charge Skin Department.

Richmond, Surrey, Royal Hospital.—Sen. H.S. At rate of £150.

Royal Free Hospital, Gray's Inn-road, W.C.—Cas. O. £150.

Royal Northern Hospital, Holloway, N.—Res. M.O. £200.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Cas. O. £150.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—Hon. S. [illegible]

Smethwick, [illegible] £600.

South Londc [illegible] *Clapham Common S.W.*—H.P. and 3 H.S.'s. Each at rate of £50.

Sudan Government Medical Department.—M.O. £E720.

Swansea Hospital.—Two H.S.'s. £150.

Swansea General and Eye Hospital.—Two Hon. Asst. S.'s.

Talgarth, near Brecon, South Wales Sanatorium, &c.—Asst. Res. M.O. £200.

West Bromwich and District General Hospital.—Cas. H.S. £200.

Weston-super-Mare Hospital.—Res. M.O. £130.

Willesden General Hospital, Harlesden, N.W.—Res. H.S. At rate of £100.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Dunstable (Bedfordshire) and Brighouse (York, West Riding).

The Home Secretary gives notice that in consequence of the death of Dr. J. E. Moorhouse, one of the Medical Referees under the Workmen's Compensation Act for the Stirling District of the Sheriffdom of Stirling, Dumbarton and Clackmannan, the appointment held by him is vacant. Applications for the post should be addressed to the Private Secretary, Scottish Office, Whitehall, London, S.W.1, and should reach him not later than Sept. 29th, 1928

Births, Marriages, and Deaths.

BIRTHS.

Brett.—On August 31st, the wife of Major Pierce Brett, M.B., R.A.M.C., Reserve of Officers, Churchfields, Salisbury, of a son.

Cane.—On Sept. 7th, at Reepham, the wife of Maurice H. Cane, M.R.C.S., of a daughter.

Fenton.—On Sept. 7th, the wife of W. J. C. Fenton, M.R.C.S., Mayors-lane, Barking, of a son.

Herman.—On Sept. 6th, at Tonbridge, the wife of A. E. Herman, F.R.C.S., of a daughter.

Haycraft.—On August 30th, at Cathedral-road, Cardiff, the wife of John Berry Haycraft, F.R.C.S. Eng., of a daughter.

Morley.—On August 28th, the wife of A. H. Morley, M.B., B.S. Lond., of a daughter.

Wishart.—On July 27th, at Toronto, Canada, the wife of D. E. Staunton Wishart, M.D., of a son.

MARRIAGES.

Cochrane—Asplin.—On Sept. 6th, at the Church of the Holy Cross, Milton, Northants, Thomas S. Cochrane, M.B., to Gwendolen May, daughter of Mr. and Mrs. Asplin, the Manor House, Milton.

Dickson—Souter.—On Sept. 5th, at King's College Chapel, Aberdeen, Alfred Thomson Barclay Dickson, M.B., Ch.B., to Isabel Elsie, eldest daughter of Prof. Alexander Souter, F.B.A., and Mrs. Souter, Humanity Manse, Aberdeen.

DEATHS.

Findlay.—[illegible] Findlay, M.B., C.M., of Nel[illegible]

Hield.—O[illegible] oma, [illegible] late Jo[illegible]

McCall.—[illegible] Graeme [illegible] aged 38.

Nash.—On Sept. 9th, at Queen Alexandra Military Hospital, Millbank, Colonel Llewellyn Thomas Manly Nash, L.R.C.P., late A.M.S., Richmond, Surrey, aged 67.

Parry.—On Sept. 3rd, at Dinas Powis, Cardiff, Edward John Parry, M.D., J.P., aged 78.

Wilson.—On Sept. 9th, at Fairwarp, Sussex, Albert Wilson, M.D. Edin.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

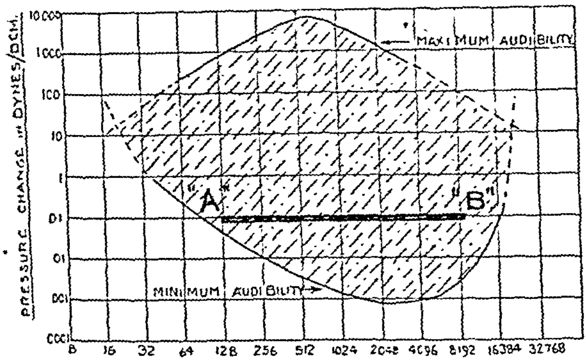
A GRAMOPHONE FOR THE DEAF.

By C. M. R. Balbi, A.M.I.E.E.

People who are not totally deaf but only "hard of hearing" are much isolated from their fellow beings because they are unable to hear general conversation. They suffer from an additional hardship if they also cannot hear instrumental or vocal music, since music can give especial pleasure to men whose life is spent for the most part in a world of silence.

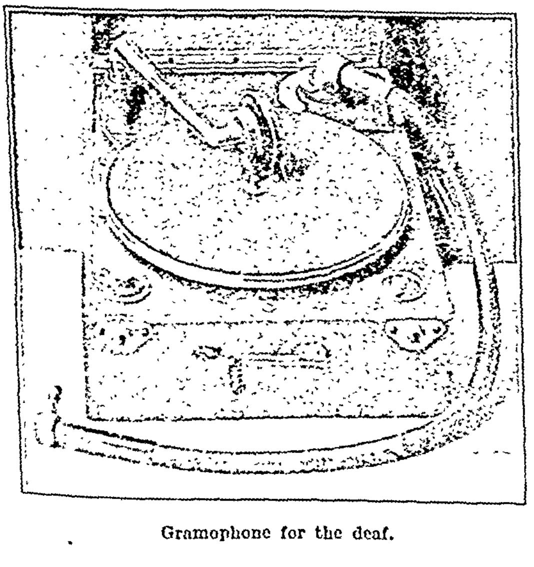
To meet the needs of those who are thus afflicted I have designed a gramophone which will produce a greater intensity than the ordinary instrument. The standard of sound intensity of an ordinary gramophone heard in a room is that of a piano or other musical instrument about equal. When this is expressed in the units of audiometric measurements * the standard may be said to vary about a mean of 0·1 dynes per sq. cm. (*root-mean-square pressure*) as represented by AB in the audiogram shown in Fig. 1.

Fig. 1.



Standard of sound intensity of a gramophone as represented by "A.B."

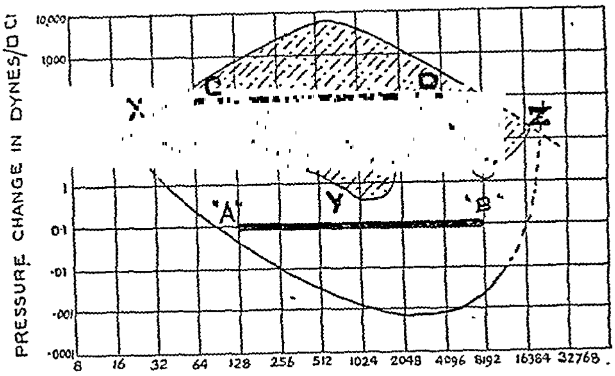
Fig. 4.



Gramophone for the deaf.

If we take an imaginary audiogram of a deaf person XYZ as shown in Fig. 2, then the level of the intensity AB would not be sufficient to make him hear. The intensity would have to be raised to the level CD—i.e., 100 dynes per sq. cm.—to make him hear, and means must be found to accomplish this. By examining the average intensity of sound at different points along the acoustic passages of a gramophone, such as are indicated in Fig. 3, it is found that the average intensities are as follows:—

Fig. 2.

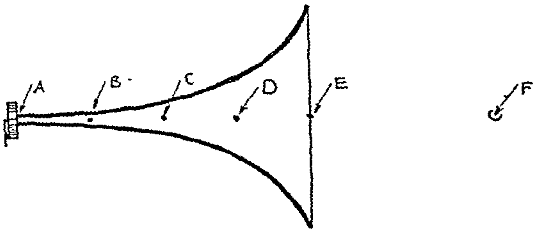


Standard of sound intensity required by a deaf person as represented by "CD."

Point A (sound-box)	.. ..	=*1100 dynes per sq. cm.*
„ B	.. ..	=1000 „ „
„ C	.. ..	= 100 „ „
„ D	.. ..	= 40 „ „
„ E (end of horn)	.. ..	= 10 „ „
„ F (6 ft. from end of horn)		= 0·1 „ „

The intensity at the point B in the horn would thus be more than sufficient to enable the deaf person represented by the audiogram XYZ to hear. It is an easy matter to tap the reproduced sound of the gramophone at this point and to conduct it to the ear of the sufferer by means of a flexible tube similar to that of a conversation tube.

Fig. 3.



Points in acoustic passages at which measurements were taken

This has been done, and in the special gramophone for the deaf which I have designed (Fig. 4) a further refinement has been added in the form of an adjustable volume control so that the deaf may regulate for themselves the intensity that suits them best. By listening at the special outlet provided the deaf are able to hear any recorded item or piece of music.

I have also designed on these principles a loud speaker which enables the deaf to obtain broadcast reception with the necessary apparatus.

"SOME CAUSES OF RACIAL DECAY."

In his Galton lecture delivered before the Eugenics Society on Feb. 16th last Mr. C. J. Bond inquired into the distribution of natural capacity in the population and the need for a national stocktaking. His interesting thesis was examined in a leading article which appeared in The Lancet of Feb. 25th (page 401). The lecture has now been reprinted by the People's League of Health in the form of an attractive pamphlet which can be obtained from the secretary of the League at 12, Stratford-place, London, W. 1, for 6d.

STUDENT'S GUIDE: SESSION 1928-29.

ADDENDA.

African Medical Officers.—In addition to the membership of the West African Medical Staff, which is limited to British subjects of European parentage, there are a number of Government appointments for African medical officers in the West African Colonies. These appointments carry a salary on the scale £500-20-£600, and there is a higher scale, £600-30-£720. In addition, in Nigeria and on the Gold Coast, arrangements have been made for the employment of a few young African medical men temporarily on the hospital staffs, with a view to appointment to the Government service later, if suitable. In such cases a salary of £400 a year is paid.

Diploma in Bacteriology.—Dr. H. S. Raper, Dean of the Manchester Medical School, calls attention to the fact that a diploma in bacteriology has been granted by Manchester University for several years, with some candidates each year. While no mention was made of this on page 420, the fact was noted under the heading Victoria University of Manchester, on page 381, that a diploma in bacteriology is awarded by examination to registered medical practitioners.

Ancoats Hospital, Manchester.—No mention was made of this hospital among the hospitals offering educational facilities to Manchester medical students. The honorary staff of the Ancoats Hospital give both undergraduate and post-graduate clinical instruction and a fair number of students attend the out-patient clinics. The hospital contains 114 beds and deals with 20,000 accidents and urgency cases per annum. There are six resident posts open to men and women. The General Superintendent and Secretary is Mr. Herbert J. Dafforne.

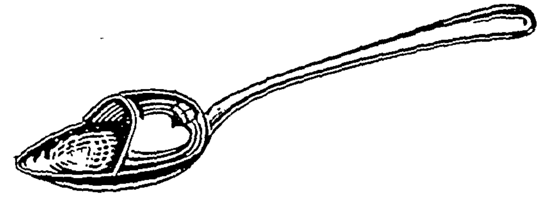
Since our Students' Guide was published a special number of the *Medical Officer* (Sept. 1st.) has appeared, containing full information as to degrees and diplomas in Public Health, along with an address on the Public Health Service as a career, by Dr. J. Howard Jones, President-elect of the Society of Medical Officers of Health.

The September issue of the *Edinburgh Medical Journal* is also a special educational number containing a concise guide (28 pages) to medical education in Scotland.

The *British Dental Journal* for Sept. 1st contains an address on Dentistry in its Relation to the Public Health Service, by Dr. W. M. Frazer and a supplement of 16 pages, giving the dental regulations adopted by the examining bodies and a useful idea of the cost of the dental curriculum in various centres.

A USEFUL SPOON.

THE "Verity" non-spilling spoon, of which we give an illustration, has been designed for administering medicine and other liquids to infants and invalids. In the ordinary horizontal position it holds one teaspoonful, and by tilting the spoon, or placing it upon the table after filling, the liquid runs into an enclosed part, from which it cannot be easily spilled. The inventor rightly believes that when an ordinary spoon is used for giving medicine to children a part of the dose is generally lost in transit, and sometimes too large a dose may be given because an inaccurate attempt has been made to compensate for this loss. Use of the "Verity" spoon should make for precision and should, incidentally, prevent sticky fluid from being spilt over clothing. It is obtainable at the price of 3*s.* post free from the sole distributors, Discon, Ltd., (Dept. S), 12, Henrietta-street, London, W.C. 2.



The "Verity" non-spilling spoon.

INDUSTRIAL METHYLATED SPIRIT AS A BEVERAGE.

IN the current number of the *Analyst* Mr. D. Henville, the Stepney public analyst, recalls the complaint of a number of persons charged with drunkenness at the Old-street Police Court last year that their symptoms were produced by the nature rather than the amount of the liquor imbibed. Neither methyl nor isopropyl alcohol, however, was found in the class of wine complained of and the abnormal symptoms remained unexplained. Early this year, however, it was noted that industrial methylated spirit was being sold in the district as a beverage, and the discovery confirms the repeatedly observed ill-effects of methyl alcohol whenever it is taken into the human system. Some time ago attention was called [1] to some work done in the United States, in which it was sought to show that methyl alcohol was a relatively harmless substance. Mr. Henville describes a technique for the detection of isopropyl alcohol, based on its oxidation to acetone and the identification of the latter by means of the nitro-prusside reaction, by which as little as 0·1 per cent. can be detected in a liquid containing 10 per cent. of ethyl alcohol.

A PAMPHLET ON DISEASE IN CHINA.

ANY medical man on his way to take up work in China, especially if for the first time, would do well (if he can read German) to study on the voyage a pamphlet on "The Epidemiology and Tropical Diseases of China" (pp. 69, with 13 of bibliography added, price about 5*s.*) by Dr. E. G. Nauck, being the latest supplement to the *Archiv für Schiffs- und Tropen-Hygiene.* Dr. Nauck, formerly of the Hamburg Institute and recently on the staff of the Union Medical College, Pekin, discusses the history, pathology, industrial origin, and treatment of most of the important diseases of China. Like most German authorities, he generously honours the memory of Manson, who showed how the problems of tropical medicine were to be solved. He notes that much of our knowledge is due to missionaries and that antimosquito regulations were made in Hong-Kong so long ago as 1900. By directing attention to the many lacunæ in our information, he stimulates the reader to aim at completing them.

NEW PREPARATIONS.

Calsoma.—This preparation, which comes from the Abbott Laboratories, North Chicago, consists of the tribasic phosphates of calcium and magnesium, combined with sodium biphosphate, and magnesium citrate in effervescent form. The intention has been to provide a neutralising agent for excessive acidity without producing alkalinity, and the drug has been found to be a valuable gastric antacid. In our issue of June 16th last, when our present knowledge of alkaline salts as therapeutic agents in gastric disease was briefly summarised, it was pointed out that careful laboratory experiments by Messrs. Freezer, Gibson, and Matthews, which were published in Guy's Hospital Reports, indicated tribasic magnesium phosphate to be the most suitable agent for the rapid counter-action of gastric acidity. At the same time, experimenters made the suggestion that tribasic calcium phosphate, citrates, and calcium carbonate are almost equally effective. The manufacturers of calsoma, it would appear, have produced a preparation very closely following these suggestions. The effervescent powder is granular, is put up in two-ounce bottles, and for a single dose two teaspoonfuls are added to a glass of cold water and is taken after meals at the period which personal experience shows to synchronise with the onset of heartburn. For children under 10 years of age one teaspoonful is indicated. There is clinical evidence that in gastric ulcer the drug may be safely used over long periods.

Trinitrine Caffėinėe (Dubois).—This preparation has been sent to us by the Anglo-French Drug Co., 238A, Gray's Inn-road, London, W.C. In its new pharmaceutical form the drug is supplied in sugar-coated, soft-centred pills from which, when placed in the mouth and chewed the nitroglycerine is immediately liberated and absorbed, prompt action resulting. Each pill contains in addition to 3 cg. of trinitrin (1 per cent. sol.) 2 cg. of pure caffein, which is found to prolong the action of the trinitrin, while intended to counteract the weakness following on anginal attacks. The directions warn the consumer that the maximum dose in the 24 hours should be ten pills.

Hepatex is a concentrated extract of liver produced in the laboratories of Messrs. Evans Sons, Lescher and Webb, at Froston Lodge, Runcorn, in accordance with a method evolved by their own research workers. The liquid is so concentrated that 1 oz. contains the active principles of 16 oz. of fresh liver, and it can be taken undiluted in teaspoonful doses or in soup and similar vehicles. Hepatex is supplied in four-ounce bottles, which is sufficient for eight days' full treatment.

Medical Diary.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.
TUESDAY, Sept. 18th.—3.15 P.M., Dr. R. Wade: Anæsthesia.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.1:
MONDAY, Sept. 17th.—1.30 P.M.: Examination of the Ear.
WEDNESDAY, Sept. 19th.—1.30 P.M.: Examination of the Nose.

RHEUMATIC HEART DISEASE IN CHILDHOOD.

Delivered before the Medical Society of London

BY F. JOHN POYNTON, M.D., F.R.C.P. LOND.,
PHYSICIAN TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET; PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL.

LECTURE II.*

Delivered on Feb. 28th, 1928.

IN this lecture I shall discuss the advantage that I believe would result from basing the study of heart disease as far as possible upon its development in the young, and building upon this foundation the further manifestations of heart disease in the adult. This should be of particular value in the study of the infective diseases of the heart. We should teach first the earliest signs of cardiac disorder, those which occur at an age when the heart is at its greatest perfection, rather than the later and complex signs which distinguish a heart scarred by past disease r degenerated by alcohol or damage to the coronary essels. We should dwell upon the efforts made by he young heart to recover from an acute infection, and upon our knowledge of the factors that tend to prevent further infection and damage rather than upon minute differences in the action of cardiac tonics and their effects on a worn-out heart. We should indicate first of all how to prolong the life of the heart by prevention and anticipation, and thus create around the subject an atmosphere of hope rather than one of that melancholy which must surround our feeble efforts at combating chronic morbus cordis.

The physician with wide experience of the symptoms of heart disease in the young can best appreciate hose peculiar to the adult. In the rheumatic form f childhood all or any parts of the heart may be ttacked, and its study demands accurate clinical bservation, great patience, and watchful care in treatment, with a mind quick to appreciate and apply advances in knowledge, both therapeutic and strictly scientific.

It may be of service to put forward some features that have attracted my attention, for comparison with the experience of others, and to mention some of the landmarks which have seemed to me of value.

AGE OF ONSET.

The early age at which rheumatic heart disease may appear is remarkable and of vital importance. There are a few records of women suffering from acute rheumatism in pregnancy and of the detection of a murmur in the fœtus in utero. When I was pathologist at St. Mary's Hospital I made a post-mortem examination upon a two-days-old infant whose mother had suffered from rheumatic fever in pregnancy. The child was very cyanosed and the post-mortem examination showed large vegetations upon the mitral valve, spreading to the aortic and containing masses of streptococci. This case was the one which urged me to investigate the cause of acute rheumatism, and it is somewhat ironical that Paine and I spent our first two years in searching or Achalme's bacillus and discarding streptococci! have seen chorea with acute cardiac dilatation t 10 months, and a child with chorea and mitral isease at 2½ years, followed by rheumatic relapses nd definite mitral stenosis by the fourth year. These early cases are most instructive, on account of their clinical course and histories and because it is at this early age that we are likely to meet with considerable difficulties in diagnosis.

The highest incidence of rheumatic heart disease is, I believe, around the tenth year, and my statistics, based on over 1000 first attacks and compiled over 30 years, support this statement. My impression is that acute rheumatism is more frequent before the fifth year than is generally recognised, for in 1908 I had no great difficulty in collecting 52 cases, all under personal observation. Forty-three of them had organic heart disease, eight were fatal, and five were complete invalids. A review of the last 100 cases of acute rheumatism admitted to my ward at the Hospital for Sick Children, Great Ormond-street, showed that 13 had the first attack of rheumatism between two and five years. One died at 4 years and 11 months of carditis; six had organic valvular disease; four had repeated attacks of chorea and valvular disease; one had chorea; and one arthritis.

The following are five examples of early rheumatic heart disease.

1. A female, aged $4^{10}/_{12}$, 14 days before admission to hospital had a sore-throat followed by multiple arthritis, and then by carditis, which proved fatal.

2. A male, aged 4 years, living in a damp house, was brought to the hospital for chorea. He was found to have mitral endocarditis with an enlarged heart.

3. A female, aged 2¾, had for seven days suffered from a "cold." This was followed by chorea, mitral endocarditis, and cardiac dilatation. There were recurrences of rheumatism, and at 4 years she had obvious mitral stenosis.

4. A female, aged 4¼, living in a damp house, had been ailing for six months. There were wasting, anæmia, nocturnal pains in the joints, and later, arthritis. On examination there was great cardiac dilatation with mitral endocarditis. The cardiac lesion had been unsuspected.

5. A female, aged 14½, three months before admission had become pale and progressively more feeble without any definite symptoms, then followed a slight chorea, then carditis with venous thrombosis, pericarditis, broncho-pneumonia, and death.

MODES OF ONSET OF RHEUMATIC HEART DISEASE.

This question is one which must necessarily be closely associated with the problem of deciding what is to be considered reliable evidence of heart disease. There will always, I imagine, be cases that elude us, and in the absence of arthritis and chorea we must expect parents sometimes to fail in recognising that their children are ill. A great number of cases of rheumatic heart disease in childhood fall into one of two groups, the first beginning with a sore-throat, arthritis, and muscular pains, the second with chorea. Then comes a smaller group in which there is a severe and dangerous attack of acute rheumatism with carditis and many manifestations. We are then left with a group which may be called primary cardiac rheumatism. This is not a clear-cut division, for though rheumatism may undoubtedly attack the heart predominantly and without any other noticeable collateral sign of infection, closer investigation often reveals a sore-throat, some suspicious pains, or even a passing arthritis so evanescent as to be neglected. Or the child may have had a considerable period of poor health, losing weight and strength, and becomin anæmic and short of breath, nervous and irritable it may be feverish or troubled by night terrors o attacks of acetonæmia. Within this group is a smal subgroup of cases in which the onset commence with a startling disturbance of rhythm—e.g., a heart-block or auricular flutter.

First Signs of Heart Disease.

In the rheumatic child acute dilatation is the earliest evidence, and I am a strong supporter of the great value of percussion. When the late Dr. D. B. Lees was studying dilatation of the heart I traced out many cardiac outlines in normal and cardiac children, and in fatal cases tested their accuracy by needles driven into the chest at intervals along the line of tracing. I am convinced that in childhood the deep cardiac dullness can be accurately ascertained, but I do not say—and this I emphasise—that this holds good in the adult. The peculiarly light form of percussion needed requires careful

---

5482

practice, and I have repeatedly been able to convince students how accurate percussion can be once they have realised the method. It is difficult to imagine a more essential undertaking in the whole field of clinical cardiology. An early rheumatic dilatation in childhood may precede endocarditis and pericarditis, and may occur irrespective of either. The complete picture is well known: the quickened pulse, the feeble impulse, the outline enlarged to the right, the left, and sometimes upwards, the short first sound with sometimes a soft systolic bruit internal to the apex, and an accentuated pulmonary second sound. If we do not accept the value of dilatation we are driven for our first evidence to the signs of endocarditis or pericarditis, and thus overlook one of the cardinal principles in heart disease; that first thoughts should be directed to the myocardium. This view of the value of percussion is disputed, and I agree with Dr. John Parkinson that the most satisfactory proof of an early heart involvement is the demonstration by electrocardiogram of such an event as heart-block. I hold, however, that the most useful information is most often gained from demonstration of dilatation by percussion.

The usual type of dilatation is acute, but on very rare occasions it may be fulminating. Those who have seen this clinical landmark of heart disease—an acute asystole as the result of a fatal primary rheumatic dilatation—can never forget the ashen pallor, the vomiting and horrible restlessness, the running pulse and embryonic heart sounds, the rapidly enlarging liver, and the pulmonary œdema without any general dropsy, save a little puffiness round the ankles and possibly of the face.

Another more frequent type of dilatation, with an nteresting bearing upon adult heart affections, is the subacute and chronic type usually associated in childhood, as in adult life, with much nervous disturbance. The dilatation does not subside and the heart remains large and feeble for a long time. As a rule a triad of symptoms develops, due respectively to the heart, the nervous system, and the digestive system. As a result the children are breathless on exertion, and may have fainting attacks and cardiac pain. They have a rapid and sometimes irregular pulse, the rate of which is influenced so greatly by emotion that we are often doubtful how to divorce the nervous from the cardiac element. The heart beat may be forcible but is ineffective. They suffer from flatulence and dyspepsia, which further complicate the condition. They improve with rest and care but rapidly become fatigued by over-exertion, and quickly relapse if it is continued. In some of these cases one suspects either an element of hyperthyroidism or else that the child has had from birth a constitutional weakness of the myocardium, which may be soft, fat, and flabby. An important point is the absence of valvular damage, so that if the dilatation is overlooked the child's condition may be considered entirely due to "nerves," and if he is old enough to go to a boarding-school he is likely to receive scant sympathy from the "muscular Christian" order of schoolmaster.

After puberty the nervous symptoms come much to the fore, particularly with females. Cardiac pains intensify, and the result is a condition of debility, lack of confidence, and general uselessness, as exhausting for the friends as for the patient.

My view, founded on observation, that acute rheumatism may produce in childhood the condition of "irritable heart," is strengthened by my experience of "D.A.H." among soldiers, and receives interesting and valuable support from an unpublished investigation carried out by my friend, Dr. John Parkinson, when on active service. He analysed with much care the histories of 3000 soldiers suffering from medical illnesses. In the first 1000 he found 172 men who had suffered from a definite attack of acute rheumatism without valvular disease earlier in life, and in this 1000 20 per cent. of the total of 630 cases of D.A.H. were found in the rheumatic group. In the second 1000 170 gave the same history of previous acute rheumatism, and 20·5 per cent. of the 610 cases of D.A.H. fell in this group. In the third 1000 148 gave a similar history, and 17·4 per cent. of the 664 cases of D.A.H. were in the rheumatic group. Thus an investigation concerned only with adults reached the same conclusion, that acute rheumatism without endocarditis is one of the most important agencies in the history of the "irritable" heart.

DISTURBANCES OF RHYTHM.

The disturbances are probably the result of focal lesions in the connective tissue framework of the heart in the region of the bundle of His. The technical skill and necessary equipment for their study cannot be expected of physicians in general, and the exact significance of the electrocardiographic tracings is, in some cases, difficult to assess. A considerable bibliography has sprung up, and among the various papers those of J. Parkinson, Hope Gosse, and E. B. Gunson, in 1920, and A. E. Cohn and Homer Swift in 1924, are particularly helpful.

Sinus Arrhythmia.—The English writers remark that the presence of sinus arrhythmia does not signify that the heart has escaped infection, and with this my clinical experience is entirely in accord. They give a tracing that shows the combination of heart-block with sinus arrhythmia, and heart-block in acute rheumatism is evidence of myocardial damage.

Heart-block may vary from a mere prolongation of the P.R. interval to a complete block. H. G. Butterfield, in the volume of Heart for 1911–12, published a case which has always appealed to me. This was a girl, aged 16, who showed a partial heart-block for the last 11 days of her life while suffering from acute rheumatic carditis. After death a minute diplo-streptococcus was isolated from the pericardial exudation and inflamed valves. Aschoff's nodules were demonstrated in the myocardium, and a widely diffused inflammatory exudate, most intense in the region of the auriculo-ventricular node, was discovered. Naish and Kennedy [1] published a case of a boy of 16 suffering from carditis; similar changes were found in the auriculo-ventricular node. They also directed attention to the sudden onset of arrhythmia in a boy of 8. There could be no more striking example of complete heart-block, ushering in a very severe first attack of acute rheumatic carditis, than the case I published in the Archives of Disease in Childhood for February, 1927.

A boy of 13 developed a sore-throat and, four days later pain in the chest, fainting attacks, and vomiting. When I saw him there was obvious heart-block, the ventricles beating at 36, the auricles at 72, per minute. After about a week the block vanished, to be followed by arthritis, most severe chorea, and endocarditis of the aortic and mitral valves.

Several features in this case confirmed the observations of others—e.g., the transient block, in spite of the very severe carditis which followed; fever which was doubtless, in part, due to the sore-throat, and the early syncopal attacks which occurred before I saw the boy but which may reasonably be interpreted as of the Stokes-Adams type. Such cases are rare. A simple transient bradycardia may also occur in rheumatic carditis.

Auricular flutter may occur in childhood quite apart from rheumatism, and may even be congenital. In infancy the symptoms are remarkable—screaming, cyanosis, vomiting, drawing up of the legs, breathlessness and rigidity, cardiac dilatation, and sometimes acute failure. I have followed a case for years, but I have never met with such severe symptoms in acute carditis. Flutter must, I suppose, point to myocardial damage, though this may be quite transient and the flutter be a matter of seconds. When four months old this patient was nearly moribund from heart failure and had numberless attacks afterwards, yet now, at the age of 5, is well grown and much less liable to attacks.

Paroxysmal tachycardia may follow an attack of carditis.

---

[1] THE LANCET, 1914, ii., 1242.

Premature contractions are more commonly auricular than ventricular. Parkinson, Hope Gosse, and Gunson, pointing out the association of auricular premature contractions with flutter and heart-block, incline to the view that they are evidence of definite myocardial damage. Ventricular premature contractions are not so suggestive. There may be very considerable difficulty in distinguishing between premature auricular contractions and auricular fibrillation without electrocardiographic tracings.

Auricular fibrillation is a recognised feature in chronic rheumatic heart disease, and I saw a remarkable example in a boy of 12 who had an apparently well-compensated mitral stenosis. One day, in a hot sun, he bicycled many miles up and down hills and came home utterly exhausted and developed severe fibrillation. Sutherland has reported a case where it occurred in the acute stage of an early carditis, but I believe this to be very rare.

My conception of rheumatic disease of the myocardium is that in the acute carditis of childhood the general myocardial poisoning is the outstanding lesion in the production of clinical symptoms, and that, in comparison, the interstitial focal lesions are comparatively insignificant.

VALVULAR DISEASE.

The bead-like vegetations of early endocarditis, producing slight incompetence, could not in themselves cause any degree of dilatation, and the presence of actual valve deformity can only be ascertained by the constancy of a systolic murmur, which usually disappears with the dilatation. Later, if the mitral endocarditis is at all severe, the signs of hypertrophy will decide the point. There was at one time an idea that a systolic mitral murmur in a rheumatic child was of little importance. This is true enough from the mechanical aspect, both in adults and in the young, when the heart is stabilised, and the view was, I think, the result of a reaction against the vexatious and useless prohibition of exercise and ordinary activity. Nevertheless, in the rheumatic child, this murmur is an evidence of cardiac rheumatism and to this extent important, and we must certainly guard against any idea that mitral incompetence in childhood may not be most serious. In fact, such cases, when there has also been myocarditis, may run a disastrous course and never properly compensate. It may be the murmur that attracts our attention, but it is the condition of the myocardium that governs the situation. A well-known occurrence is the increase of intensity of a mitral systolic murmur when a child is once more renewing activity, and this may be brought forward as evidence of a mistake in treatment. On the contrary, however, provided the child is well and the impulse *firm and stable, it is a good sign. After* some years this murmur, even though loud and heard clearly toward the axilla, may gradually become

for shortness of breath, and I then found an advanced mitral stenosis.

Could any result be more disappointing? Yet I am not convinced that we had learnt all we might about the case, for at present the organisation for special convalescent hospitals is hardly perfect. These should be centres for clinical research as well as for supervision.

Tachycardia is sometimes transient and sometimes more or less continuous. I have noticed this symptom appear at the very onset of the cardiac disease, even before any mitral stenosis could have developed. The most conclusive of all my cases was the following.

A girl, aged 9, living in a damp house, which was liable to flooding, had been ill for four months. She had become very nervous, suffered from severe headaches, and finally developed chorea, for which I saw her in March, 1902. There was dilatation of the heart and a pulse varying between 120 and 150 per minute; the thyroid seemed a little enlarged. She was in hospital six months and never had signs of pericarditis or endocarditis, in spite of the persistent tachycardia. Many of her teeth were carious and were removed, after which the tachycardia quieted down. The explanation that it was the result of a chronic sepsis from dental suppuration was generally accepted. She remained in hospital four months after the dental extractions, leaving in June. In July she returned with severe tachycardia and great nervousness, but there was no pericarditis or obvious endocarditis, renal disease, or tuberculosis. In June, 1903, the house was flooded and she developed rheumatic pains and tachycardia. In August chorea developed again, but there was no cardiac murmur. In 1904 she had another attack of chorea, and now there were signs of mitral stenosis with tachycardia. In 1905 a further attack of chorea occurred, with tachycardia, and there was further evidence of mitral stenosis. I saw her for the last time in June, 1910; she was then aged 17, and in domestic service, with an enlarged heart and every sign of mitral stenosis. Upon any excitement the pulse-rate rose to 150 per minute.

Cases such as these lead me to dwell repeatedly upon the nervous element in the cardiac disease of rheumatic children, and they teach a lesson which I think is of value in the study of heart disease in adult life.

Lastly, even in childhood, malignant endocarditis may supervene upon a mitral stenosis, although I believe this to be rare.

The rare cases of congenital mitral stenosis show changes in the valve that point to a reaction to infection rather than malformation, and I believe that most of the mysterious cases of mitral *stenosis* are the results of a primary cardiac rheumatism. How insidious and unexpected such cases may be is exemplified by a boy, aged 5, who came under my observation for a mysterious nephritis with blood and casts in the urine. This condition lasted many weeks with only the slightest rise in temperature; during that time warning signs of mitral stenosis developed, but there was no other rheumatic manifestation. The renal condition eventually recovered, but two months later definite chorea appeared [illegible] practice, and I have repeatedly been able to convince students how accurate percussion can be once they have realised the method. It is difficult to imagine a more essential undertaking in the whole field of clinical cardiology. An early rheumatic dilatation in childhood may precede endocarditis and pericarditis, and may occur irrespective of either. The complete picture is well known: the quickened pulse, the feeble impulse, the outline enlarged to the right, the left, and sometimes upwards, the short first sound with sometimes a soft systolic bruit internal to the apex, and an accentuated pulmonary second sound. If we do not accept the value of dilatation we are driven for our first evidence to the signs of endocarditis or pericarditis, and thus overlook one of the cardinal principles in heart disease; that first thoughts should be directed to the myocardium. This view of the value of percussion is disputed, and I agree with Dr. John Parkinson that the most satisfactory proof of an early heart involvement is the demonstration by electrocardiogram of such an event as heart-block. I hold, however, that the most useful information is most often gained from demonstration of dilatation by percussion.

The usual type of dilatation is acute, but on very rare occasions it may be fulminating. Those who have seen this clinical landmark of heart disease—an acute asystole as the result of a fatal primary rheumatic dilatation—can never forget the ashen pallor, the vomiting and horrible restlessness, the running pulse and embryonic heart sounds, the rapidly enlarging liver, and the pulmonary œdema without any general dropsy, save a little puffiness round the ankles and possibly of the face.

Another more frequent type of dilatation, with an nteresting bearing upon adult heart affections, is the subacute and chronic type usually associated in childhood, as in adult life, with much nervous disturbance. The dilatation does not subside and the heart remains large and feeble for a long time. As a rule a triad of symptoms develops, due respectively to the heart, the nervous system, and the digestive system. As a result the children are breathless on exertion, and may have fainting attacks and cardiac pain. They have a rapid and sometimes irregular pulse, the rate of which is influenced so greatly by emotion that we are often doubtful how to divorce the nervous from the cardiac element. The heart beat may be forcible but is ineffective. They suffer from flatulence and dyspepsia, which further complicate the condition. They improve with rest and care but rapidly become fatigued by over-exertion, and quickly relapse if it is continued. In some of these cases one suspects either an element of hyperthyroidism or else that the child has had from birth a constitutional weakness of the myocardium, which may be soft, fat, and flabby. An important point is the absence of valvular damage, so that if the dilatation is overlooked the child's condition may be considered entirely due to "nerves," and if he is old enough to go to a boarding-school he is likely to receive scant sympathy from the "muscular Christian" order of schoolmaster.

After puberty the nervous symptoms come much to the fore, particularly with females. Cardiac pains intensify, and the result is a condition of debility, lack of confidence, and general uselessness, as exhausting for the friends as for the patient.

My view, founded on observation, that acute rheumatism may produce in childhood the condition of "irritable heart," is strengthened by my experience of "D.A.H." among soldiers, and receives interesting and valuable support from an unpublished investigation carried out by my friend, Dr. John Parkinson, when on active service. He analysed with much care the histories of 3000 soldiers suffering from medical illnesses. In the first 1000 he found 172 men who had suffered from a definite attack of acute rheumatism without valvular disease earlier in life, and in this 1000 20 per cent. of the total of 630 cases of D.A.H. were found in the rheumatic group. In the second 1000 170 gave the same history of previous acute rheumatism, and 20·5 per cent. of the 610 cases of D.A.H. fell in this group. In the third 1000 148 gave a similar history, and 17·4 per cent. of the 664 cases of D.A.H. were in the rheumatic group. Thus an investigation concerned only with adults reached the same conclusion, that acute rheumatism without endocarditis is one of the most important agencies in the history of the "irritable" heart.

DISTURBANCES OF RHYTHM.

The disturbances are probably the result of focal lesions in the connective tissue framework of the heart in the region of the bundle of His. The technical skill and necessary equipment for their study cannot be expected of physicians in general, and the exact significance of the electrocardiographic tracings is, in some cases, difficult to assess. A considerable bibliography has sprung up, and among the various papers those of J. Parkinson, Hope Gosse, and E. B. Gunson, in 1920, and A. E. Cohn and Homer Swift in 1924, are particularly helpful.

Sinus Arrhythmia.—The English writers remark that the presence of sinus arrhythmia does not signify that the heart has escaped infection, and with this my clinical experience is entirely in accord. They give a tracing that shows the combination of heart-block with sinus arrhythmia, and heart-block in acute rheumatism is evidence of myocardial damage.

Heart-block may vary from a mere prolongation of the P.R. interval to a complete block. H. G. Butterfield, in the volume of Heart for 1911–12, published a case which has always appealed to me. This was a girl, aged 16, who showed a partial heart-block for the last 11 days of her life while suffering from acute rheumatic carditis. After death a minute diplo-streptococcus was isolated from the pericardial exudation and inflamed valves. Aschoff's nodules were demonstrated in the myocardium, and a widely diffused inflammatory exudate, most intense in the region of the auriculo-ventricular node, was discovered. Paroxysmal tachycardia may follow an attack of carditis.

---

[1] THE LANCET, 1914, ii., 1242.

may arise in differentiating some cases of aplastic anæmia and acute leukæmia from acute rheumatism. In all three there may be sore-throats and obscure pains in the limbs. The cardiac signs also may be most puzzling, for in the primary anæmias a loud systolic mitral murmur may be audible, and when they are extremely severe a basal diastolic murmur may be detected. The pulse is rapid, and the first sound at the impulse so abrupt as to simulate very closely the lesion of mitral stenosis. In all three here may be fever, breathlessness, purpura, and some enlargement of the spleen. If the leukæmia shows a leucopenia, the differential count requires considerable skill, and the blood of an aplastic anæmia also requires skilled investigation. I have seen remarkable examples of the difficulty in the diagnosis of these cases, particularly when the original one of rheumatism has been made in error. The anæmia is generally more predominant in the blood disease than in rheumatism, and the so-called "rheumatic symptoms" usually resolve themselves merely into vague pains.

It is interesting to observe, when one of the curious remissions occurs in a primary anæmia, that almost all the cardiac signs also disappear, to recur with the relapse. This has no parallel in rheumatism.

THE THYROID.

It is possible that the thyroid gland may play a greater part in the disturbances of the heart in rheumatism than we realise. In this country Llewellyn Jones Llewellyn has for many years insisted upon its importance in rheumatic affections, and French writers have alluded to rheumatic thyroiditis in adolescents. I have recently seen four examples of thyroid enlargement with tachycardia, tremor, and acute rheumatic morbus cordis, though in none was there apparently any thyroiditis. The problem is difficult, for it is exceptional to find any obvious enlargement of the thyroid in children suffering from acute rheumatism, and so we are driven at present to the assumption that damage, if it is frequent, must be due to an increase or alteration in the secretion without any perceptible change in the size of the gland. Sometimes, but very exceptionally, I have noticed swelling of this gland in chorea, and in our ignorance of the nature of the rheumatic poisons and our knowledge of the remarkable nervousness of the rheumatic child we have reasons for investigating this subject further.

SUMMARY.

It is clear that endocarditis in all its phases can be studied in the child, but in the adult we are usually concerned less with the development of endocarditis than with the results it has produced by scarring. In the child we learn in detail the history of pericarditis, and, though rheumatic pericarditis may occur in a patient over 70, opportunities for a complete study in adult life are far fewer. We learn also from the first the importance of the myocardium, and in the child we get striking illustrations of the symptoms that result from its general damage. We see how the "weak heart" may arise, and how, in the adult, this may give way under stress and strain. We are led to appreciate the nervous element, which is of such importance in the history of heart disease at all ages, and to realise how early in life this element may assert itself. The remarkable vitality and recuperative power of the child's heart impresses upon us the necessity for studying the factors which in adult life sap this vitality. There is the natural decline of cardiac power with the arrival of old age, but there are also the acquired factors, such as atheroma of the coronary vessels, high tension, or he damage done by poisons such as alcohol. Realising he freedom of the child's heart from these dangers, and guided by our knowledge of juvenile rheumatic heart disease, we are more easily able to appreciate such differences in the behaviour of these damaged adult hearts as the appearance of angina pectoris, the sudden disaster of a coronary thrombosis, or the defeat of a heart in the long battle against the strain of hypertension. We can see more closely the essential difference between the rheumatic child who breaks down from the renewed attacks of the active disease and the adult who, surviving an early rheumatism, breaks down from the gross deformities of the valves which have been left as its legacy.

We can also appreciate more fully the differing character of the lesions and symptoms that occur when an infection of another type peculiar to adult life—the acquired infection of syphilis—attacks the heart and blood-vessels.

We bring with us the same mental attitude to adult heart disease that we do to the heart disease of the child, and are led instinctively to search for the early warnings and early events that lead to its development.

We find our most promising fields for the study of mitral stenosis, and probably of malignant endocarditis, in the young. We can also learn the best methods for the prevention and amelioration of morbus cordis.

Finally, a problem in the study of heart disease in childhood which may eventually need careful thought is this: how will arrangements be made for the student of the future to obtain a general view of acute rheumatism in its true perspective if, as seems possible, he is to be educated by an orthopædic specialist in rheumatic arthritis, by a neurologist in chorea, by a children's specialist in acute rheumatic heart disease, and by a cardiac specialist in chronic heart disease? What will he eventually know of the general disease "acute rheumatism"—the chief cause of morbus cordis in this country? Should we not remember, before it is too late, words of that great genius, Roger Bacon, "As with an eye torn out, or a foot cut off, so it is with the different departments of wisdom; none can attain its proper result separately, since all are parts of one and the same complete wisdom"? Realising that this was the central theme of his *opus magnus* and the guiding star of that mighty intellect, should we not pause and think?

THE REGULATION OF RESPIRATION.

A SUMMARY OF RECENT EXPERIMENTS.*

BY ROBERT GESELL, M.D.,
PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF MICHIGAN.

SEVERAL years ago, as a result of experiments on the effects of hæmorrhage and reinjection on pulmonary ventilation, I called attention to serious exceptions to the prevailing theories of respiratory control. For example, a systematic review of the relation of blood acidity to pulmonary ventilation revealed a more frequent inverse than a direct relation of pulmonary ventilation to the hydrogen-ion concentration of the blood. The common inverse relation of pulmonary ventilation to alveolar and arterial carbon dioxide pressure served as an exception to a primary control by changes in the arterial and alveolar carbon dioxide. Increased pulmonary ventilation associated with either low or excessively high alveolar oxygen pressure was an exception to the theory of the direct effect of oxygen on respiratory activity.

Our informaton on the chemistry of the blood, on the aerobic and anaerobic acid metabolism of the cell, and on the behaviour of the cell membrane to the movement of acid and base, hardly warranted the assumption of parallel changes in acidity within and without the metabolizing cell. The probabilities rather favoured a frequent occurrence of opposite changes in acidity within the cells and in the blood, and appeared to offer an opportunity of formulating an all-inclusive theory of respiratory control, avoiding the exceptions to the prevailing theories. In brief, a direct relation was assumed between the acidity of the respiratory centre itself and pulmonary ventilation.

---

* An address delivered at the opening of the university clinics and new medical laboratories at the University of Chicago.

a slight rise of temperature may rouse suspicion. The weakening of the second sound in the aortic area, with the development of a soft systolic murmur and then of a soft diastolic murmur to the left of the sternum are well recognised, but cannot be over-emphasised, for this lesion is more often overlooked than any. These cases develop along two lines; either the mitral or the aortic lesion becomes predominant, and before childhood is past we may recognise clearly that the patient is doomed to suffer from aortic disease. In severe cases of carditis, extreme damage may occur in a few weeks, and within a fortnight the pulse may have already acquired the Corrigan features. The pulse may even disappear when the arm is raised, and sudden death can occur before the age of 12. On the other hand, I believe that some aortic lesions are so slight as to be recoverable. I am led to this from clinical observation, and from examples in the post-mortem room of slight thickening of the cusps where no aortic lesion had been detected. No children are more nervous than the rheumatic ones with aortic lesions of any severity, and, even though the heart has apparently compensated, this nervousness and inability to stand school-strain is a striking feature.

MALIGNANT ENDOCARDITIS.

In my first lecture I dwelt upon the tendency for cases of aortic and mitral disease to develop malignant endocarditis in later life; this may also occur in childhood after what appears to be a severe recurrent attack of acute rheumatism.

A boy, aged 16, suffered from acute rheumatism with carditis at the age of 6, and after that had three more definite attacks. His mother had suffered from rheumatic fever. Three weeks before admission to hospital he had pains in the ankles and knees and round the heart, and his mother thought that it was another attack of rheumatism. He was anæmic and wasted, and there was irregular pyrexia, with signs of aortic and mitral disease and infarctions in the spleen and kidneys. After death none of the vegetations seen on the valves exceeded the size of a pea, but the sections showed masses of streptococci.

This was the type of case which interested Litten in 1899 and led him to believe that rheumatism was becoming more septic in type.

I think we are most likely to throw further light upon this form of endocarditis by studying its development in children and adolescents who are known to have rheumatic heart disease. I hope that in the future many valuable records of rheumatic cases of morbus cordis, supervised over years, will be published, and that an increasing volume of evidence upon the onset of the malignant type will be forthcoming. Shall we find then that the circumstances of the onset were indistinguishable from those of a rheumatic attack, or will there almost invariably be clear evidence of some new type of infective illness grafted on the rheumatism, or proof that the new infection occurs in cases in which we have never felt satisfied that the rheumatism has ceased to be active? Experience shows that in many adult cases we have no guide at all to the causation of malignant endocarditis, but continuous records of the histories of rheumatic heart affections may eventually enable us to decide upon the cause or causes for the break in the history which produces this condition. It is necessary in such an inquiry to dismiss entirely from our minds any classification of malignant endocarditis based on its duration, and to be prepared to find fulminating, subacute, and chronic cases all developing in the rheumatic heart.

Here again you will recognise that the study of heart disease in the young makes a sound basis for the study of heart disease in general.

A certain degree of aortic stenosis is not infrequent in combined aortic and mitral disease, and if it develops later in childhood and adolescence it may relieve the heart of some of its difficulties, but a predominant aortic stenosis appears to me to be very rare, though I have for some years been watching a boy who suffers from an extreme degree of stenosis.

Pericarditis.—The consideration of pericarditis as an entity apart from endo- and myocarditis greatly hampers the education of the student. It is easy to grasp the idea of an inflamed serous membrane pouring out fluid, which gradually subsides, leaving the pericardium adherent, but this does not represent rheumatic pericarditis. In childhood there is rarely much fluid poured out, and the wide area of cardiac dullness is mainly the result of dilatation due to myocardial weakness. There may be no fluid, but much thickening of the pericardium, and the main danger of pericarditis is the concurrent myocardial weakness. In fact, it is impossible to consider rheumatic pericarditis apart from the other factors in a carditis. Virulent carditis with pericarditis may be afebrile. Acute dilatation and an excited and rapid action of the heart may precede the appearance of pericardial friction by several days, and even by a week or more. There may be no distress, and in some cases the discovery of the lesion comes as a complete surprise. There are cases in which it does far less damage than a severe myocarditis, so that its occurrence, though always serious, is not necessarily alarming.

Recovery, in the sense that the child may be able to leave hospital, can occur under five years even when there are very severe general carditis, chorea, profound anæmia, numerous nodules, and severe polyarthritis. Extensive pleurisy and mediastinitis are very grave complications, leading as they do to the worst type of adherent pericardium. The occurrence of pericarditis without endocarditis suggests some infection other than rheumatic, but I believe it may result from rheumatism.

Lastly, in some cases we may see the wave-like character of the rheumatic infection: an outburst, then a remission, then another outburst and remission, in some cases prolonged over months.

Venous thrombosis is an interesting complication in the severe carditis of childhood; I have seen eight examples. Seven of these implicated the large veins of the head and neck, two including the superior vena cava. At one time I thought these thromboses might have been mechanical, for they had all been associated with severe carditis, and it seemed reasonable to suppose that pericardial adhesions might have been a factor. In the eighth case the occurrence of thrombosis at the lower end of the inferior vena cava in a boy suffering from severe chorea and an endocarditis from which he made a good recovery, negatived the mechanical explanation. A. F. Voelcker's case of chorea and thrombosis without any cardiac lesion is still more conclusive. The condition is probably an acute phlebitis of rheumatic origin. As a rule the first noticeable sign is an œdema of one arm and then, if it is extensive, of the chest and face; there may be pain, tenderness, and resistance along the veins. In one of the fatal cases the superior vena cava and all the tributaries were occluded, and there was a pulmonary embolism, due to soft clot being detached from the lower end of the thrombus in the superior vena cava. I have never seen venous thrombosis in any other form of heart disease in childhood, but there can be no doubt of its occurrence and reality in rheumatic carditis.

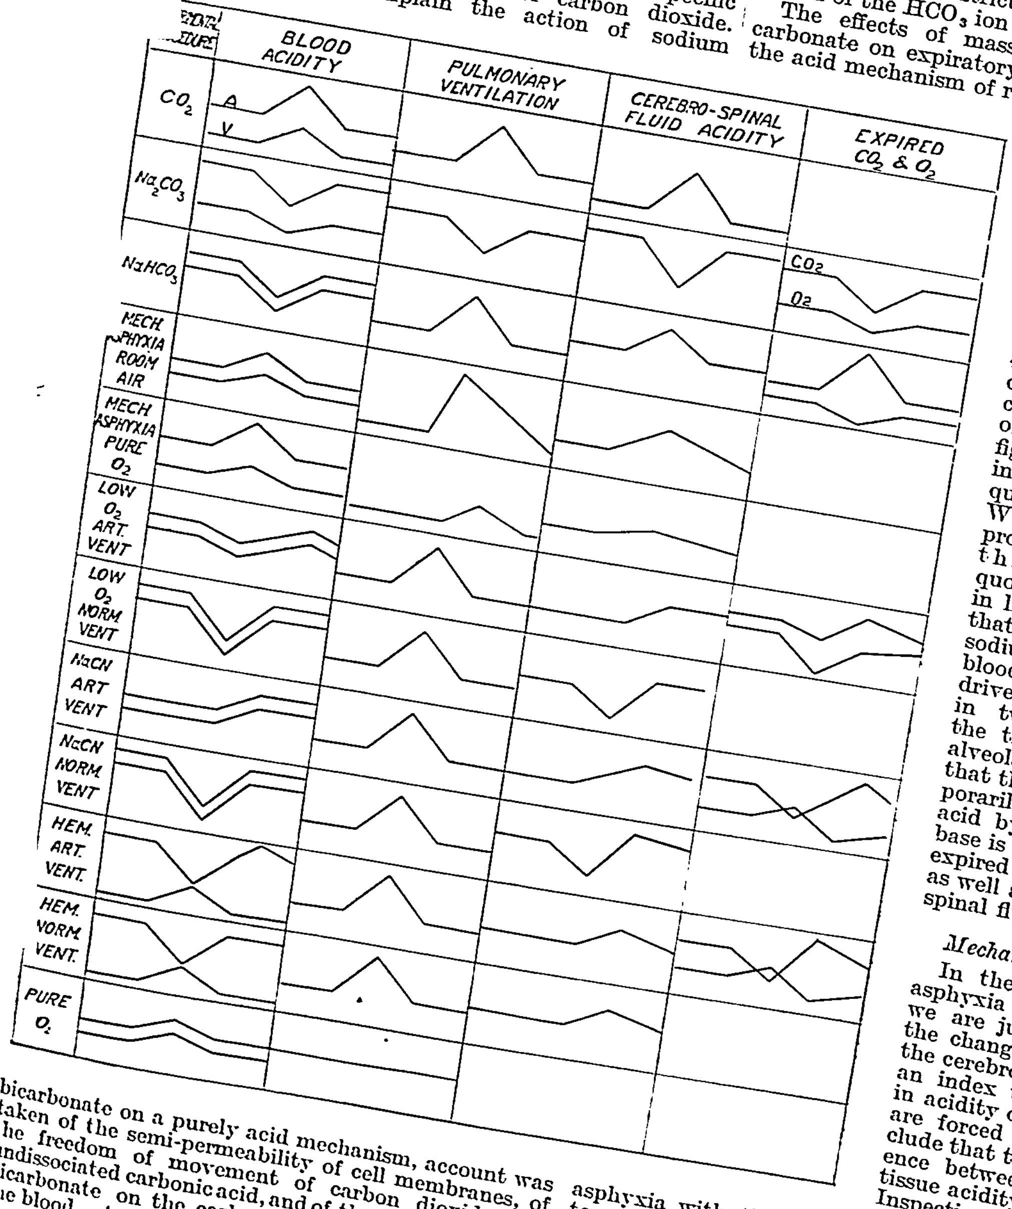
Gangrene of the extremities I have met with in the severe mitral stenosis of young children. Gangrene may also occur in the malignant endocarditis of rheumatic children from arterial occlusion; in one such case, complicated by a femoral aneurysm, the entire limb became gangrenous before death.

Except for a slight degree of *aortitis*, seen after death in a few cases, I have not met with a severe inflammation of the arteries in acute rheumatism (or, if it occurred, I have failed to recognise it), and I have never seen extensive implication of the arteries in any post-mortem examination on a rheumatic child. Vaso-motor spasm is sometimes a sequela of acute rheumatism and causes cyanosis of a limb or a Raynaud-like affection of the fingers and hands.

The striking *anæmia* produced by virulent rheumatism is thoroughly recognised, and difficulties primarily as a result of increased diffusion of carbon dioxide. On this point the experiments on sodium bicarbonate seem more to the point, but in any event the depressed ventilation appears to be associated with decreased acidity of the tissues.

The stimulating effects of intravenous injection of odium bicarbonate constituted one of the major ifficulties in arriving at a satisfactory theory of espiratory control, and led to theories of the specific ction of the HCO_3 ion and of carbon dioxide. attempting to explain the action of sodium bicarbonate on a purely acid mechanism, account was taken of the semi-permeability of cell membranes, of the freedom of movement of carbon dioxide and undissociated carbonic acid, and of the effects of sodium bicarbonate on the carbon dioxide buffer system of the blood. Assuming first that the addition of sodium bicarbonate affects the equilibrium of the buffer system with an increase in the freely diffusible carbon dioxide and carbonic acid, a back pressure of carbon dioxide is immediately established, retarding the normal movement of acid from tissue to blood. Increasing tissue acidity should result, granting that the semi-permeability of the cell membranes acts as sufficient barrier to the increased metallic kations. It is obviously extremely difficult to perform the direct experiment of following changes in acidity of a neurone of the respiratory centre with injection of sodium bicarbonate, but inasmuch as the cerebro-spinal fluid is separated from the blood by membranes which appear to possess selective action, it seemed worth while to determine the effects of intravenous injection of sodium bicarbonate on the acidity of the fluid. Increased acidity was found to occur. If we may infer that similar changes in acidity occurred within the brain cells, the respiratory response may be explainable on a strictly acid basis and the specific action of the HCO_3 ion abandoned.

The effects of massive injection of sodium bicarbonate on expiratory gases support the theory of the acid mechanism of respiratory control. It will be seen, for example, that t carbon dioxide eliminati is enormously increase Oxidations are also i creased but not in propo tion to the carbon dioxid elimination. In one experi ment the expired carbon dioxide was increased from 4·34 per cent. to 9·10 per cent., a total increase of 4·76 per cent. The associated increase in oxygen consumption amounted to only 1·6 per cent. These figures correspond to an increase in the expiratory quotient from 0·91 to 1·42. While several factors probably contribute to this high expiratory quotient, the results are in line with the postulate that the addition of sodium bicarbonate to the blood may momentarily drive the carbon dioxide in two directions—into the tissues and into the alveolar air. The view that the tissues may temporarily be turned more acid by the injection of base is thus upheld by the expired gas experiments as well as by the cerebro-spinal fluid experiments.



Mechanical Asphyxia.

In the mechanical asphyxia experiments, if we are justified in using the changes in acidity of the cerebro-spinal fluid as an index to the changes in acidity of the brain, we are forced again to conclude that the correspondence between blood and tissue acidity is uncertain. Inspection of the chart shows that mechanical asphyxia with the lungs filled with room air leads to a greater increase in acidity of the cerebro-spinal fluid than asphyxia with the lungs filled with oxygen, though the increase in acidity of the blood is considerably less. These acid-base relations in tissue and blood are presumably explainable by changes in acid metabolism at the cells, and in disturbances in the transport and elimination of carbon dioxide due to a broken coördination of the dual function of hæmoglobin. The increased acidity of the cerebro-spinal fluid is probably a result of impaired oxidations and impaired transport of acid, with a resultant diffusion of fixed and free acid into the fluid. The smaller increase in acidity of the arterial blood with the lungs filled with room air is traceable to the alkaline effect of liberation of free base, which goes hand in hand with progressive reduction of oxyhæmoglobin. A highly reduced blood, heavily laden with acid, incapable of the normal liberation of oxygen and base at the

With the use of various continuous methods, acute respiratory disturbances produced by administration of carbon dioxide, sodium carbonate, sodium bicarbonate, mechanical asphyxia, low and high alveolar oxygen, sodium cyanide, and hæmorrhage and reinjection were followed and analysed with respect to the acid base equilibrium of the tissues and body fluids.

The accompanying figure shows in a very schematic way the more outstanding results of our experiments. The first column tabulates the types of procedure, the second indicates the changes in acidity of the circulating arterial and venous blood, the third correlates the associated changes in pulmonary ventilation. The following column gives the changes in acidity of the cerebro-spinal fluid. the next shows the changes in expired carbon dioxide and oxygen using constant artificial ventilation, and the last column shows changes in carotid and femoral flow of blood.

An analysis of the second and third columns, showing changes in acidity of the arterial and venous blood and changes in pulmonary ventilation, will give a notion of the relation of pulmonary ventilation to blood acidity. The administration of carbon dioxide turns both the arterial and venous blood more acid, and pulmonary ventilation increases. Readministration of room air is accompanied by decreased acidity and a return to normal ventilation. Intravenous injection of sodium carbonate turns both the arterial and venous blood more alkaline, and pulmonary ventilation subsides. With recovery the blood swings back to normal acid values and ventilation increases. These observations fall into line with the older theory of respiratory control through the free hydrogen ions of the arterial blood, but the injection of sodium bicarbonate reveals an important exception. As the arterial and venous blood turn alkaline, pulmonary ventilation increases, and as the blood again swings, acid ventilation diminishes.

The next exception is found in the experiments on mechanical asphyxia with the lungs filled with room air, and with the lungs filled with pure oxygen. The gases were administered by artificial ventilation in volume sufficient to establish apnœa. The pump was then stopped. The changes in acidity of the arterial blood and the onset of respiratory movements were recorded. When the lungs were filled with room air, the acidity of the arterial blood increased slowly and respiratory movements came on rapidly. But when the lungs were filled with oxygen the acidity increased rapidly and the onset of increased respiratory movements was delayed. Another common exception to the theory of respiratory control by the free hydrogen ions in the arterial blood is seen in the effects of low alveolar oxygen, whether administered by artificial ventilation or by normal ventilation. In either case both the arterial and venous blood turn alkaline and ventilation is increased. On readministration of room air the blood turns acid and ventilation subsides. The intravenous injection of sodium cyanide may turn the arterial and venous blood either acid or alkaline, depending upon whether artificial ventilation is administered or whether ventilation is normally controlled. In either case respiratory movements are increased. The effects of cyanide may then be said to support and contradict the blood acidity theory of control.

Whether ventilation is artificial or normal, hæmorrhage turns the arterial blood more alkaline, at the same time increasing respiratory movements. Reinjection turns the arterial blood more acid and depresses ventilation. On the other hand, if we follow the changes in acidity of the venous blood, we find the relation between blood acidity and ventilation reversed. The increased acidity of the venous blood during hæmorrhage is associated with increased respiratory effort, and the decreased acidity following reinjection is associated with decreased respiratory effort.

To summarize, in three procedures there is a direct relation between the hydrogen-ion concentration of the arterial blood and pulmonary ventilation: the administration of carbon dioxide, sodium carbonate, or cyanide during constant artificial ventilation. In five procedures there is an inverse relation between the hydrogen-ion concentration of the arterial blood and pulmonary ventilation: intravenous injection of sodium bicarbonate, mechanical asphyxia, administration of a gaseous mixture low in oxygen, intravenous injection of cyanide during normal ventilation, and hæmorrhage. In all procedures other than hæmorrhage the directional changes in the acidity of the arterial and venous blood are the same. In hæmorrhage the directional changes are opposite. Despite the fact that the arterial blood, which flows more slowly through the lungs, is more thoroughly ventilated, both with respect to oxygenation and elimination of carbon dioxide, the highly alkalinized arterial blood, after passing through the tissues comes out more acid than normal. Obviously the slackened circulation through the tissues has resulted in greater acidification. This supports the view that acidity of the tissues may perhaps be a more important factor than acidity of the blood in the control of ventilation.

To follow up this view we may turn again to procedure number one. Though the administration of carbon dioxide turns both the arterial and venous blood more acid, the increase in acidity of the arterial blood is more abrupt and extensive than that of the venous blood. This suggests that carbon dioxide has passed from blood to tissues, so that the tissues have served as buffer to the blood. The slower return to normal acid values on the venous side on readministration of room air suggests the passage of accumulated carbon dioxide from the tissues back to the blood. The evidence is in favour of increased tissue acidity from administration of carbon dioxide. This is supported by the changes in hydrogen-ion concentration of the cerebro-spinal fluid. During the administration of carbon dioxide the fluid turns distinctly acid, and with the readministration of room air its acidity diminishes.

Effects of Sodium Carbonate.

When sodium carbonate is injected the picture is reversed. The presence of a free base capable of combining with carbon dioxide and lowering the carbon dioxide pressure in the blood leads to a greater movement of carbon dioxide from the tissues to the blood. A comparison of the acidity curves of the arterial and venous blood indicates the absorption of carbon dioxide by the blood as it passes through the tissues, for the increase in alkalinity of the arterial blood is relatively great compared with the increase in the venous blood. The decreased hydrogen-ion concentration of the cerebro-spinal fluid suggests the passage of carbon dioxide from the brain-tissue fluids into the blood.

The possibility of movement of free base from the blood into the tissue fluids should be also considered. In this respect the experiments on expired gases are helpful. Constant artificial ventilation is administered during pneumothorax; changes in expired carbon dioxide and expired oxygen indicate changes in carbon dioxide elimination and oxygen consumption. Upstroke on either record indicates an increasing content of either gas in the expired air. With a continuously administered gas, such as room air, upstroke on the carbon dioxide record indicates increasing carbon dioxide elimination, and upstroke on the oxygen record indicates decreasing oxygen consumption. Where the oxygen content of the gas is changed by administration, special analysis of the oxygen record is required to determine the changes in oxygen consumption. Inspection of the diagram of changes in expired gases on the injection of sodium carbonate during the administration of room air shows two changes, decreased elimination of carbon dioxide by the lungs and increased oxygen consumption. The coincidence of increased oxidation and decreased elimination of carbon dioxide is satisfactory evidence of the lowering of the carbon dioxide tension of the blood and accelerated movement of carbon dioxide from the tissues into the blood. It is, therefore. conceivable that the brain may have turned less acid, oxidative removal of lactic acid. It is interesting to note that the expiratory quotient may be reduced below normal during the recovery period, when carbon dioxide elimination may be considerably higher than normal. This marks a period of relative retention which soon gives way to absolute retention of carbon dioxide.

The changes in tissue acidity produced by cyanide and low oxygen are probably very similar, though the mechanism producing them is somewhat different. In each there appears to be an altered acid metabolism in favour of increased anaerobic production of acid, combined with a break in the coördination of the dual function of hæmoglobin. With cyanide administration the coördination is disturbed by a more or less permanently oxidised state of the hæmoglobin. Alkali is neither liberated in abundance at the tissues nor recalled in the lungs, for the tissues are unable to use the oxygen with which they are provided. With ow alveolar oxygen the coördination is disturbed by more or less permanently reduced state of the emoglobin. The tissues are unable to obtain the ygen which they could use.

Effects of Hæmorrhage.

Whereas the same directional change in acidity of e arterial and venous blood is the rule for most cedures, hæmorrhage is characterised by opposite anges in hydrogen-ion concentration. That this difference is attributable to the effects of volume flow of blood is clearly demonstrated by the fact that the arterial blood turns alkaline with hæmorrhage when constant artificial ventilation is administered as well as when augmented ventilation is permitted during normal control. Obviously the greater movement of air under normal conditions is not the sole contributing cause of the increased alkalinity of the arterial blood. It stands to reason that, if the degree of ventilation is a function of the amount of air to which a unit volume of blood is exposed in a unit of time, the ventilation of the blood may be increased by either augmenting the movement of air, or decreasing the flow of blood. The large increase in alkalinity of the arterial blood with constant artificial ventilation graphically illustrates the significance of volume flow of blood in the acid-base equilibrium of tissues and tissue fluids. Just as volume flow of blood through the lungs determines the alveolar and arterial carbon dioxide pressure, so does the volume flow of blood through the tissues determine the tissue and venous acid pressures. If decreased flow of blood through the lungs permits a more complete elimination of carbon dioxide per unit of blood, decreased flow of blood through the tissues must entail a greater accession of acid per unit of lood. Even granting an unmodified acid metabolism, diminished flow must lead to increased venous acid ressure with a damming-back of acid in the tissues. But adding to this the usual picture of impaired xidations with its associated disturbances in the dual nction of hæmoglobin, increased acidity of the tissues more clearly indicated. Certainly, if the arterial ood which has just been turned 0·3 to 0·4 pH more kaline as a result of hæmorrhage will leave the tissues distinctly more acid than normal, there is little room to doubt that the tissues have also turned more acid. In the expired gas experiments hæmorrhage reduced the oxygen consumption and carbon dioxide elimination, and reinjection of blood elicited typical carbon dioxide overshooting, associated with hyperconsumption of oxygen. A comparison of the curve of expired carbon dioxide and the arterial acidity curve will show the same correspondence as in the cyanide and low oxygen experiments with constant artificial ventilation. The increase in acidity of the cerebro-spinal fluid after hæmorrhage supplements the evidence for increased tissue acidity with decreased flow of blood and decreased acidity with increased flow of blood.

Conclusion.

Our experiments establish a lack of correspondence between blood acidity and pulmonary ventilation on the one hand, and indicate a correspondence between tissue acidity and pulmonary ventilation on the other hand. Granting that this relation is a causal one, we have advanced one step in the solution of the problem of respiratory control, but the exact mechanism by which acidity operates cannot be predicted until the problem of automatic discharge of rhythmically active cells is better understood. This, admittedly, is a fundamental biological problem of the widest scope. If the rhythmic discharge of the respiratory neurones is a membrane phenomenon, dependent on the structure and composition of the membrane and the nature of the fluid on each side of it, the relation between changes in the acidity of the immediate cell environment and changes in ventilation should be analysed as carefully as the data will permit. Up to the present no direct method has been employed for studying changes in acidity of the tissue fluids in the brain. The closest approach to the problem has been the study of changes in acidity of the cerebro-spinal fluid. If the assumption is correct that the cerebro-spinal fluid reflects changes in acidity of the tissue fluids in the brain, and if acidity is the primary factor in respiratory control, then changes in hydrogen-ion concentration within the cell rather than in the immediate cell environment is the predominant factor. This is indicated in the experiments on the effects of administration of low oxygen and of cyanide on the acidity of the cerebro-spinal fluid. When low alveolar oxygen is administered by artificial ventilation, the cerebro-spinal fluid may show no immediate change or may turn distinctly acid, but when the oxygen is administered by normal ventilation the change is sharply alkaline, yet ventilation is markedly stimulated under both conditions. When sodium cyanide is administered during artificial ventilation the cerebro-spinal fluid turns acid, but if it be injected during normal ventilation the change is alkaline. Respiration is stimulated in either procedure. While these results by no means indicate that acidity of the immediate cell environment is without effect upon the behaviour of the respiratory centre, they do suggest that changes in the acidity of the interior of the cell is a more determinant factor. However, the elaboration of this phase of the subject must remain in abeyance until further data are obtained.

The results here described represent the work of a number of individuals. The problem of respiratory control was an outgrowth of the studies on blood volume and tissue nutrition begun at the University of California in which E. Blair, C. S. Capp, F. Foote, C. A. Moyle, and R. T. Trotter participated. The work was continued at Washington University, where a theory of respiratory control was outlined and then at the University of Michigan, where several methods and procedures were developed to test the theory. C. S. Capp assisted in the preliminary experiments on the continuous registration of pH changes with the manganese dioxide electrode. These uncompleted experiments were continued the following year and the method applied to animal experiments with the help of A. B. Hertzman. The method for the continuous electrometric registration of volume flow of blood was developed with the help of D. W. Bronk, and the animal experiments continued with the help of D. W. Bronk, T. Bernthal, and N. Codero. The electrometric methods of registering changes in expired oxygen and carbon dioxide were developed with the help of D. A. McGinty, who also participated in the later animal experiments. In this brief summary of our work no effort is made to cover the work of others.

Bequest of a Body.—The late Mr. H. Reeve Everitt, solicitor, of Lowestoft and Norwich, left £100 "and my body to Dr. Arthur Cleveland, in order that he may arrange an autopsy thereon for the benefit of science, and I have left to him the before-mentioned legacy of £100 expressly to cover the cost of this operation and for a meeting of such members of the medical fraternity as he may choose to invite to discuss such unusual points o professional interest as may arise."

tissues, returns to the lungs with a small increment of carbon dioxide. Failure in oxidation at the lungs leads to retention of carbon dioxide by the blood. A highly reduced alkaline hæmoglobin is, therefore, in equilibrium with a relatively low alveolar carbon dioxide tension. During mechanical asphyxia with the lungs filled with oxygen a highly oxidised blood, lightly laden with carbon dioxide and capable of great liberation of oxygen and alkali at the tissues, returns with a large increment of carbon dioxide. Subsequent oxidation of the hæmoglobin at the lungs efficiently expels carbon dioxide. A well-oxidised hæmoglobin is in equilibrium with a high alveolar carbon dioxide tension. The high acidity of the oxidised hæmoglobin is thus indicative of an efficient transport of acid and suggestive of a correspondingly low acidity of the tissues. If this is true, the effects of mechanical asphyxia on respiratory movements with low and high alveolar oxygen pressure may also be placed on an acid basis.

Effects of Low Alveolar Oxygen.

Though the arterial and venous blood turn distinctly alkaline on the administration of low oxygen, the evidence points to a synchronous increase in acidity of the tissues. The major decrease in the hydrogen-ion concentration of the blood is a result of a higher state of reduction of the hæmoglobin with a consequent liberation of free base. This is established by a comparison of the effects of administration of the same gaseous mixture by constant artificial ventilation and by normal ventilation. In the latter, where the animal augments its ventilation, the alkalinity of the blood may be only moderately increased by additional washing-out of carbon dioxide. The increased alkalinity of the blood with normal administration of low oxygen may, therefore, be largely a result of a chemical change which is not related to improved elimination of carbon dioxide. To be sure, a reduction of oxyhæmoglobin at the tissues is conducive to a lowering of the carbon dioxide pressure in the blood and the maintenance of an effective diffusion gradient for the movement of carbon dioxide from the tissues. However, unless the blood is subsequently oxidised and freed of its acid at the lungs so that reduction may be repeated at the tissues, a highly reduced and alkalinised blood will not augment the elimination of carbon dioxide, but will rather lead to a retention of acid. To these conditions must be added the effects of impaired oxidations on the acid metabolism of the tissues, which complete the picture of a broken coördination of the dual function of hæmoglobin. In accordance with theory, not only is the transport and elimination of acid hampered but the formation is momentarily augmented as well.

Indirect evidence for impairment of oxidations and increased tissue acidity during a period of lowered alveolar oxygen is found in the changes in acidity of the blood on readministration of room air during constant artificial ventilation. There is a distinct acid overshooting of the blood. The arterial and venous blood turn more acid than normal and gradually return to the preadministration values. Apparently acid has been accumulating in the body though the blood was turning more alkaline. As further evidence we may note the effects of lowered alveolar oxygen on the hydrogen-ion concentration of the cerebro-spinal fluid. Lowered oxygen increases the acidity, and readministration of room air leads to recovery. The expired gas experiments add to the picture. With the administration of low oxygen the elimination of carbon dioxide falls off at once. If acid is being formed at the usual rate it must thus necessarily be retained. Readministration of room air promptly leads to increased carbon dioxide elimination, which gives way to overshooting and recovery. The carbon dioxide overshooting is accompanied by supernormal oxygen consumption, indicating impairment of oxidations during the period of lowered alveolar oxygen. It is interesting to note the correspondence of the blood acidity and the expired carbon dioxide curves with the administration of low oxygen and readministration of room air by artificial ventilation.

Though the evidence is favourable for increasing acidity of the tissues during the administration of low oxygen by artificial ventilation, it is not as decisive with normal ventilation because of the added washing-out of carbon dioxide from augmented ventilation. The acidity records of the blood under these conditions show decidedly less acid overshooting, particularly with short administrations of low oxygen; but when the administrations are prolonged and severe, distinct acid overshooting invariably occurs, despite the fact that ventilation may be greater than normal. This is evidence for excessive formation of fixed acids in the tissues and subsequent diffusion into the blood stream, for it is difficult to see how the blood can remain more acid than normal during hyperventilation unless the buffer base is reduced by fixed acids from the tissues. The ultimate increased acidity of the cerebro-spinal fluid is further evidence of increased tissue acidity from lowered alveolar oxygen.

Effects of Sodium Cyanide.

Though the initial effects of intravenous injection of sodium cyanide on the blood may be either acid or alkaline, depending upon whether artificial ventilation is administered or whether ventilation is normally controlled, the ultimate effect is increased blood acidity. Here, as with low alveolar oxygen, the acid overshooting is definitely greater with artificial ventilation. Nevertheless, the fact that hyperacidity ultimately results, despite the alkalinising effects of hyperventilation, indicates excessive diffusion of fixed acid from the tissues to the blood, which in turn indicates increased tissue acidity. This is supported by the ultimate effects of cyanide on the acidity of the cerebro-spinal fluid. With artificial ventilation the cerebro-spinal fluid turns acid, and slowly recovers as oxidations return to normal. With normal ventilation the cerebro-spinal fluid may temporarily swing alkaline with the blood, but later it turns more acid than normal. The lymph, as an intermediate fluid lying between the blood and the tissues, must be influenced by chemical changes in both. Knowing the abrupt reduction of oxidations in the tissues, the sudden reduction of carbon dioxide pressure in the arterial blood, and the rapidity of diffusion of carbon dioxide, it is not surprising to find an initial alkaline change with cyanide injection. Likewise, knowing the increased anaerobic formation of lactic acid and the slow diffusion of this acid, it is not surprising to note a delayed increase in the acidity of the cerebro-spinal fluid, although ventilation may be greater than normal. That oxidations are impaired by cyanide is well known and is apparent in the curves of the expired gas experiments. Immediately after injection expired oxygen increases, but with recovery decreases below the normal level. This delayed hyperconsumption of oxygen is a common sequel to the preceding reduction of oxidations, and may be looked upon as a compensatory phenomenon. Overshooting of carbon dioxide elimination accompanies hyperconsumption of oxygen. The changes in gaseous metabolism thus correspond with those produced by administration of low oxygen followed by readministration of room air. The curves of expired carbon dioxide agree in contour with the blood acidity curves when cyanide is given during constant ventilation.

The expired gas experiments in which the expiratory quotients were followed seem to indicate more explicitly the changes in acid metabolism occurring with cyanide administration and recovery. For example, during the early period of administration the expiratory quotient increases, and during recovery it may fall below normal. In one experiment the expiratory quotient rose from 0·98 to 2·02 and subsequently fell to 0·91. In another experiment it rose from 0·93 to 1·39 and fell during recovery to 0·82. The increased expiratory quotient during the initially decreased expiratory exchange is believed to agree with an increased anaerobic production of fixed acid. The subsequent decrease in the expiratory quotient is believed to agree with retention of carbon dioxide and with the dual mechanism of oxidative and non-ase No. 29; mentioned above, showed a striking infection on the fourth day of treatment—i.e., ter the intravenous injection of 300 c.cm. of serum. e primary focus was typical and about 30 mm. in meter, and was situated at the inner side of the ertion of the right deltoid. At first the patient eared to be making good progress, but on the th day there appeared a new crop of vesicles and acent inflammation covering an area of about sq. cm., extending almost to the elbow flexure. lue course a large superficial slough resulted. The subsequent ulcer was successfully overcome by skin-grafting.

Included in the series are two fatal cases. Both came late under treatment. One patient died 15 hours after admission, and the other, moribund on arrival, died four hours afterwards.

Diagnosis.

From the foregoing it is claimed that the early administration of anti-anthrax serum in sufficiently large doses has a marked curative effect in the disease. The recognition of cutaneous anthrax at an early moment is by no means easy, and consequently appropriate treatment may be seriously delayed. The city and port of Liverpool have the largest trade in wool, hair, and hides in the world; in the district there are many tanneries, &c. Hence the local medical practitioners are to some extent on the alert for the possibility of anthrax in the human subject.

An angry "pimple" or papule, without pus, surrounded by a disproportionately large inflammatory areola, especially if it is situated at or near a "rubbed" area, such as the collar or coat-cuff region, should arouse suspicion. Rapid increase of inflammatory redness and swelling, and the formation of a small dark centre with a ring of vesicles should demand instant action. Pain of an acute type is not always present. The term "pustule" is, in my view, unfortunate and misleading. I have not yet seen a "malignant pustule" in which, in the early sloughing phrase, there was any pus evident. The fully developed lesion is strikingly characteristic, showing the brown, purple, or purple-black centre, the ring of yellowish vesicles, and the red, hard, surrounding cellulitis, involving an area extending out of all proportion to the primary focus of infection. The occupation of the patient—e.g., butcher, farmer, tanner, dock labourer, or worker in hair, wool, or allied trades—may give a hint. The likelihood of infection from shaving brushes has now, fortunately, been minimised.

Discovery of *Bacillus anthracis* by examination of a film made from a swab taken from the part is, of course, conclusive evidence. Kneading of the lesion or rupture of a vesicle gives enough serous exudate with which to make a swab and culture. Usually the large Gram-positive anthrax bacillus is easily found, but I have met cases in which, though locally and constitutionally the evidence left no doubt as to the diagnosis of anthrax, the organism could not be found in a direct film, its presence being proved only by culture or animal inoculation. In any doubtful circumstance the wisest course is to give serum. The bacteriological confirmation can then be undertaken without any harmful delay.

Amongst other conditions sent to this hospital as anthrax are simple pustules, boils, carbuncles, insect bites, cellulitis, and accidental vaccinia.

Thanks to the efforts of Dr. A. A. Mussen, the medical officer of health, employers of wool and hair workers are with increasing frequency sending to the Fazakerley Hospital any person who may show even a slightly suspicious "spot" for examination. With the same object propaganda by means of posters about the docks and allied warehouses and factories in which hides, &c., may be handled, will render those concerned more alive to the benefits which follow early recognition and treatment of anthrax infection.

In the past year I have given anti-anthrax serum, empirically, in 10 c.cm. doses, subcutaneously, as a prophylactic, to persons definitely exposed to anthrax infection, in nine instances. These included sanitary inspectors, farmers, and slaughterers who handled the carcasses of cows which had died of anthrax. Although skin scratches or other open wounds were present, none of the men injected developed the disease.

In conclusion I gratefully acknowledge the permission of Dr. Claude Rundle, Medical Superintendent of the City Hospitals, Fazakerley, to describe the cases quoted.

THE TREATMENT OF EPIDERMOPHYTOSIS OF THE TOES (MANGO TOE) AND CERTAIN OTHER FORMS OF EPIDERMOPHYTOSIS BY A FUCHSIN PAINT.

By Sir ALDO CASTELLANI, Hon. K.C.M.G.,
M.D. Florence, F.R.C.P. Lond.,
PROFESSOR OF TROPICAL MEDICINE, TULANE UNIVERSITY, NEW ORLEANS, U.S.A.; DIRECTOR OF TROPICAL MEDICINE AND DERMATOLOGY, ROSS INSTITUTE; LECTURER ON MYCOSES, LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

EPIDERMOPHYTOSIS of the toes is extremely common in the tropics, where it is known by a variety of names—mango toe, Hong-Kong toe, Cantlie's foot-tetter, &c. In recent years the condition has become quite common also in countries situated in the temperate zones, including this country. It is caused, as proved by Sabouraud and Whitfield, by the same fungi that cause ordinary dhobie itch (tinea cruris, tinea inguinalis), the principal species of these fungi being *Epidermophyton cruris*, Castellani, 1905 (synonym *E. inguinalis*, Sabouraud, 1907), and *Epidermophyton rubrum*, Castellani, 1909. Both these fungi were found and described by me in Ceylon in cases of dhobie itch.

The treatment is most difficult as every tropical practitioner and every dermatologist can well testify; it is easy enough to induce a temporary disappearance of the symptoms, but a complete eradication of the infection is in many cases almost impossible, the condition usually recurring after a period of apparent cure. Three years ago, after carrying out a fairly large number of experiments, I introduced in the treatment of the condition a fuchsin paint which has given me very satisfactory results.

Formula of the paint.—The paint has the following formula: saturated alcoholic solution of basic fuchsin 10 c.cm., 5 per cent. aqueous carbolic acid solution 100 c.cm. Filter and add boric acid 1 g. After two hours add 5 c.cm. of acetone; two hours later add resorcin 10 g. The paint should be kept in a dark coloured bottle with glass stopper.

The paint is the ordinary carbol-fuchsin used in bacteriological laboratories for staining tubercle bacilli, to which 1 per cent. boric acid, 5 per cent. acetone, and 10 per cent. resorcin have been added. As a matter of fact simple carbol-fuchsin alone gives good results, but the addition of the boric acid and the acetone seems to enhance its action and make it more penetrating, and resorcin certainly increases its efficacy in most cases. It is applied to the affected parts with a small wad of cotton-wool or a small sponge every day, in some cases several times a day, or every other day or twice a week; if very acute eczematoid symptoms are present it may be diluted with the same amount of water, but usually it may be safely applied undiluted even to most acute eczematoid conditions provided they are of true epidermophytic origin. Certain cases—very exceptional—seem to answer better when the resorcin is omitted from the paint.

Epidermophytosis interdigitalis pedum (mango toe).—In all acute and chronic cases of epidermophytosis

THE SERUM TREATMENT OF CUTANEOUS ANTHRAX.

WITH NOTES ON DIAGNOSIS.

By ALBERT E. HODGSON, M.D. EDIN.,
D.P.H. CAMB.,
SENIOR MEDICAL OFFICER, CITY HOSPITALS, FAZAKERLEY, LIVERPOOL.

IN dealing with the treatment of cutaneous anthrax most modern text-books, whilst recognising the value of anti-anthrax serum and recommending its use, still advise surgical excision of the local lesion. During the past four and a half years the cases enumerated in the following table, which have come under my care, have been treated solely with serum, without any resort to excision of the "malignant pustule," the only local application being eusol fomentations.

Results of Serum Treatment.

No.	Age and sex.	Days ill on admission.	Site of lesion.	Serum injected in c.cm.	Number of injections.	Result.
1	42 F	5	Left cheek	400	5	Recovery
2	40 M	5	L. forearm	360	5	"
3	20 F	3	L. upper arm	80	3	"
4	40 M	2	Angle of jaw	220	4	"
5	22 M	5	Back of neck	645	6	"
6	49 M	4	R. forearm*	840	7	"
7	23 M	4	Lower lip	360	4	"
8	49 M	4	Neck, behind ear	370	5	"
9	22 M	3	Back of neck	270	3	"
10	34 F	3	L. cheek	180	3	"

Except on four occasions, when an intramuscular injection was made, the serum was given intravenously.
* Two foci. † 15 hours after admission.
‡ 4 hours after admission.

With few exceptions the intravenous route has been chosen for the injection of serum by reason of its prompt therapeutic effect, a distinct advantage in so rapidly ingravescent a disease as anthrax.

The usual glass funnel and tube apparatus is used and the gravitation method of injection is employed, the serum, &c., being warmed in a water bath at 100° F.

The possibility of the occurrence of anaphylactic symptoms must be borne in mind and, if considered desirable, a preliminary test injection of 0·5 c.cm. of serum subcutaneously, half an hour before the major injection, may be made. My experience has led me to omit this test injection, and to begin with 50 c.cm. sterile normal saline solution to which five drops of serum have been added. This is allowed to flow into the vein slowly. In the absence of any untoward signs the concentration of the mixture in the funnel is gradually increased until pure serum is passing. One of the veins in the ante-cubital space is usually chosen for the injection, though in fat subjects the dorsal veins of the hand are sometimes easier of access.

At all times, however, when giving an intravenous injection of serum, it is wise to have at hand a hypodermic syringe, ready charged with atropin sulph., gr. 1/100, for use in case of sudden respiratory spasmodic changes. Twice, in the series under review, have sudden cyanosis and threatened respiratory spasm caused some degree of alarm. In these circumstances the intravenous method has been abandoned and the serum given intramuscularly. Often the patient will complain of a feeling of oppression and heat, and may perspire; but these symptoms usually disappear as confidence increases with subsequent injections.

Dosage and Effects of Serum.

As in other therapeutic sera, no precise rule can be enunciated, but early administration, and that with a generous hand, is the first element of success. As will be seen by a reference to the table, my choice is definitely tending to a large initial dose and quick repetition of the injections, as circumstances demand.

Three factors which operate in each case are: (1) The duration of the disease when the case first comes for injection—i.e., the day of disease; (2) the degree of toxæmia; and (3) the site of the lesion.

Day of Disease.—The earlier the serum is given the more quickly and easily is the advance of the local lesion and the resultant absorption of toxins arrested. Up to three days, generally speaking, the disease is controllable, but after this the treatment rapidly becomes more anxious and prolonged.

Degree of Toxæmia.—The personal resistance of the patient has an undoubted bearing on this, and possibly there may be some variability in virulence of the infecting organism also, since it is noticeable that one case appears to develop signs of toxæmia more rapidly than another, whilst, on the other hand, the effects of the serum are more quickly shown in some cases than in others. A putty-like pallor of the face, listlessness, low tension pulse, sighing respiration, unduly raised temperature, and restlessness alone or variously combined are ominous.

Site of the Lesion.—An anthrax infection within or near the anterior triangle of the neck is always closely attended by the possibility of the swelling and œdema involving the root of the tongue, the pharynx, or particularly, the larynx, and hence this area demands an early large dose of serum in order, as promptly as can be, to limit local inflammatory swelling. Similarly a lesion near the eyelids may by subsequent sloughing produce disfiguring contracture. It may be taken as a rough rule that the further away from the neck that infection is located, the less likely is trouble to be encountered.

The effects of the serum are evidenced locally in about 24 hours by a cessation of further inflammatory swelling, the formation of vesicles abates, the temperature may be somewhat lower, and the patient feels easier. Later the induration shows a slow though definite decline and the part is less swollen. Coincident with these changes the temperature and the pulse-rate fall, usually by a lysis covering two, three, or more days, according to the severity of the case. Meanwhile the vesicles have ruptured or collapsed, and the central dark necrotic zone shows around itself a narrow ring of inflammatory "casting off" reaction. It is my practice to continue giving serum daily until the temperature has definitely fallen to normal level. In passing, I would emphasise that a reliable and fully potent serum is essential to successful treatment in a condition so rapid in its progress as anthrax. In the cases here tabulated I have used the serum of three different makers, and of these I must state that for potency and prompt antitoxic response that supplied by Messrs. Parke, Davis is definitely superior to the others.

The further behaviour of the cases, once serum treatment has been completed, is remarkably free from serious incident. Serum rashes, alone or accompanied by arthralgia and pyrexia, as might be expected after the administration of large amounts, were comparatively severe when they occurred, but a fair proportion of the patients escaped entirely.

The healing of the local focus varied in length of time from 14 days to 35 days, according to the area of the initial lesion and the mass of the resulting slough. Except in one case (No. 29) the final scar was comparatively unnoticeable. One man (No. 14), a mild case, reported to me that he had frontal neuralgia for three months after his scar had healed.

solution and 6 c.cm. of hen's serum. The final dilution of the inoculum was thus 1 in 100. The mixture was distributed in amounts of 2 c.cm. into Carrel's tissue culture flasks,[1] ype D, which were incubated aerobically at 37° C., without aps. The cultures were tested after various periods of cubation by grinding the whole of the contents of each sk with sand and centrifugalising. The supernatant fluid s controlled for the presence of bacteria by aerobic broth culture and titrated as outlined above.

Experimental.

Expt. 1. Titration of the Primary Inoculum.—The first titration was made at the time the inoculum was prepared. The highest dilution tested, 1 in 500, produced a lesion. A second titration, made after he inoculum had been stored in the ice-chest for en days, resulted in a dilution of 1 in 2500 producing lesion. A dilution of 1 in 12,500 caused no reaction.

Expt. 2. First Series of Cultures of Virus.—After storage for six days in the cold room the primary inoculum was used for the first series of cultures. The titre of the inoculum was 1 in 2500 (Expt. 1), and its dilution in these cultures was 1 in 100. Cultures were titrated in duplicate. The results are summarised below.

After incubation for 1 day, 1 in 125 pos.*
" " 3 days, 1 in 625 pos.*
" " 5 " 1 in 625 pos.*
" " 7 " 1 in 3125 pos.*
(Pos. = vaccinia lesion. Neg. = no vaccinia lesion.)
* Highest dilution tested.

Expt. 3. Second Series of Cultures of Virus.—The inoculum for this series was the supernatant fluid from a culture of Expt. 2 which had been incubated for five days. It was free from bacteria as tested by aerobic culture in broth, and had been in the cold room for four days before it was used for this experiment. The dilution of the inoculum in these cultures was 1 in 100. Cultures were titrated in duplicate.

After incubation for 1 day, 1 in 5 pos., 1 in 25 neg.
" " 5 days, 1 in 625 pos.*
" " 8 days, 1 in 625 pos.*
* Highest dilution tested.

A dilution of 1 in 625 in this series represented a dilution of 1 in 625×10^4 of the primary inoculum.

Expt. 4. Third Series of Cultures of Virus.—The inoculum was the supernatant fluid of a five-day culture from Expt. 3. It had been in the cold room for two days, was free from bacteria as tested by erobic culture in broth. and was diluted 1 in 100 in tting up the cultures. Cultures were again titrated duplicate.

After incubation for 1 day, 1 in 5 pos., 1 in 25 neg.
" " 5 days, 1 in 625 pos.*
" " 8 days, 1 in 625 pos.*
* Highest dilution tested.

A dilution of 1 in 625 in this series represented a dilution of 1 in 625×10^6 of the primary inoculum.

Expt. 5. Fourth Series of Cultures of Virus.—The inoculum was the supernatant fluid of an eight-day culture from Expt. 4. It was not stored before use and was diluted 1 in 100 in setting up the cultures. Cultures were titrated in duplicate.

After incubation for 1 day, 1 in 25 pos., 1 in 125 neg.
" " 5 days, (a) 1 in 125 pos., 1 in 625 neg.
" " 5 days, (b) 1 in 625 pos.*
* Highest dilution tested.

A dilution of 1 in 625 in this series represented a ilution of 1 in 625×10^8 of the primary inoculum. xcept for the five-day cultures in this experiment the ults of titrating duplicate cultures were identical oughout. The supernatant fluid from the five-day ltures was free from bacteria as tested by aerobic broth cultures.

Expt. 6. Neutralisation of Primary Inoculum, Virus from Third and Fourth Series of Cultures and Lymph from Government Laboratory by Anti-vaccinia Serum.—Neutralisation experiments were made with anti-vaccinia rabbit serum. Virus was diluted with Tyrode's solution and divided into two parts. To one part an equal volume of Tyrode's solution was added and to the other an equal volume of anti-vaccinia serum. After the mixtures had stood for two hours at room temperature, 0·2 c.cm. of each was inoculated intradermally into the skin of a rabbit. The viruses tested and the final dilutions were as follows: (*a*) primary inoculum 1 in 50; (*b*) Government lymph 1 in 50; (*c*) supernatant fluid from an eight-day culture, Expt. 4, 1 in 5; (*d*) supernatant fluid from a five-day culture (*a*) Expt. 5, 1 in 5.

In each instance the virus in Tyrode's solution produced a lesion and no lesion resulted from the virus with serum.

Expt. 7. Had the Medium alone after Incubation an Adjuvant Effect on Infectivity of Virus?—Cultures were made as described except that they contained no inoculum. After they had been incubated for six days at 37° C. the contents of the flasks were put into a mortar and primary inoculum was added, so that it became diluted 1 in 100. The mixture was then treated as a culture—i.e., it was ground in sand and centrifugalised. The supernatant fluid was titrated and compared with the titration of corresponding dilutions of the primary inoculum in Tyrode's solution. The titrations produced identical results. In each instance a dilution of the primary inoculum of 1 in 2500 caused a lesion; a dilution of 1 in 12,500 did not.

Discussion.

During four successive cultures vaccinia virus has increased approximately 25×10^6 times. There was also evidence of increase in comparing the titrations of cultures after incubation for one day and after incubation for five to eight days in Expts. 2, 3, 4, and 5. The experiments were not carried beyond the fourth series of cultures.

In comparing the results of this technique with the growth of vaccinia virus in tissue cultures it is of interest to note the uniformity of results obtained. Whereas only a varying proportion of tissue cultures give evidence of multiplication of the virus, we were impressed by the regularity of the results of titration of cultures in duplicate after incubation for from five to eight days, and also by the similarity of results in successive experiments.

In these cultures we were not able to detect any tissue growth; after 24 hours the small pieces of kidney had begun to disintegrate, and by the third day autolysis of the tissue was extensive.

We wish to express our thanks to Prof. J. C. G. Ledingham, F.R.S., who kindly provided the anti-vaccinia serum, and to Dr. F. R. Blaxall, who supplied some Government lymph.

VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE.—The report of the work of this hospital for 1927 contains some remarkable figures. Since 1907 the number of in-patients has increased from 6445 to 13,806, of new out-patients from 32,444 to 130,352, of out-patient attendances from 93,244 to 383,464; operations last year numbered 14,523 as compared with 5078 in 1907. The waiting-list has been periodically reviewed, yet it still contained 1840 names. The abnormal growth in out-patients' attendances is causing the house committee to inquire into the possibility of curtailing some part of the work. The number of motor accident cases has increased by 138 to 1121, and the 572 beds available were inadequate throughout the year. At the end of the present month the infirmary will come into possession of the adjoining premises, until now occupied as an orthopædic hospital by the Ministry of Pensions, and the honorary medical and surgical staff have outlined a scheme for the adaptation of part of the premises as paying wards, but no decision has been reached. Meanwhile the appeal for £150,000 for extensions made last year is being pressed forward.

---

[1] Carrel, A.: Jour. Exper. Med., 1923, xxxviii., 407.

interdigitalis pedum the result is generally satisfactory, especially so in cases with secondary pyogenic infection. In the past, when the associated pyogenic infection was very heavy and there was present diffuse redness with small pustules and abrasions, I used, at first, to keep the parts moist with a saturated boric lotion or a boric resorcin lotion, for two or three days before starting the fuchsin paint. Now, however, in every case, I use the fuchsin treatment immediately with good results. With regard to the details of the treatment,—viz., frequency of applications, length of treatment, &c.—each case has, of course, to be treated on its own merits, but a safe general rule is to apply the paint freely two or three times daily for a week, then give three days' rest, then apply the paint again once or twice daily, for another week. In some cases the treatment has to be carried out for a much longer period of time.

Other types of epidermophytosis. Mycotic pruritus ani et vulvæ.—In addition to epidermophytosis of the toes I found the paint useful in certain other types of epidermophytosis. As I have stated elsewhere a fairly large number of cases of pruritus ani and pruritus vulvæ are of mycotic origin; very often we are dealing with a latent epidermophytosis with superadded saccharomycetic, cryptococcal, monilial, and bacterial infections. In a number of these cases the paint acts well.

Illustrative case.—Mrs. A. (London) complained for several weeks of unbearable vaginal and anal pruritus. On examination an eczematoid condition of the labia majora and of the perianal region was present; the patient complained of pruritus also in the labia minora and in the clitoris. The paint was applied freely not only to the external surface of the labia majora but also to the internal surface, and also to the labia minora and clitoris; at first diluted with equal part of water, then neat as it caused no smarting. The application was done at first every other day, then twice a week, then once a week. Within three weeks the condition was completely cured. From this case, before starting the treatment, an epidermophyton (*E. rubrum*) was grown and, in addition, a monilia and various bacteria, also a most peculiar organism which I was uncertain at first how to classify as certain forms of it resembled a cryptococcus, others a thick bacillus. I have described it elsewhere under the name *Bacillus multiformis.* (Proc. Soc. Exper. Biol. and Med., 1928, xxv., 539.)

Epidermophytosis cruris (inguinalis); epidermophytosis corporis.—While most cases of tinea cruris (dhobie itch) answer well to the usual routine treatment by salicylic-benzoic acid ointment (Whitfield's ointment) consisting of salicylic acid grs. xxx., benzoic acid grs. xxx., and vaseline 1 oz., or my older salicylic-sulphur ointment (ac. salicyl. grs. xxx., sulphur præc. grs. xxx., vaseline ad ℥i.) in a certain percentage of cases the result is unsatisfactory, and in some of these I have found the paint useful. As a method of routine, however, the use of ointments is much simpler and preferable.

Cases of epidermophytosis simulating moist eczema.—In these the paint seems to be very successful, especially when the lesions are on the arms, hands, and feet.

Epidermophytic pompholyx.—The deep, tense vesicles should be opened and then the paint applied frequently all over the affected region, usually the fingers and palms of the hands. In this type of epidermophytosis the paint does not answer so well as in the pure eczematous type. In certain cases it is of advantage—provided there are no moist eczematoid lesions associated with the pompholyx—to apply frequently for two days before starting the fuchsin treatment a lotion containing menthol or thymol grs. ii.–v., ac. salicylici grs. xxx.–ʒi., resorcin grs. xv.–xxx., spir. rect. ℥ii.–iv., aq. dest. ad ℥vi.

Post-epidermophytosis pruritus.—In previous publications I have called attention to the occurrence of post-epidermophytosis pruritus—viz., cases in which after the usual routine treatment all the objective symptoms of epidermophytosis disappear but the pruritus remains for weeks and months. The pruritus may be of different origin: (*a*) although the clinical signs have disappeared the mycotic infection is still present; (*b*) over-treatment and mild hypersensitivity to the various antimycotic ointments; (*c*) nervous origin; in some highly strung individuals the pruritus remains long after the infection has disappeared. In the first group of cases the application of the carbol-fuchsin paint will be found useful.

Conclusion.

A paint consisting of carbol-fuchsin 100 c.cm., boric acid 1 g., acetone 5 c.cm., resorcin 10 g., gives very satisfactory results in the treatment of epidermophytosis of the toes (mango toe), both in the acute type and chronic type with presence or absence of secondary bacterial infections. It is useful also in certain other forms of epidermophytosis, especially in cases showing signs of moist eczematous dermatitis, the very cases in which salves are contraindicated, as in such cases, as a rule, they increase the inflammatory symptoms. With regard to ordinary dhobie itch (tinea cruris, tinea inguinalis) the paint acts well, but the routine treatment by Whitfield's salicylic-benzoic ointment or my old salicylic-sulphur ointment is much simpler and to be preferred.

A disadvantage of using the paint is the deep red colouring of the skin, but patients who have suffered from epidermophytosis interdigitalis pedum for years and have tried all sorts of treatment do not object to it. So far I have not come across—among over a hundred patients—a single case of hypersensitiveness to the paint, but no doubt if this method of treatment should become generalised, such hypersensitive individuals will be found, and therefore at first the paint should be applied with care and in small amount.

Refcrence.—Castellani: Gehrmann Lectures on Fungi and Fungal Diseases, delivered before the University of Illinois, Chicago, 1926, and published in the Archives of Dermatology and Syphilology, October, November, December, 1927; January, February, and March, 1928.

CULTIVATION OF VACCINIA VIRUS WITHOUT TISSUE CULTURE.

By H. B. MAITLAND, M.D. TORONTO,
M.R.C.S. ENG.,
PROFESSOR OF BACTERIOLOGY;
AND
MARY COWAN MAITLAND, M.B. TORONTO,
RESEARCH ASSISTANT, FOOT-AND-MOUTH DISEASE RESEARCH COMMITTEE.

(From the Department of Bacteriology and Preventive Medicine in the University of Manchester.)

THE set of experiments which form the subject of this note was made during the course of systematic investigations on the cultivation of filterable viruses. Indications had been obtained that it would be desirable to determine whether the virus of vaccinia would multiply under the conditions of culture to be described.

Technique.

Commercial vaccine lymph was inoculated into the testes of an adult rabbit. After four days the testes were markedly swollen and hæmorrhagic. They were removed and ground in sand and m/50 phosphate, pH 7·6. The mixture was centrifugalised and the supernatant fluid (about 5 c.cm.) was used for the primary inoculum. It was free from bacteria as tested by aerobic broth culture.

Titrations were made by inoculating 0·2 c.cm. of a series of dilutions intradermally into the skin of the back of adult rabbits. The diluting fluid throughout was m/50 phosphate, pH 7·6.

The method of preparing and testing cultures was as follows. Blood was withdrawn from a hen and after it had clotted the serum was collected. The hen was killed with chloroform and ether, and the kidneys, which were removed aseptically, were minced finely with scissors. Into a flask was put 0·66 c.cm. (approximately) of minced kidney and 1·33 c.cm. of inoculum diluted 1 in 6·6 with Tyrode's solution. The mixture was allowed to stand in the cold room for four hours. Then were added 12 c.cm. of Tyrode's solution and 6 c.cm. of hen's serum. The final dilution of the inoculum was thus 1 in 100. The mixture was distributed in amounts of 2 c.cm. into Carrel's tissue culture flasks,[1] type D, which were incubated aerobically at 37° C., without caps. The cultures were tested after various periods of incubation by grinding the whole of the contents of each flask with sand and centrifugalising. The supernatant fluid was controlled for the presence of bacteria by aerobic broth ulture and titrated as outlined above.

Experimental.

Expt. 1. Titration of the Primary Inoculum.—The st titration was made at the time the inoculum is prepared. The highest dilution tested, 1 in 500, oduced a lesion. A second titration, made after inoculum had been stored in the ice-chest for days, resulted in a dilution of 1 in 2500 producing a lesion. A dilution of 1 in 12,500 caused no reaction.

Expt. 2. First Series of Cultures of Virus.—After storage for six days in the cold room the primary inoculum was used for the first series of cultures. The titre of the inoculum was 1 in 2500 (Expt. 1), and its dilution in these cultures was 1 in 100. Cultures were titrated in duplicate. The results are summarised below.

After incubation for 1 day, 1 in 125 pos.*
,, ,, 3 days, 1 in 625 pos.*
,, ,, 5 ,, 1 in 625 pos.*
,, ,, 7 ,, 1 in 3125 pos.*
(Pos. = vaccinia lesion. Neg. = no vaccinia lesion.)
* Highest dilution tested.

Expt. 3. Second Series of Cultures of Virus.—The oculum for this series was the supernatant fluid om a culture of Expt. 2 which had been incubated five days. It was free from bacteria as tested by obic culture in broth, and had been in the cold room for four days before it was used for this experiment. The dilution of the inoculum in these cultures as 1 in 100. Cultures were titrated in duplicate.

After incubation for 1 day, 1 in 5 pos., 1 in 25 neg.
,, ,, 5 days, 1 in 625 pos.*
,, ,, 8 days, 1 in 625 pos.*
* Highest dilution tested.

dilution of 1 in 625 in this series represented a ilution of 1 in 625×10^4 of the primary inoculum.

Expt. 4. Third Series of Cultures of Virus.—The inoculum was the supernatant fluid of a five-day culture from Expt. 3. It had been in the cold room for two days, was free from bacteria as tested by aerobic culture in broth, and was diluted 1 in 100 in setting up the cultures. Cultures were again titrated in duplicate.

After incubation for 1 day, 1 in 5 pos., 1 in 25 neg.
,, ,, 5 days, 1 in 625 pos.*
,, ,, 8 days, 1 in 625 pos.*
* Highest dilution tested.

A dilution of 1 in 625 in this series represented a ution of 1 in 625×10^6 of the primary inoculum.

xpt. 5. Fourth Series of Cultures of Virus.—The ulum was the supernatant fluid of an eight-day re from Expt. 4. It was not stored before use as diluted 1 in 100 in setting up the cultures. res were titrated in duplicate.

After incubation for 1 day, 1 in 25 pos., 1 in 125 neg.
,, ,, 5 days, (a) 1 in 125 pos., 1 in 625 neg.
,, ,, 5 days, (b) 1 in 625 pos.*
* Highest dilution tested.

A dilution of 1 in 625 in this series represented a ilution of 1 in 625×10^8 of the primary inoculum. xcept for the five-day cultures in this experiment the sults of titrating duplicate cultures were identical oughout. The supernatant fluid from the five-day tures was free from bacteria as tested by aerobic th cultures.

Expt. 6. Neutralisation of Primary Inoculum, Virus from Third and Fourth Series of Cultures and Lymph from Government Laboratory by Anti-vaccinia Serum.—Neutralisation experiments were made with anti-vaccinia rabbit serum. Virus was diluted with Tyrode's solution and divided into two parts. To one part an equal volume of Tyrode's solution was added and to the other an equal volume of anti-vaccinia serum. After the mixtures had stood for two hours at room temperature, 0·2 c.cm. of each was inoculated intradermally into the skin of a rabbit. The viruses tested and the final dilutions were as follows: (*a*) primary inoculum 1 in 50; (*b*) Government lymph 1 in 50; (*c*) supernatant fluid from an eight-day culture, Expt. 4, 1 in 5; (*d*) supernatant fluid from a five-day culture (*a*) Expt. 5, 1 in 5.

In each instance the virus in Tyrode's solution produced a lesion and no lesion resulted from the virus with serum.

Expt. 7. Had the Medium alone after Incubation an Adjuvant Effect on Infectivity of Virus?—Cultures were made as described except that they contained no inoculum. After they had been incubated for six days at 37° C. the contents of the flasks were put into a mortar and primary inoculum was added, so that it became diluted 1 in 100. The mixture was then treated as a culture—i.e., it was ground in sand and centrifugalised. The supernatant fluid was titrated and compared with the titration of corresponding dilutions of the primary inoculum in Tyrode's solution. The titrations produced identical results. In each instance a dilution of the primary inoculum of 1 in 2500 caused a lesion; a dilution of 1 in 12,500 did not.

Discussion.

During four successive cultures vaccinia virus has increased approximately 25×10^6 times. There was also evidence of increase in comparing the titrations of cultures after incubation for one day and after incubation for five to eight days in Expts. 2, 3, 4, and 5. The experiments were not carried beyond the fourth series of cultures.

In comparing the results of this technique with the growth of vaccinia virus in tissue cultures it is of interest to note the uniformity of results obtained. Whereas only a varying proportion of tissue cultures give evidence of multiplication of the virus, we were impressed by the regularity of the results of titration of cultures in duplicate after incubation for from five to eight days, and also by the similarity of results in successive experiments.

In these cultures we were not able to detect any tissue growth; after 24 hours the small pieces of kidney had begun to disintegrate, and by the third day autolysis of the tissue was extensive.

We wish to express our thanks to Prof. J. C. G. Ledingham, F.R.S., who kindly provided the anti-vaccinia serum, and to Dr. F. R. Blaxall, who supplied some Government lymph.

---

VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE.—The report of the work of this hospital for 1927 contains some remarkable figures. Since 1907 the number of in-patients has increased from 6445 to 13,806, of new out-patients from 32,444 to 130,352, of out-patient attendances from 93,244 to 383,464; operations last year numbered 14,523 as compared with 5678 in 1907. The waiting-list has been periodically reviewed, yet it still contained 1810 names. The abnormal growth in out-patients' attendances is causing the house committee to inquire into the possibility of curtailing some part of the work. The number of motor accident cases has increased by 138 to 1124, and the 572 beds available were inadequate throughout the year. At the end of the present month the infirmary will come into possession of the adjoining premises, until now occupied as an orthopædic hospital by the Ministry of Pensions, and the honorary medical and surgical staff have outlined a scheme for the adaptation of part of the premises as paying wards, but no decision has been reached. Meanwhile the appeal for £150,000 for extensions made last year is being pressed forward.

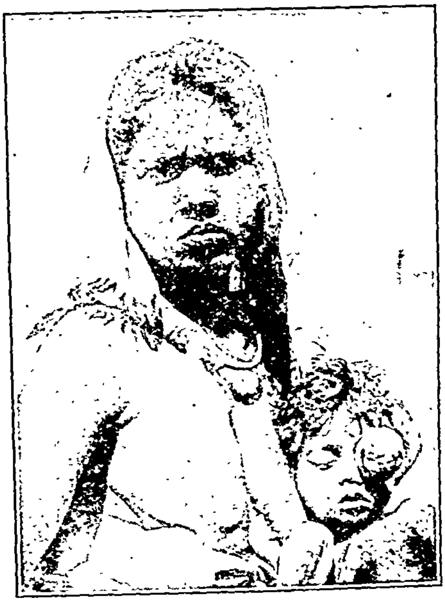
Clinical and Laboratory Notes.

A CASE OF GLIOSARCOMA OF THE RETINA IN A CHILD OF THREE.

By E. Charlton Hudson, M.B., B.S. Lond.,
MEDICAL SUPERINTENDENT, SANTAL MISSIONARY HOSPITAL, BENGAL.

In the following somewhat rare case the patient was carried a distance of 30 miles, probably on foot, by the parents, from whom the history was elicited with difficulty as they were very ignorant and poor villagers.

A Hindu (Bengali) female child, aged 3, was first seen on March 17th, 1928. She had been born normal with perfect eyes, and there was no history of any injury. Four months before admission her eyes had begun to "water"; then the left eye became red and, later, cloudy. The left eye was said first to have retracted for about a month; then it began to bulge.



Child, front view. Note intact but over-stretched margin of eyelids formed into a ring. Note also two large circular fungating ulcers. The mother with plenty of milk was still suckling her only child at 3 years.

When brought to hospital the child was so irritable that gr. 1/12th morphia had to be given hypodermically before examination, but the tumour did not seem particularly painful. The left eye was found to have been completely destroyed by an ulcerating tumour, the size of a lemon, protruding from the orbit and evaginating the palpebral conjunctiva. The eyelids were intact but greatly stretched. The tumour was firm and fleshy with a feeling of resilience. The child was otherwise normal and in fair condition (feeding on rice, &c., and still suckling from its mother). The right eye was sound and there were no signs of any secondary deposits elsewhere in the body, glands or otherwise.

Treatment.—Complete exenteration of the orbit, as far as possible in one piece, was performed under a general anæsthetic (A.C.E. and ether) on March 22nd. It was a difficult operation on account of tension of the orbital contents and the advisability of removal in one piece intact. The external canthus was slit to give greater freedom for extraction. No operating gloves were used. During the removal a cystic portion burst and a semi-fluid exuded in the form of soft, lumpy, glial contents of a crushed blackberry colour, suggesting degenerating tissue stained by blood. This came from the upper and medial quadrant of the tumour, slightly decreasing its volume and so facilitating extraction. The greater portion of the tumour was fairly firm. There was no invasion of the orbit and the periosteum was stripped clean everywhere up to the margin. The growth appeared to have extended backwards along the optic nerve to the base of the brain through the optic foramen, as the optic nerve was somewhat pulpy. The nerve was cut through as far back as possible. There was little bleeding of the stump, and this was controlled by hot saline flush and pressure pad, as artery forceps proved of little value. The redundant over-stretched eyelids were then trimmed and the cilial margins cut away. The orbit was packed with gauze soaked in acriflavine and liquid paraffin mixture.

The child had a reactionary post-operative temperature of 101° F. the same evening, which had dropped to normal the next day, rising again to 100° F. on the third day, and thereafter normal until an incidental attack of dysentery set in and passed off after treatment.

The first dressing was carried out under general anæsthesia on the third day, when the stump of the optic nerve was cauterised with pure carbolic acid and a ribbon gauze dressing of acriflavine and paraffin repeated. Thenceforward similar daily dressings of very light packing after irrigating with electrolytic chlorine were carried out for about 14 days, when acriflavine and paraffin were discontinued.

The child made much better progress than was expected considering the primitive aseptic and antiseptic conditions in a new hospital in the jungle 22 miles from the railway. The parents, against medical advice, took the child away 31 days after the operation, before the wound was healed or a skin graft had been attempted. Nothing has been heard since.

THE COOKING OF LIVER FOR THE TREATMENT OF PERNICIOUS ANÆMIA.

By C. E. Pollock, M.R.C.S. Eng.,
MAJOR-GENERAL, LATE A.M.S.

Liver as usually cooked soon palls. Being myself an involuntary member of the "honourable company of liverers," and not relishing the prospect of having to eat the same preparation of liver four or five days a week, I set to work to find ways of converting our mainstay of life into an attractive item on the menu. I give the results obtained up to the present, and with further experience I hope to add to the list.

When cooking liver the following general rules should be observed:—

(*a*) Fresh ox liver is more effective than calf liver.

(*b*) The cooking should be short, and the temperature should be kept as low as possible—just sufficient to make the liver seem to have been cooked.

(*c*) No more fat should be used than is actually necessary for each dish.

(*d*) Grilling makes the liver tough.

(*e*) Only a little salt should be used in the cooking; more can be added when it is eaten.

(*f*) Any sweet flavouring, such as chutney, should be used sparingly.

Some Recipes.

Liver Sandwiches.—The following has been successfully used by friends for a child. Put the raw liver through a mincer and remove any fibrous parts. Spread the minced liver on thinly cut slices of bread and butter, or a piece of toast which has been split in two. In either case use little or no butter. Add pepper and salt according to taste, sprinkle it freely with fresh lemon juice, and a trace of grated onion. A few dabs of Bovril. or a thin layer of grated cooked ham improves the flavour. Finely chopped pickles may be used in place of ham.

Fried Liver.—Cut the liver into rather thin slices. Put a small quantity of butter, margarine, or a slice of not very fat bacon into the frying-pan and heat to low frying temperature. Cook gently for five to ten minutes to suit the individual's taste.

Dry Curry.—Slice the liver as above. Put into the frying-pan a little butter and a dessert-spoonful of chutney with a squeeze of lemon juice. Heat this while stirring it to a low frying temperature. Roll the slices of liver in dry curry powder and place them in the pan. Cook gently for five to ten minutes.

Liver Purées.—(*a*) Prepare a white sauce. Stir in 6 oz. of grated raw carrot, if it is coarse, or, if young carrots are obtainable, the same quantity finely chopped. Boil gently for a few minutes. Stir in the minced raw liver and let it stand for three minutes on the warm top of the stove, away from the flame.

(b) Prepare a brown gravy, using as little fatty substance as possible. Bring this to the boil, then move the pan away from the flame, and stir in the minced raw liver. Let it stand for three to five minutes. Green peas or finely sliced young carrots improve the flavour. Serve on toast.

(c) Prepare a breakfast-cupful of Bovril or Marmite. Bring it to the boil, stir in the minced liver, and let it stand for a couple of minutes on the top of the hot stove. This is very useful when the liver is required at short notice.

Liver Soups.—Prepare a breakfast-cupful of any of the following soups: tomato, veal broth, chicken, or rabbit broth. Many others, such as potato soup, game soup, milk and celery soup, make a pleasant variation. Bring the soup up to the boil. Take the pan off the fire, stir in the minced raw liver, and let it stand for a few minutes.

Minced Liver on Toast.—Prepare a tasty gravy flavoured with a sauce such as A.1 or Harvey's. Chop the liver and cook gently in the gravy for three minutes, spread it on the toast, and serve hot.

Liver and Eggs.—Minced raw liver may be beaten up with milk and eggs and served as scrambled eggs. An omelette may be filled with minced liver cooked slightly in a tasty gravy.

Liver Roll.—Mince together 12 oz. of liver, 6 oz. of beef (preferably steak), and 6 oz. of rather lean bacon. Add a trace of finely chopped onion. Mix a teacupful of bread-crumbs with the minced liver and bacon. Beat up one egg and stir it into the liver mixture, flavouring the whole with a little tomato sauce. Wrap it in grease-proof paper, and cook in a steamer from one to one and a half hours. Let t get cold and eat it as a sandwich, or in place of cold neat. This is a useful preparation when travelling.

Risotto.—Boil some rice in the ordinary way. Cut the liver into dice of about half an inch, and cook in a savoury sauce, tomato for preference. Place the cooked rice in a hot dish, making a hollow in the middle. Put the liver into this. If preferred, the liver may be sprinkled with lemon juice and lightly fried. In this case a well-flavoured sauce should be served to pour over the rice. Cooked macaroni may be used in place of rice.

Stuffed Potatoes.—Bake or boil two large potatoes in their skins. When cooked cut off the upper third. Scoop out one-third of the potato. Into the space thus formed put minced liver, previously cooked in brown gravy and well seasoned with ketchup and lemon juice. Mash the removed potato, and use some of it to form a cap to the liver. Place a thin slice of bacon over the top, and put them into a hot oven for three minutes.

Chicken and Liver Fricassee.—Minced liver mixes well with chicken fricassee prepared in the ordinary way.

Toad-in-the-Hole.—Liver may be used in this dish in place of beef. When making the batter stir in a teaspoonful of ketchup. Cold cooked liver and potato salad made with mayonnaise is excellent for an occasional change, but contains too much oil to be used frequently.

With experience other recipes will suggest themselves to the interested cook, and the anæmic brother will bless her ingenuity.

A CASE OF
MULTIPLE COMPOUND FRACTURE OF THE SKULL.
WITH RECOVERY.

BY C. R. H. TICHBORNE, L.A.H. DUB., M.S.A.,
MEDICAL OFFICER, KONDOA-IRANGI, TANGANYIKA.

IN his village of Sandawe a man had a quarrel with his wife; on the pretence of cutting wood, he took her out into the bush, and there attempted brutally to murder her. The woman was brought into hospital with six wounds on her head, five of which were complete compound fractures of the vault of the skull: at first appearance the head seemed almost severed from her body. the injuries were three days old, the head wrapped in a filthy blood-stained native cloth, was covered with mud, the several muscles and torn scalp sloughing, and a general septic state prevailed. Under these conditions the prognosis seemed hopeless; nevertheless the patient did live, and attended the court three months subsequently. Besides a scalp wound 3 in. long and reaching to the bone, there were five complete compound fractures of the vault of the skull; these wounds were inflicted by a panga. The fractures were: one left temporal, one frontal, one right parietal, one left parietal, and one fracture of occipital bone 5 in. long, and 1½ in. gap; all these fractures communicated with the surface of the brain, and in all cases the cerebral meninges were exposed. It would seem almost miraculous, considering the anatomical relations of the middle meningeal artery, especially its anterior branch, also the temporals externally, that these vessels could have escaped rupture with ensuing fatal hæmorrhage.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

THE following are some of the 1927 statistics of five English, one Welsh, and two Scottish counties:—

Name of county and estimated mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant mortality.	Diarrhœa, &c., under 2 years.	Maternal mortality from childbirth.
Surrey (792,300)	14·2	10·7	0·71	1·81	2·0	1·6	46	2·0	3·0
Warwickshire (377,900)	17·3	11·2	0·76	1·36	2·1	1·5	66	3·8	2·9
East Sussex (268,200)	12·6	12·4	0·67	1·66	2·0	2·3	44	1·8	5·0
Northamptonshire (215,000)	14·4	11·8	0·89	1·48	2·2	1·9	51	1·9	5·1
Cumberland (216,130)	17·2	13·6	0·85	1·40	2·8	2·0	81	6·7	5·4
Breconshire (61,150)	16·7	12·8	0·98	1·04	2·8	2·0	79	5·8	7·8
Aberdeen* (107,224)	21·2	13·4	0·83	1·55	2·1	2·0	73†	3·9	3·9

* Extra burghal or landward area. † Including the burghs, except Peterhead and Fraserburgh.

Surrey.

Dr. T. Ruddock West, deputy M.O.H., describes the continued attention given to the river Wandle. The rapid building up of the districts in this valley has given rise to engineering and legal problems owing to the sudden increases in the volume of the river after the fall of rain on the much larger proportion of impermeable surface. As the swollen river subsides the oil is deposited and gives rise to offensive smell and unsightly conditions. The Carshalton section of the river, which was subject to much chemical pollution, is now free from pollution from trade wastes and sewage, while the stretch of the river from the female orphanage to Beddington Park has been cleaned and the velocity of the stream much improved. During the year there were 149 notifications of puerperal fever and pyrexia with six applications for a second opinion and eight for admission to hospital. It is thought that the facilities provided will be more used when the scheme becomes widely known. The number of cases admitted to maternity homes under the Council's scheme shows a steady increase. Thus the admissions during the last five years were 44, 54, 104, 160, and 183.

The whole-time chief veterinary officer appointed by the council took up his duties in July. Pending arrangements for the periodical inspection of all dairy herds notifications of milk containing tubercle bacilli or streptococci of bovine mastitis are investigated. It is frequently found that although the notifications received may refer to only one farm, the sample contains other milk purchased by the vending farmer. As the result of 11 "outside" notifications of tuberculous milk four animals were dealt with under the Order, and of five others suffering from tubercle four were slaughtered by the owners and one died during the investigation. In seven cases no confirmatory evidence by microscopical and biological tests of tuberculous infection was obtained. In the case of the four milk samples containing streptococci four animals were discovered suffering from mastitis, and the owners' attention was drawn to the fact that it was an offence to sell such milk.

The number of blind persons on the register is gradually increasing. At the end of 1924 there were 523 and at the end of 1927, 744. The council subscribe £100 per annum to the National Library for the Blind and in return the library supplies books and music to blind persons in Surrey. The school report shows that the parents of 219 children objected to routine medical inspection. In 40 cases the objection was withdrawn after explanation and in 46 the inspection schedule was completed by a private practitioner. The school nurses also act as health and tuberculosis visitors. The cost of installing drinking fountains of special type to take the place of the drinking vessels (mostly enamelled iron mugs) used in common by the scholars is considered by the council to be prohibitive. Great success is claimed for the system instituted in June, 1925, by which contacts of certain infectious diseases remain at school under the supervision of the school nurse instead of being excluded. Owing to the epidemic of influenza which swept the county during January and February the number of days of school closure compares unfavourably with the previous year. In the case of several schools, after meetings of the parents at which the procedure was explained, immunisation of children against diphtheria has been practised. Nearly 1000 children have been immunised. There are now within the county 73 minor ailment, 31 dental, and 27 eye clinics. When one more additional dental surgeon has been appointed in 1928 dental treatment will be available for the school-children at every age. Under the orthopædic scheme, which included seven centres, 729 children received 12,222 treatments.

Warwickshire.

Dr. A. Hamilton Wood reports that after an absence from the county since July, 1925, small-pox appeared in epidemic form during the last quarter. There were 55 cases notified chiefly in Nuneaton, Foleshill, and the Atherstone and Coventry rural districts. At the time of writing the report the disease was under control. The outbreak, says Dr. Wood, would have been even more limited if the offer of vaccination had been generally accepted. The disease was usually of a mild type, but in some cases led to disfigurement. There was an outbreak of enteric fever causing 22 cases in Southam. The source of the outbreak was a well contaminated with sewage, as evidenced by bacteriological examination and the discovery of leakage from a drain. There were 12 notifications of encephalitis lethargica in the urban and 12 in the rural districts and 16 deaths.

Some improvement is reported as to river pollution. The condition of the Tame is likely to be improved by the efforts of the Upper Tame Joint Committee and the extension of the bio-aeration process at the Birmingham Tame and Rea works. The pollution by paper mills is to be reduced by the introduction of machinery which will extract fibre from the residue, to be used again instead of its being discharged as waste. The state of the Avon is improved by better treatment at the Rugby works. Coventry, which is in a difficult position, owing to the fact that the volume of the effluent in dry weather is equal to that of the river, is contemplating new works at an estimated cost of £226,000. It is thought that the ten miles stretch of the river between Baginton and Warwick may, as the result of these schemes, become once more capable of maintaining fish life. The policy of the county council is to investigate all cases of tuberculous milk reported from outside, and in addition to take 100 bulk samples. There were 31 outside notifications, which resulted in 12 cows being slaughtered under the Tuberculosis Order. Of 85 bulk samples examined biologically three were found to be tubercle-infected. During the year about 2000 swabs were examined from diphtheria cases and contacts, but only five virulence tests were carried out. It is thought that full advantage will be taken of the virulence test in future when its extreme usefulness is appreciated.

The orthopædic scheme comprises five clinics, but another clinic is required in the north of the county to complete the scheme. Of 52 cases of puerperal fever and pyrexia a second opinion was asked for in six cases, and 12 cases were removed to hospital. If the case is treated at home the nurse-midwife takes charge and is compensated for the loss which she incurs by handing over her normal cases to other midwives. The higher death-rate and infant mortality as compared with the previous year was accounted for by the influenza epidemic, which was responsible for 211 deaths as against 85 in 1926.

East Sussex.

Dr. A. G. R. Foulerton gives the result of following up tuberculous milk samples notified by outside authorities from Sept. 1st, 1925, to Dec. 31st, 1927. During these 28 months the notifications numbered 31, and as a result 34 farms were inspected and 14 cows dealt with under the Tuberculosis Order. A table shows the average infant mortality in the county for the four years 1924–27 as 44·7 and the figures for the three preceding six-year periods as 80·2, 70·9, and 53·8. During the same four periods the infant mortality for England and Wales was 119, 100·8, 82·5, and 72·2. The deaths from tuberculosis during the year numbered 181 and the number of cases on the revised register is 1027. In April, 1928, there were only four parishes, with a total population of 1463, without the services of a district nurse. At the end of the year there were 25 registered maternity homes in the county. Dr. J. R. Dingley, the medical superintendent, reports that an orthopædic visiting surgeon has been appointed for Darvell Hall Sanatorium. Dr. Dingley is impressed with the satisfactory results obtained by artificial pneumothorax in suitable cases, and favours its more extensive use for early cases. Occasionally he finds sanocrysin of benefit. In furtherance of the scheme for occupational therapy a workshop has been equipped for the patients and is in the charge of a skilled joiner, an ex-patient.

Northamptonshire.

Dr. L. Meredith Davies reports an epidemic of influenza between the third week in January and the first week in March, during which time 139 school departments were closed for varying periods. A somewhat excessive prevalence of paratyphoid fever, chiefly in the Kettering neighbourhood, during the latter half of the year was exhaustively investigated and was thought to be associated with a carrier employed at a large bakery. One case of small-pox was imported from Durham. The occupations followed by the new cases of tuberculosis do not suggest that the incidence of tuberculosis in the boot and shoe industry is unduly high. Artificial light treatment at the Wellingborough dispensary appears to give the best results in the case of tuberculous glands with discharging sinuses and is somewhat less beneficial for lupus, while its value for pulmonary disease is doubtful. Dr. Davies discusses the failure to get early cases of phthisis under treatment and is inclined to favour the establishment of preventoria as in Germany and America, the adoption of the "Grancher" system, and the more extensive use of open-air schools, both day and residential. The notifications of ophthalmia neonatorum numbered

28, of which 23 were treated at home and 5 in hospital, including 2 babies born in the hospital. One case of total blindness resulted, but the circumstances of this case are not given.

The orthopædic scheme now comprises five clinics based on the Manfield Hospital. The 14 notified cases of puerperal fever were investigated. Ten of the cases were treated in hospital and special nurses were rovided for two. Particulars are also given of the 7 notified cases of puerperal pyrexia, 7 of which were eated in hospital, and for 3 of which special nurses were provided. There were no applications from practitioners for antistreptococcal serum or for bacteriological examinations. Nine complaints of tuberculous milk were received from the L.C.C., but only two infected cows were discovered and dealt with under the Order. In several districts veterinary nspection is in force. Fifteen tuberculous cows were iscovered by the Kettering inspector, of which two were not in milk and in three the disease was "not advanced." All 15 were dealt with under the Order. Four tuberculous cows were found by inspection in the Wellingborough district, one in Oundle, and none in the other five districts.

Cumberland.

Dr. F. H. Morison states that many of the recommendations for improvements and extensions made in the years 1924 and 1925 have been carried out. As regards future developments, he recommends two which will not be expensive. The first is a subsidised bed for children at the Cumberland Infirmary, which might be used for operations for rupture, squint and eye conditions, skin diseases, and for observation in obscure cases. The second is the provision of a bacteriological laboratory in the county, which would not be an additional expense but take the place of laboratory work now done for the county in Manchester and London. Other more costly needs which he presses are: 1. The appointment of a woman medical officer to coördinate maternity and child welfare work, to enable new centres to be opened, and to develop antenatal work among expectant mothers. 2. Additions to the dental staff. At present there is only one dental surgeon and one nurse, and half of the school-children receive no dental treatment at all. In order to provide an efficient dental scheme five dental officers and five nurses would be required, but the appointment of a second dental officer and nurse would at least enable urgent cases all over the county to receive prompt attention. 3. The provision of an open-air school, or at least the retention of beds in such a school, or in a seaside convalescent home. 4. Provision for the isolation of advanced cases of pulmonary tuberculosis and of beds for observation purposes. 5. The establishment of some such scheme as the Grancher system for child contacts of open tuberculosis. 6. The establishment of clinics and dispensaries at Arlecdon, Frizington, and Aspatria, and the provision of clinic treatment, perhaps by a caravan, for a large part of the east of the county. Dr. Morison also presses for the energetic operation of the Housing (Rural Workers) Act of 1926 by the full coöperation of the county council with the local authorities.

Breconshire.

Dr. Herbert Davies records an epidemic of small-pox in the Brynmawr district. The first case was notified in the beginning of May, and 59 cases were notified during the year with no deaths. The epidemic was more severe in Monmouthshire and Glamorganshire. The county council subsidise the district nursing associations and in return the nurses, who also act as midwives, perform the duties of school nurse and health visitor. A scheme is in force whereby midwives attending cases more than three miles from their home are paid an allowance of 3*d*. per mile after the first three miles for each day of their attendance, but no payments were made under this scheme during the year. As in most districts the death-rate from respiratory diseases in 1927 was increased by the prevalence of influenza.

Aberdeen.

Dr. Harry J. Rae reports that the scheme begun in 1925 for the immunisation of children against diphtheria and scarlet fever has been continued with vigour. Up to the end of February about one-third of the school population, 8500 children, had been tested and 7000 of them actively immunised. As regards results, during the period mentioned 1333 cases of scarlet fever were notified. The cases notified included 21 of the tested children, in 7 of whom the disease appeared within a month of the last inoculation, while four others were discharged from hospital as not having had scarlet fever. The net result, therefore, was 10 mild cases of scarlet fever among the 7000 immunised children. During the same period 257 cases of diphtheria were notified, only two of whom had received preventive inoculations. Two separate outbreaks of milk-borne paratyphoid fever occurred, both in the Deer district. The first began in the end of May and caused about 32 cases in the burgh of Peterhead. The mother of the family, which carried out the work of the dairy farm, was found to be a carrier. The husband made application for compensation owing to loss of his work. The authorities did not think compensation could be legally made under Section 164 of the Public Health (Scotland) Act, 1897. The claim was ultimately settled by finding employment for the man under the road surveyor of the Deer district. In this outbreak the evidence pointed to the fact that the milk was infected on one occasion only. The second outbreak, also of paratyphoid B, occurred in November. The actual carrier in this case was not clearly demonstrated, and the milk appeared to have been infected on one or, at most, on two occasions.

There were 346 notifications of pneumonia. Institutional treatment is encouraged, and there is plenty of accommodation at the city hospital or at Woodend hospital. Removal is recommended up to the fourth day provided the patient's condition is good and there is no cardiac embarrassment. Many practitioners in the county favour domiciliary treatment, one objection to which is that the patients return to work too soon. In eight cases special nurses were supplied through the health department. Dr. Rae thinks that the extensive adoption of the Housing (Rural Workers) Act would do more to meet the housing shortage in the county than any preceding housing Act, and points out that this Act applies to burghal areas and to the dwellings of persons other than agricultural labourers. Routine inspection by the county veterinary inspector discovered 69 suspect cows, of which ten had tuberculosis of the udder.

Fife.

Dr. G. Pratt Yule draws attention to the steady decline, year by year, of both the deaths from and the notifications of tuberculosis. The tuberculosis officer, Dr. G. McGillivray, thinks that the risk of case-to-case infection in a family has been greatly lessened by education. Most of the cases in Fife come from one- and two-roomed houses. Nevertheless, out of 241 new cases of tubercle in 1927 only 14 were contacts. In 36 others some kind of a family history of tuberculosis was obtained, but none of "living in contact." In 191 cases there was no family history of tuberculosis. Some years ago the state of affairs was quite different, when windows were seldom opened and no precautions taken with regard to coughing or sneezing and the disposal of sputum. Kirkcaldy is the only one of the four districts which continues to add to its housing programme. Dunfermline has discontinued owing to the state of the coal trade. Cupar and St. Andrews have contented themselves with subsidising private enterprise. All the four districts have adopted approved schemes under the Housing (Rural Workers) Act, but only four applications under this Act were received in 1927. There are nearly 6000 dairy cows in the county, and in 1927, the first completed year of regular inspection, was carried through by the county veterinary surgeon, Mr. R. G. Anderson.

MENTAL HOSPITAL REPORTS.

THE *West Sussex County Mental Hospital, Graylingwell*, near *Chichester*, has had an unusual influx of patients and is now 47 over the statutory accommodation, which is for 800. For the moment the most urgent need is for female beds, but during the last few months the admissions have been chiefly males. Of the 153 admissions 48 were aged 60 or more, and many of them were quite hopeless. Nevertheless there was a recovery-rate of 30·7 per cent. The general health was good, except for a mild epidemic of influenza, two cases of chicken-pox, and three of typhoid. The death-rate was 7·54 per cent. Dances and cinema performances take place weekly and a wireless apparatus is to be installed. Eight nurses and three attendants obtained their M.P.A. certificate during the year. Thirty of the 37 pages of the report are purely statistical.

The *Dorset County Mental Hospital* had 880 patients on the books at the end of the financial year and is considering plans for extension, although this figure shows a small diminution in the number of women patients. The recovery-rate is 48·22 per cent., rising to 68 per cent. if cases "discharged relieved" are included. The death-rate was 6·47 per cent. The general health was very good and the tuberculosis incidence has been halved. Although there are typhoid carriers in the hospital there has been no epidemic sickness of any kind except influenza in the spring. The laboratory has carried out over a thousand routine investigations and has also initiated research into the acetic anhydride or Boltz test and Buscaino's silver nitrate reaction. A "leucocytic survey" was made of all patients towards the end of the year, with a view to detecting focal sepsis. Acetonuria was found to have no significance in mental disease. Of 13 cases of general paralysis treated with tryparsamide, three have gone back to work, three are much improved, and four have died. Seven showed much mental inprovement. Occupational therapy is a new departure in this hospital and is already producing most excellent results; the department is self-supporting, for the handicraft work finds a ready sale. The out-patient clinic is held weekly at the Dorset County Hospital. A solarium for the men patients has been completed and various other alterations have been carried out in order to bring the hospital up to modern standards. The operating theatre is now in use. Patients are allowed to wear their own clothes and two wards on each side have open doors. Seventy-seven men and 14 women have full parole. Eight more nurses obtained the M.P.A. certificate during the year, and it is interesting to note that 28 members of the staff have more than 21 years' service to their credit.

The *Devon County Mental Hospital* records, in an illustrated report, a year of activity among its 1211 patients. To relieve congestion, 41 chronic harmless patients were removed to the care of local authorities. The recovery-rate was 36·65 per cent., but the figure for the private patients alone was 47 per cent., The death-rate was 9 per cent., the cause being verified by autopsy in 67·8 per cent. of cases. There has been a steady increase in the routine work of the laboratory, and 1860 investigations are listed. Blood films of patients who have had ultra-violet light treatment are being investigated. The consulting surgeon performed 21 operations and the dental surgeon examined 453 patients, including all new admissions. The ophthalmic surgeon saw 60 patients and prescribed glasses for 36. Definite benefit is being obtained from the ultra-violet ray installation. Five men with general paralysis were treated by induced malaria and three of them were discharged; one became worse. The out-patient clinic in Exeter treated 34 patients during the year. The new fruit garden supplied patients with 640 lb. of raspberries. Eighty-nine patients have had daily parole within the estate and 57 more have been allowed into the village and on walks. There has been no abuse of the privileges. The Hospital Fire Brigade won a prize at the National Fire Brigades' Association demonstration at Exmouth. The list of entertainments for patients occupies three and a half pages of small type; 15 of the 25 cricket matches were won by the hospital eleven. The handicrafts occupy a very large number of patients. Every effort is made to impress on probationer nurses that they come to the hospital to be taught and must go through a course of training and examinations just as general nurses do; 31·8 per cent. now have their M.P.A. certificate.

The *Stafford Mental Hospitals Board* houses just over a thousand patients at its Stafford Hospital, 943 at Burntwood, and 1134 at Cheddleton.—At *Stafford* the recovery-rate was 40 per cent. and the death-rate 7·62 per cent. The deficiency in sleeping accommodation has been partially relieved by the completion of a new annexe for tuberculous male patients and the use of the Isolation Hospital for men convalescents. A reception hospital is planned. The laboratory research has been hindered by the illness of one of the medical officers, but routine work goes on as usual and investigation has been continued into the usefulness of venom hæmolysis as a means of diagnosis. Patients are sent home on trial and have parole in the grounds, but not beyond. Forty-six male and 10 female nurses are certificated or registered. Ultra-violet ray treatment is giving good results.—At *Burntwood* the recovery-rate was 24·34 per cent. and the death-rate 9·63 per cent. The hospital is overcrowded and there is urgent need for an admission block. There were 88 cases of influenza, three of typhoid fever, and two fatal cases of dysentery, the source of which has been sought in vain. Vita-glass has been fitted in the men's sun room and has proved well worth the expense. Violet-ray and continuous bath apparatus are to be provided. Trial and parole are allowed to a number of patients. Forty-nine nurses are certificated or registered.—At *Cheddleton* there is the same overcrowding and there is urgent need for verandahs, X ray apparatus, and admission and convalescent blocks. The increase in the number of cases of dementia præcox and general paralysis continues. Malarial treatment for the latter is giving great satisfaction. Fourteen patients died of tuberculosis, although only one could be diagnosed on admission. Dysentery continues to cause anxiety, and careful search has not revealed the source of infection. The medical superintendent speaks trenchantly of the need for more nurses and of the difficulties of work in an out-of-date building with inadequate financial resources. Parole is granted to a number of patients, and three wards are administered on the open-door system. Twenty-six per cent. of the women and 60 per cent. of the men nurses are certificated or registered. The staff includes a visiting orthopædic sister, an electro-therapeutic sister, and a schoolmistress.

The *Joint Counties Mental Hospital at Carmarthen* housed 655 patients at the end of 1927, and had a recovery-rate for the year of 27·9 per cent. The death-rate was 11·39 per cent. One baby was born in hospital, and the mother has since recovered. There was a heavy epidemic of influenza in the spring and 21 cases of diarrhœa and 6 of tuberculosis were notified. The dental surgeon visited weekly and examined 200 patients. He found very little caries, but a good deal of gum trouble. The hospital lacks a number of facilities for treatment commonly regarded nowadays as indispensable. For instance, there is no electric-supply and, consequently, X rays, violet rays, and electric baths are impossible. The water-supply is inadequate, but the sewage has now been connected up with the town drains. The visiting Commissioners complain of the state of the sanitary annexes, of the darkness of the workroom and kitchen, of carelessness in storing poisons, and in keeping clinical records, and of the absence of verandahs, and of any attempt to keep the patients either employed or amused. They remark: "There is an excellent pathological laboratory which has not been used for some years. . . . We hope that due regard will be paid . . . to the desirability of appointing a medical man with some knowledge, experience, and interest in this field of work."

At the *Glamorgan County Mental Hospital* at *Bridgend* there is overcrowding to the extent of 133 on the male side, and plans have been approved for a new reception block and other buildings. There were 1933 patients in residence at the end of 1927. The recovery-rate for the year was 31·1 per cent., nd the death-rate 8·9 per cent. General paralysis ccounted for most of the deaths, but disease of the heart and blood-vessels came next in order. The cause of death was verified by autopsy in 80 out of the 172 cases. A baby was born and the mother recovered. The general health was good, save for influenza and three cases of dysentery. The surgeon was not called on for any major operation, but the dental surgeon saw over 400 patients and performed 1408 extractions under local anæsthesia. Seventy patients were sent out on trial, ten with money allow-nces, and a good deal of parole is allowed on the nale side, but none on the female. Twenty-one urses gained their M.P.A. certificate during the ear.

The *Monmouthshire Mental Hospital* at *Aberga-nny* had 1158 patients at the end of 1927. The recovery-rate was 36 per cent. and the death-rate 5·2 per cent.—the lowest ever recorded at this hospital. The rate among the women was as low as 3·9 per cent. This speaks well for the efforts made in a hospital which, as a building, lacks many modern amenities. Central heating has been installed and one of the wards on each side is being converted into an admission ward with an open verandah nd a hydrotherapy room. The general health was ood except for influenza, and the institution is now ree from dysentery. The visiting surgeon performed ree operations during the year and the dental rgeon visited weekly. A number of patients have role, and efforts are made to find occupation for of them. Three more nurses have obtained their tificate.

he *Down County Mental Hospital, Downpatrick,* strates its report with many photographs of the dings. There were 756 patients on the books at the end of the year. The recovery-rate was 46·2 per cent. and the death-rate 6·9 per cent. There were 44 vacancies, accommodation having been increased by the new nurses' quarters. The farm continues to be a pecuniary asset as well as providing excellent occupation for the patients, who are mainly drawn from an agricultural population. The increase in the number of entertainments and recreations continues, and the medical staff investigate cases thoroughly and individually. The more elaborate laboratory work is carried out in Belfast and London; last year an epidemic was averted by the prompt recognition of a "carrier" colitis. More than half the patients are usefully employed. About a hundred men go outside the walls every day and as many women once a week. The dental surgeon visits weekly, and there are physicians and surgeons on the consulting staff. Nine more nurses have gained their certificate, bringing the total to 51.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 8TH, 1928.

Notifications.—The following cases of infectious isease were notified during the week:—Small-pox, 23 (last week, 102); scarlet fever, 1790; diphtheria, 31; enteric fever, 108 (last week, 122); pneumonia, 38; puerperal fever, 38; puerperal pyrexia, 102; rebro-spinal fever, 3; acute poliomyelitis, 17; cephalitis lethargica, 29; continued fever, 3; sentery, 8; ophthalmia neonatorum, 102. No of cholera, plague, or typhus fever was notified ing the week.

The following counties each notified 3 or more cases of enteric fever:—London, 23; Devon, 3; Essex, 12 (of which Colchester 6); Hertford, 3; Lancaster, 6; Middlesex, 5; Southampton, 3; Surrey, 6; Sussex East, 4; Yorks West Riding, 3; Denbigh, 3. The total of 108 includes 39 cases of paratyphoid fever, of which 13 were notified in London and 5 in Surrey.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Sept. 11th–12th was as follows:—Small-pox, 9 under treatment, 2 under observation; scarlet fever, 1552; diphtheria, 1444; enteric fever, 105; measles, 120; whooping-cough, 247; puerperal fever, 14 (plus 7 babies); encephalitis lethargica, 72; poliomyelitis, 2; "other diseases," 22. At St. Margaret's Hospital there were 17 babies (plus 10 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 4 (0) from enteric fever, 14 (2) from measles, 5 (0) from scarlet fever, 17 (6) from whooping-cough, 17 (3) from diphtheria, 120 (39) from diarrhœa and enteritis under two years, and 18 (2) from influenza. The figures in parentheses are those for London itself.

The fatal cases of enteric fever were reported from Bristol, Stockport, Burnley, Newcastle-on-Tyne, and Tynemouth. Of the 12 fatal cases of measles 3 were reported from Birmingham, Belfast reporting 4 in the same week. There was a large increase in the number of deaths from diarrhœa, of which Liverpool reported 10; Birmingham, 9; Manchester Leeds, and Newcastle-on-Tyne 5 each; and West Ham, 4; while Glasgow and Dublin reported 10 and 6 respectively. The number of stillbirths registered during the week was 263 in the great towns (corresponding to a rate of 89 per 1000 births), including 60 in London.

INFECTIOUS DISEASE IN NORTHERN IRELAND.—According to a return just issued by the General Register Office in Belfast (H.M. Stationery Office, 1s.) the following cases of infectious disease were notified to the Ministry of Home Affairs during the second quarter of 1928—namely:—Enteric fever, 99 (70); typhus, 4 (4); small-pox, 0 (0); scarlet fever, 782 (458); diphtheria, 254 (123); pneumonia, 50 (2); cerebro-spinal meningitis, 3 (3); encephalitis lethargica, 1 (1); erysipelas, 41 (19); tuberculosis, 280 (262); measles, 3 (0); chicken-pox, 70 (0); puerperal fever, 10 (8); ophthalmia neonatorum, 4 (4); membranous croup, 1 (1). The figures in parentheses are for the County Borough of Belfast. It should be remembered that tuberculosis is not notifiable in many districts, that measles is only notifiable in Bangor, and chicken-pox only in Bangor and a few small districts. The returns for cerebro-spinal meningitis and encephalitis lethargica are also incomplete.

DONATIONS AND BEQUESTS.—Mr. William Horne Cook, Edinburgh, left nearly £3000 to charities, including £1000 to the Royal Edinburgh Hospital for Sick Children, of which he had acted as treasurer, and £500 each to Muirfield Convalescent Home for Sick Children and the Edinburgh Royal Infirmary.—Mr. Robert Hilder, Threshall Priory, Stansted, Essex, and of the London Stock Exchange, left, besides other bequests, £5000 to St Mary's Hospital, Paddington, as an endowment for five beds in memory of his late wife's brother, Richard Mynors, formerly chief assistant to Sir William Broadbent at that hospital, and £5000 to the Bishops Stortford Hospital.—Mr. James Walker Oxley, retired banker, of Westwood, Headingley, Leeds, left £5000 4 per cent. Preference Stock of the L.M. & S. Railway each to the Leeds Public Dispensary, the Leeds Tradesmen's Benevolent Institution, and the Leeds District Nursing Fund for the Sick Poor.—Miss Ellen Davis, of Highfield Lodge, Lincoln, left £1000 to the Lincoln County Hospital, Lincoln.—Mrs. Caroline Ashley Smith, of Onslow-gardens, South Kensington, left £500 each to the Ramsgate General Hospital and the Princess Louise Hospital for Children, Kensington, W.—Leaving over £47,000, Dr. Alfred Charles Augustus Packman, of Grove House, Rochester, bequeathed the bulk of his estate in trust for his brothers and sisters, and on the death of the survivor of them between the Royal Medical Benevolent Fund and the West Riding of Yorkshire Medical Charity.—Miss Martha Mills, of Nottingham, left, among other bequests, £1000 to the Nottingham General Hospital, for the endowment of a bed in memory of her brother-in-law, Morris Weisblum; £100 to Dr. Barnardo's Homes; £50 to the Lord Roberts Memorial Workshops, London; £50 to St. Dunstan's Institute for Blinded Soldiers and Sailors; £50 to Ellersley House, Nottingham, Home for Paralysed Soldiers and Sailors; £50 to Lord Mayor Treloar's Homes for Crippled Children; and £100 to the Nottingham General Hospital.

Reviews and Notices of Books.

BRAIN AND MIND,

Or the Nervous System of Man. By R. J. A. BERRY, M.D., F.R.C.S., F.R.S. Edin., Dean of the Faculty of Medicine and Professor of Anatomy in the University of Melbourne, &c. New York: The Macmillan Company. 1928. Pp. 608. 31*s.* 6*d.*

THE appearance of Prof. R. J. A. Berry's interesting and provocative book is doubtless a sign of the times; it proceeds logically from the simple to the complex, from structure to function, from the physiological to the psychical; it insists on psychology as a department of biology, on neuronic insufficiency as the necessary antecedent of mental disease. In his opening sentences Prof. Berry indicates his personal standpoint in the clearest fashion: "it is not uncommon to find the human mind spoken of as though it were something which had no physical basis whatever, but was the result of a Psyche or soul, whereas the truth is that all mental phenomena are strictly dependable on physical construction, and that the elementary basis of such construction is always the neuron or nerve cell." Thus is the gauntlet thrown down in challenging fashion; no neuron, no mind, is the author's battle-cry. The reception of this finely written and closely reasoned thesis by the individual reader's mind will no doubt depend on the latter's preconceptions and mental training; he may welcome it as elaborating in a convincing way what he has felt all along to be the only rational manner of envisaging the facts; or, on the other hand, he may remain coldly unimpressed, satisfied that no amount of objective correlation of cerebral structure with psychical manifestation will explain the essential difference of the two orders of things, psychical and physical.

It is well, none the less, that the materialistic viewpoint (the epithet may be used in this connexion without misunderstanding) should be adequately stated, and that the body of evidence which can be advanced in its support should be properly marshalled and duly evaluated. That a professor of anatomy should do this for us cannot surprise those who are acquainted with Prof. Berry's previous work and research; after all, why should he not? No one whose knowledge of intimate neural structure is as profound as his can fail to see that by itself this marvellous complexity is nothing; its meaning, its purpose, its activity, form the fascination never absent from pure morphology. The only material physical distinction between man and the lower animals is that he possesses about three times as many cerebral neurons as does any other animal; and that his increased mentality is solely due to this cause cannot seriously be called in question. On the pathological side, the conclusion is that all the abnormalities of neural function, whether currently they are held to belong to the domain of psychopathology, psychiatry, or neurology, fall into four groups—absence, diminution, perversion, or exaggeration, respectively, of the functions of the three great structural divisions of the central nervous system—viz., receptor, internuncial, and effector neurons.

Straightforward as is Prof. Berry's exposition of his thesis, and impressive as are his numerous illustrations taken from clinical medicine, we should have been glad to have his views on the possible influence of function on structure; assuming that such a process is not only conceivable but on occasion actual, we should have been interested in his explanation of its bearing on his own line of argument. There must surely be interplay between vitalism and structuralism; in an appreciative preface written by Dr. Foster Kennedy, of New York, he insists that nurture is requisite, as well as nature, if the neuron is to flower; and we may recall the dictum of the veteran Prof. von Monakow, that every psychical process presents certainly a physiological effect in the brain, whether we will or not.

THE CLINICAL EXAMINATION OF THE NERVOUS SYSTEM.

Fourth edition. By G. H. MONRAD-KROHN, M.D., F.R.C.P., Professor of Medicine in the Royal Frederick University, Oslo, &c. With a foreword by T. GRAINGER STEWART, M.D., F.R.C.P., Physician to the National Hospital, Queen-square, &c. London: H. K. Lewis and Co., Ltd. 1928. Pp. 209. 7*s.* 6*d.*

WE have reviewed Prof. Monrad-Krohn's handbook on previous occasions, and compliment its author on the appearance of a fourth edition—a sure sign of appreciation and of its intrinsic merits. Comparatively little change has been made in the latest edition. Two or three pages on the interpretation of X ray photographs of the skull have been added. The book contains much useful and practical information in small compass, and deserves to be still more widely known.

THE PRINCIPLES AND PRACTICE OF OBSTETRICS.

Fifth edition. By JOSEPH B. DELEE, A.M., M.D., Professor of Obstetrics at the Northwestern University Medical School; Obstetrician to the Chicago Lying-in Hospital and Dispensary, and to the Mercy Hospital, &c. London and Philadelphia: W. B. Saunders Company. 1928. Pp. 1140. 55*s.*

THE fourth edition of this well-known text-book of obstetrics was published at the end of 1924, and even in this short space of time extensive alterations have been found necessary in both text and illustrations. The book is very complete and will be of value to those who take more than a superficial interest in this branch of medicine. The views of Dr. DeLee on pregnancy and labour are well known in this country. There are probably few who agree with him that more than half the pregnancies which occur in a civilised state are pathological; in spite of this view, however, he does not advocate excessive interference with the normal course of nature. The scientific side of the subject is dealt with fully, and hundreds of references are given to the various original papers from which quotations are made. In dealing with treatment, the author discusses the measures which have from time to time been advocated, and then describes his own practice. Midwifery under adverse conditions does not receive the amount of attention that might be expected in a book of this size.

In the previous edition Dr. DeLee was full of praise for the transperitoneal cervical Cæsarean operation, and we are interested to note that his further experience confirms his original opinion. The operation has now been performed at the Chicago Lying-in Hospital 620 times with six deaths. In 1924 it had been performed 266 times, so that this one hospital alone apparently has to deal with nearly 100 cases a year which require Cæsarean section. Thirteen excellent illustrations show the various stages of the operation. Catgut only is used for the uterine sutures. In both the classical and the low operation no attempt seems to be made to produce a thick scar in the uterus; it would be interesting to know how often the scar stretches. In the chapter on placenta prævia no mention is made of Willett's scalp forceps now used with great success in this country. It is not easy to discover the author's views on the treatment of eclampsia. He seems to approve of both the operative and the conservative methods under different conditions. If the conservative method is chosen, he advises that labour be terminated as soon as possible—i.e., as soon as the cervix is fully dilated. "If the head is engaged, forceps; if not, version is chosen." He approves of venesection, but considers eliminative measures to be useless. Chloroform should never be used to produce anæsthesia, and in his opinion ethylene is to be preferred to ether. He mentions that veratrone was recommended for the treatment of eclampsia in 1859, and places this form of treatment in the same category as amputation of the breasts. The chapter on forceps is most informative. In it the evolution of the modern instruments is discussed in detail. Dr. DeLee is not as enthusiastic as are most continental writers about the value of the Kjelland forceps.

This book has established itself as one of the leading works on obstetrics in the world. It is too large for the junior student, but for those engaged in the teaching of midwifery, and for those reading for higher examinations, it is invaluable. We would have preferred the weight to be less than five and a quarter pounds, but the illustrations and printing are beyond criticism.

A SHORT HISTORY OF MEDICINE.

Introducing Medical Principles to Students and Non-medical Readers. By CHARLES SINGER, M.D., D.Litt., F.R.C.P. Oxford: The Clarendon Press: London: Humphrey Milford, Oxford University Press. 1928. Pp. 368. 7*s.* 6*d.*

Dr. Singer has here attempted to trace the process by which medicine had its source in a number of isolated sciences, united into one stream in the eighteenth century with the rise of the scientific method of inductive reasoning, and divided in our own age into an ever-widening delta of ever-multiplying specialties. His aim is, by treating of medical ideas rather than of medical men, principles rather than details of practice, to indicate the Entelechy—or soul—underlying the bewildering network of modern medical science. He fears lest facts be piled up too fast for the philosophers to rationalise them, and pleads for the understanding of medicine as a whole and of its purpose in human affairs. The story of the infancy of medicine is kept within very strict bounds, and more than half the book is devoted to its modern developments, the beginnings of which Dr. Singer sees at about the year 1825, which he takes as the start of his Period of Scientific Subdivision. He traces in detail the development of the ideas which are now expressed in forms so much a commonplace of medical life that the realisation of their comparatively recent origin comes as a surprise. He shows, for instance, how the experimental foundations of modern medicine were laid by the work of the great physiologists Johannes Müller, Claude Bernard, and Karl Ludwig less than a hundred years ago. The cell theory and the study of cellular pathology did not exist before the work of Bichat at about the time of the French Revolution, and other keystones of medical science such as the germ theory, anæsthesia, and immunity are, of course, still more modern. The conquest of the tropics, the growing enlightenment in the field of psychology, the revolution in nursing, and the latest advances in pharmacology bring the absorbing story down to the present day.

The book is compact and well balanced, and is replete with charts and the interesting and recondite illustrations upon which the author is an authority. The Oxford fount and the rich paper make the volume a delight to the touch and eye. No one requiring a summary of the position of medical science, and its place in modern life, could wish for a more lucid author or a more favourable vehicle.

AIDS TO ORGANIC CHEMISTRY.

By STANLEY F. SMITH. London: Baillière, Tindall and Cox. 1928. Pp. 114. 3*s.*

Mr. Smith has taken the course of organic chemistry at St. Thomas's Hospital Medical School as the basis of a little book intended to help medical and science students in reviewing a subject which they often find to be elusive. Prof. R. H. A. Plimmer, whose course has thus been annotated, points out in a prefatory note where Mr. Smith has been able to bridge the gaps inevitably left in the subject owing to the short time allotted to it. The notes and formulæ are well arranged and indexed, and the book should prove useful for its modest purpose.

OPERATIVE SURGERY.

Third edition. By J. SHELTON HORSLEY, M.D., F.A.C.S., Surgeon, St. Elizabeth's Hospital, Richmond, Va. London: Henry Kimpton. 1928. Pp. 893. 63*s.*

THIS book has a recognised place in contemporary surgical literature. It is built up on the usual lines, but certain subjects receive more prominence than is customary. Much space is devoted to plastic work, and the account of this branch of surgery is very good. The surgery of the vascular system is also considered fully, and is a subject upon which the author is well qualified to speak with authority. His own methods of pyloroplasty and of performing the Billroth I. operation are described, and his reasons for recommending them. We notice a certain unevenness, not in the presentation of the subject matter, but in the perception of the true value of different surgical procedures. For instance, quite detailed and illustrated accounts are given of Trendelenburg's operation for removal of a pulmonary embolus, after which no patient has survived more than a few days, and of Coffey's operation for excision of the head of the pancreas which has not yet been performed in man; on the other hand, the details of much more ordinary procedures, such as the removal of cervical ribs or hypophysectomy, are too briefly dismissed. On the whole, however, a high standard is maintained, and the book should retain its popularity.

DENTAL MEDICINE.

By F. W. BRODERICK, M.R.C.S., L.R.C.P., L.D.S. Eng., Hon. Dental Surgeon to the National Sanatorium for Diseases of the Chest, Bournemouth. London: Wm. Heinemann (Medical Books) Ltd. 1928. Pp. 364. 21*s.*

THE author of this book writes with deep sincerity and has assembled an enormous amount of material in support of his thesis, which is, very briefly, that the predominant underlying cause of dental caries is acidosis, whilst pyorrhœa alveolaris is the result of an attempt to compensate alkalosis. In support of this belief the book contains chapters dealing in considerable detail with such branches of physiology as the regulation of the hydrogen-ion concentration of the blood, the glands of internal secretion, calcium metabolism, and the chemistry and physics of the saliva. It is clear that Mr. Broderick's study of the literature on these subjects has been extensive, but it would appear that this study was not undertaken with an unbiased mind, for his numerous quotations are almost invariably selected with a view to supporting hypotheses which, in the opinion of many distinguished physiologists, are at present quite unproven. It would be unfair to so sincere and industrious a writer to dismiss his theories in silence, but it would be equally unfair to suggest that his book as it stands is a fitting one to be read and accepted by the uninstructed reader, especially if such a reader has had no more thorough medical education than is received by the average dental surgeon. For it may be said that nearly all Mr. Broderick's main conclusions could, by an equally careful selection from the published work of various reputable observers, be disproved or shown to be without a sound basis of fact. Any author is, of course, free to express his theories in writing, but to publish a book entitled "Dental Medicine" is a challenge to criticism, in that the perusers of such a book may expect from its title to find in it a reasoned exposition of the established facts concerned in the subject. We have been unable to find any important series of observations in this volume made by the author himself in support of his beliefs, and it seems fair to suggest that he would have done far more on behalf of the theories which he sponsors if he had produced a reasonable series of some hundreds of observations on his own patients, carried out with unimpeachable biochemical technique, with a view to producing actual data to support his conviction that the acid-base equilibrium of the blood is disturbed in a specific manner in each of the two great dental diseases.

FOLKLORE OF THE TEETH.

By LEO KANNER, M.D., Yankton State Hospital, South Dakota. New York: The Macmillan Company. 1928. Pp. 316. 17*s*.

THIS book appeals to a wider circle than the professional reader, doctor, or dentist; it contains a surprising amount of information, bears evidence of reading and research, and is instructive as well as interesting. The contents are arranged in the following sections: number, shape, and eruption; popular dental hygiene; toothache and its cure; artificial deformation of the teeth; teeth as used outside the oral cavity. An appendix contains a bibliography and a glossary. Shakespeare would seem to have been one of the first to put in print the information, which must have been, even in his day, as old as the hills, that not even a philosopher can endure toothache patiently, while Burns cursed his affliction in robust Scottish verse. The chapter on plant treatment of toothache is dull reading, but it could not have been omitted from a work of this kind, and the rest of the book contains on almost every page interesting items of dental folklore. The golden tooth of the Silesian boy seems to have deceived nearly everyone save a canny Scot!

Details are given of the martyrdom of St. Apollonia, whose executioners, to punish the boldness of her confession, beat out her teeth and who thereafter became the patron saint of toothache; there is a frontispiece of the saint, reproduced from the painting by Dolci, at Rome. We do not observe any direct mention of soot as a popular tooth-powder. Harold Bluetooth is mentioned; one supposes him to have been the possessor of a dead incisor; but we miss Jenny Greenteeth. It may be that the latter is pure nursemaid fiction; but such was the name of the presiding genius of a certain pool in front of a rectory house on the Welsh border 60 years ago. When the children were allowed to fish in the said pool, with a "wurrm," they were always cautioned to beware of Jenny Greenteeth. In our day the myth was somewhat exploded, for an uncle, on one of these fishing excursions, had caught Jenny Greenteeth, who turned out to be a large eel. It is possible that, to the rustic mind, she may have represented the ghostly spirit of a previous rector, who chose the pool in front of his own door as the readiest mode of committing suicide. We cannot tell.

BIONOMICS.

Animal Ecology. By C. ELTON. London: Sidgewick and Jackson. Pp. 207. 10*s*. 6*d*.

ŒCOLOGY (for there is no reason for adopting the Americanised form of what was originally a German word) is the study of the relationships of animals and plants to one another and to their inorganic surroundings. Hitherto it has been mostly studied by botanists; this is indeed the first book on animal œcology to be published in this country and one of less than half a dozen written in English. The subject is one of much interest for its own sake, and its medical and hygienic implications are considerable. The control of many parasitic diseases depends on a knowledge of the habits, life-histories, food, and enemies of the lower animals which intervene in the cycles of infection; an œcological knowledge of rats, mosquitoes, and tsetse-flies is as important as full systematic information. Mr. Elton has himself made some important contributions (*Jour. Hyg.*, 1925, xxiv., 138) to the study of the periodic waves of excessive abundance which come over animals like lemmings, hares, and voles and end generally in epidemics, and has, in this book, provided an interesting and stimulating introduction to the whole subject.

JOURNALS.

AMERICAN REVIEW OF TUBERCULOSIS. April–June, 1928.—Dr. Henry D. Chadwick discusses the X ray and clinical diagnosis of pulmonary tuberculosis in children. He draws attention to the confusion that arises when juvenile and adult types of pulmonary tuberculosis are not separated into two distinct groups. The diagnosis of the juvenile type depends on a consideration of factors, the most important of which are radiographic evidence of calcified hilar glands and nodules in the lungs, the intradermal tuberculin test, and a history of exposure to infection. Physical signs are of less importance. None can be considered pathognomonic though interscapular dullness is due in some cases to muscular spasm, the reflex effect of inflamed mediastinal lymph glands. Auscultation and percussion are chiefly of value in so far as they determine the presence or absence of other disease. Calcified glands and nodules are definite evidence of tuberculous infection. In the absence of evidence of calcification enlarged or dense hilar shadows may be due to early infection, in which case skin tests and a study of symptoms may supply further evidence of disease and indicate the need for careful supervision and treatment.—A statistical study of the results of artificial pneumothorax treatment at the Locomis Sanatorium during a period of 14 years is supplied by Dr. Andrew Peters. In a series of 273 patients no cases of gas embolism or pleural shock were encountered. Of all patients in whom any pneumothorax at all was induced, 42 per cent. were living at the end of 2 to 14 years, and 24 per cent. were reported in satisfactory condition. The end-results in the pneumothorax group were nearly twice as good as those obtained when no pneumothorax was possible. When a satisfactory collapse of the lung was secured tubercle bacilli disappeared from the sputum in 72 per cent. of the cases and over 60 per cent. were alive at the end of the period quoted.—Dr. F. M. Pottenger contributes a paper on factors fundamental to healing in tuberculosis. Primary infection is met by a non-specific response by the body cells. A reaction which is "largely non-inflammatory" results in the formation of tubercles at the points of attack. When allergy has been established as the result of the absorption of tuberculous products at the source of infection the reaction of the body cells towards bacilli and bacillary protein changes. If reinfection occurs inflammation and exudation dominate the process. The response is now specific. Primary infection is an acute disease; a secondary infection, even when the result is fatal, is marked by a chronic course. The pneumonic exudation which accompanies the spread of tuberculosis in lungs is the result of an allergic reaction. Such exudate may completely resolve and leave no scar. This is the explanation of the remarkable clearing occasionally noted in a series of comparable skiagrams of a patient's chest during the course of a disease whose early spread was shown by extensive areas of mottled shadows in the lung fields. Dr. Pottenger illustrates this by a series of plates which demonstrate very clearly how exudation may be absorbed and cavities close as the result of natural healing. This article might well be read as an introduction to that on Tissue Reaction in Tuberculosis by Dr. R. S. Cunningham, and the analysis of Modern Concepts in the Pathology of Tuberculosis contributed by Dr. Max Pinner.

Dr. Charles Terry's book on "The Opium Problem," which was reviewed in THE LANCET last week, can be obtained in England through Messrs. Baillière, Tindall and Cox, 8, Henrietta-street, London, W.C.2.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 22, 1928.

THE IMPROVISED KNEE-JOINT.

The operation of arthroplasty of the knee, or the replacement of a joint that has been lost through disease or surgical operation, has taken a long time to make progress in the favour of surgeons. More than a quarter of a century has passed since Murphy, of Chicago, whom Sir Berkeley Moynihan has described as one of the supremely great men in medicine through all generations, succeeded in making useful new joints in the place of pre-existing bony ankyloses. Other surgeons have been slow in following up his methods, until Putti, of Bologna, reopened the subject soon after the war, and showed a number of remarkably successful results from this operation. Even now only a small number of surgeons seem to be adopting the technique, among them being Prof. Hey Groves, Dr. W. R. MacAusland, and in the last few years Dr. F. H. Albee.

The reasons for a cautious advance are not far to seek. Interference with the joints of the upper limb when properly performed often give excellent results, but the conditions are very different in the lower limb, which has to bear the weight of the body besides taking a large part in its propulsion. The knee is the joint which owes its stability least to the shape of the ends of the bones which enter into it and most to the surrounding muscles, the ligamentous and cartilaginous apparatus. Hence it is obvious that the mere re-forming of bone-ends is not likely to produce a useful joint, while to attempt to make new ligaments such as normally exist inside as well as around the site of the articulation would be a hopeless task. Long atrophied muscles, moreover, do not seem to offer good hopes for a secure control of the joint. Add to this the fact that the newly made knee-joint must bear the whole body-weight at least, and often much more than that, and it is not surprising that some of the most enterprising and skilful surgeons have shrunk from attempting the operation. Besides anatomical and mechanical objections, there are others of a functional nature. The patient who has a firm bony or even fibrous ankylosis in a good position is already in the possession of an exceedingly useful, strong, and painless limb. It is true that he finds it awkward in public conveyances, supposing that he is so fortunate as to secure a seat, and in the balconies of theatres. He is handicapped in the pursuit of the more athletic sports, and riding on horseback is practically forbidden to him. When such a patient is warned that the operation is a severe one, not without danger to limb and even to life, and that the after-treatment is long, likely to be painful, and sure to call severely upon his powers of perseverance and endurance, also that complete restoration of function cannot be guaranteed, he may well decide to leave things as they are. Moreover, the workman whose trade may require him to flex his knee-joint to its full normal extent has little to hope for from arthroplasty, since even passive flexion beyond a right angle is rarely possible after the operation.

There are, however, exceptional cases in which the hope of regaining a useful knee-joint outweighs other considerations. Such, for instance, was a cavalry officer whose future career depended on his being able to ride; he formed one of Prof. Putti's most brilliant successes. Surgeons who desire to be in a position to help such cases should study a recent article by Albee.[1] He supplies valuable statistical information of results of operations by various surgeons and describes a modification of technique which has given good results in his hands. This modification is ingenious, resulting from his observation of certain defects in the remote results of some of Murphy's cases. Supposing that the wound has run an aseptic course—and no surgeon whose technique is not reliable in this respect should dream of attempting arthroplasty—the chief causes of functional failure are (1) deficient range of flexion and extension, and (2) too great lateral laxity allowing deviation of the leg into genu valgum or genu varum. With the view of preventing lateral instability, which he thinks is a more common cause of failure than lack of flexion, Albee substitutes a wedge-shaped for a rounded articular surface of the femur, making a closely corresponding surface on the head of the tibia. Mechanically this is a sound theory, for, as Albee says, "weight-bearing forces the apex of the wedge-shaped end of the femur so firmly into the tibia that the danger of lateral instability is practically eliminated." There is no reason to doubt that this is true also in practice, but the conditions which Albee postulates as necessary for the lateral security of the joint seem likely to hinder flexion. He insists that each of the two faces of the wedge, which are to lie at an angle of 120° with each other, should be plane, a form which is not likely to allow much angular antero-posterior movement, unless there is great laxity of soft parts. This difficulty does not arise when the rounded shape of the bone ends is adopted. It must be admitted that the photographs reproduced give no indication that his technique has led to restriction of antero-posterior movements of a degree to prevent a useful amount of flexion. All operators are agreed that bony ankylosis of the knee is more suitable for arthroplasty than fibrous. The difference is probably due largely to the fact that among cases of fibrous ankylosis are included all cases of healed tubercle. Yet there seems no theoretical reason why a tuberculous knee in which the disease has long ceased to exist should not afford as good a result as one with osseous ankylosis due to an acute non-tuberculous infection. Even with modern means of examination such as X rays, however, it may not be possible to determine beforehand whether the inflammatory process is completely organised or only quiescent. But when a knee-joint has been successfully excised for tubercle it is probable that all diseased tissue has been removed, and the subject of such an operation might be given a new joint if he finds his disability distressing, without fear of stirring up a latent infection. Albee reports a most satisfactory result of arthroplasty in a knee formerly tuberculous. He adds a useful hint as to the choice of cases. Patients who are neurotic, unstable, and timorous are not likely to be such good subjects for arthroplasty as the bold and calmly hopeful who have shown pluck under previous sufferings and perseverance in making the best of their disabilities. Convalescence is a tedious affair, and the final result depends largely on the prolonged coöperation of the patient.

THE NATURE OF THE ROUS TUMOUR.

The relationship of the filterable tumours of the fowl to mammalian neoplasms is one of the burning questions of cancer research at the present time. Until recently many pathologists were inclined to consider these fowl tumours as a disease sui generis, while some authorities even classified them as infective granulomata. Any observation which tends to establish an essential similarity or dissimilarity between these tumours and mammalian neoplasms is therefore of importance. Two years ago Prof. S. Russ and Mr. G. M. Scott published in our columns [1] the observation that the Rous tumour when irradiated in vitro was extremely resistant to the destructive action of X rays as compared with mammalian tumours. The same resistance was exhibited by a cell-free filtrate of the Rous tumour, which contains the causative agent of this growth. If the causative agent is resistant to irradiation one would naturally expect that the Rous tumour when irradiated in vivo would also prove to be very resistant. Indeed Russ and Scott recorded observations which proved that this was the case. Soon after the publication of their results Dr. J. C. Mottram [2] set out the results of experiments which showed that under suitable conditions the Rous tumour when irradiated in vivo could be made to regress as readily as some of the transplantable tumours of the mouse and the rat. This result was unexpected and indeed paradoxical. The causative agent is present in the tumour, and as the experiments in vitro show, is very resistant to irradiation. Nevertheless the tumour regresses. The fowl in which a tumour has undergone regression shows the same phenomenon of resistance to a second transplantation that is observed in mice and rats under similar conditions. In a recent paper [3] Dr. Mottram has recorded the results of experiments which show how this remarkable result can be accounted for. The outcome of his first series of experiments seemed to deepen the mystery. He irradiated tumours growing in fowls with doses of radium known, from previous experiments, to be sufficient to cause ultimate regression of these tumours. Before regression was complete the tumours were removed and dried in vacuo. When this dried material, which did not contain living cells, was inoculated into fresh fowls new tumours were formed. The same result was obtained with a filtered watery extract of regressing tumours. It is clear, therefore, that a tumour regressing under the influence of irradiation still contains the causative agent or virus in an active form. Why, then, does an irradiated tumour not infect the surrounding tissues and grow by extension, instead of regressing as it actually does?

The answer to this question was found by irradiating areas of the skin and then, after scarifying the skin, applying to it active filtrates of the Rous tumour. Such filtrates, though producing tumours in non-irradiated areas of scarified skin, were unable to do so in the irradiated skin. Histological examination of these skin areas showed that the fibroblasts which are abundantly present in a scarified area of non-irradiated skin are absent in previously irradiated skin. Now McIntosh and Baker have shown very conclusively that the Rous tumour arises from a transformation of the normal fibroblasts, and Dr. Mottram's observations confirm their conclusion. The apparently paradoxical behaviour of the Rous tumour towards irradiation explains itself therefore as a manifestation of the extraordinary specificity of the causative agent or virus, which can only infect the fibroblasts of the fowl, but no other cell. Irradiation of the Rous tumour in vivo damages not only the tumour cells, but also the normal cells of the host which immediately surround the tumour, so that in the neighbourhood of an irradiated tumour there are no fibroblasts which can be infected by the causative agent of the irradiated tumour. These observations are of interest not merely because they offer an adequate solution of a particularly intricate problem connected with the filterable tumours of the fowl; they also have a bearing on the more important general question of the relationship of these tumours to mammalian neoplasms. The demonstration of a specific causative agent separable from the living cell in the former group seems to justify the standpoint that these tumours form a disease sui generis entirely distinct from true neoplasms and, as already stated, until recently this was the attitude generally adopted by cancerologists. The work of Gye, although criticised in its experimental aspects, has nevertheless been instrumental in changing this attitude, and there are to-day few workers in cancer who are prepared to deny outright the true malignant nature of these tumours. The essential similarity between the reaction of the Rous tumour to irradiation and that of true mammalian new growths is evidence in support of the view of the fundamental similarity of these two types of neoplasms, and it is the more convincing as it was unexpected on a priori grounds.

DEFECTIVE OBSTETRICS.

New Zealand is justly proud of its low infantile mortality-rate; in 1900 this was 75·2 per 1000 births, last year it was 38·7—a world record. The maternal mortality-rate, on the other hand, was 4·91 per 1000 live births, compared with 3·90, the last five-yearly average for England and Wales—an increase of 0·66 on the figure for the previous year.[1] At the same time the rate for puerperal septicæmia rose from 1·37 in 1926 to 2·51 in 1927. This rate, on the graph prepared by the Government statistician, shows a peak about every ten years, and last year's figure was the highest since 1885. The death-rate from other puerperal causes was comparatively low. Prof. Henry Jellett, late Master of the Rotunda, and now consulting obstetrician to the New Zealand Government, considers that the real maternal mortality-rate is even higher than is recorded. He attributes this great loss of maternal life to two main causes: (1) the insufficient education of medical students in obstetrics, (2) the failure to provide sterilised dressings.

The unduly high proportion of cases in which forceps were used in hospital—namely, 12·5 per cent.—is in itself evidence to Dr. Jellett of faulty obstetrical training. The National School of Medicine is at Dunedin University, and in November last Dr. Jellett, in accordance with the instructions of the Minister, met the medical faculty to discuss the best methods of improving the training. To continue in what are substantially the words of his report: the inadequacy of the present methods, which is fully recognised by the faculty, is in no way due to want of effort on the part of the teachers, but rather to want of adequate clinical material and of the necessary funds. When the new regulations for the training of midwives bear fruit, the midwife will be better equipped in the art and practice of midwifery than the medical practitioner. This is a very serious state of affairs, because the midwife is only trained to conduct normal labour, and if the medical man is insufficiently educated he will be unable to deal with emergencies, and when confronted with them will fall back on radical surgical procedures instead of the milder obstetrical methods which would serve better. If the medical practitioner's education is insufficient, it is probably better that he should not attend confinements at all. The Plunket Society for infant welfare, which cares for the mother n pregnancy and the infant during its first year of fe, has made admirable progress assisted by the upport of the Government and the general public. The obstetrical department of the medical school, however, the work of which is equally important, is left in the same financial position as it occupied many years ago. It has no professor at its head, no suitable hospital in which to educate its students, and insufficient funds to pay its teachers. The public are probably unaware of the close connexion between the poverty of this department and the high maternal mortality-rate. Provision of the needed funds is presumably a matter for the Government, and one which in the present financial position of the Dominion they may find very difficult. There must, however (says Dr. Jellett), be many wealthy individuals or corporations who would be willing and able to help if the need were brought home to them, but this has, so far, not been done. The faculties of medicine and surgery have each £1600 a year, mostly from private benefactions, with which to pay their staffs; the faculty of obstetrics has a bare £530, and even this is to be reduced at the end of this year by £75. Dr. Jellett suggests that the Department of Health make a public demonstration of the needs of the obstetrical department of the medical school a part of its propaganda for the reduction of maternal mortality.

---

[1] Report of the Director-General of Health, New Zealand, for the Year ended March 31st, 1928. Department of Health 1928. Pp. 78. 1s. 6d. H 31. Wellington: W. A. G. Skinner.

The second great need, that of asepsis, is treated very fully by Dr. T. L. Paget, inspector of hospitals. He has succeeded after great exertion in making cheap and efficient sterilising equipment available in hospitals, and in minimising the spread of puerperal sepsis in maternity institutions, holding that if the same standard of asepsis were maintained in private practice as under the regulations in hospitals, puerperal sepsis rates for the Dominion would greatly diminish. This depends not only on the education of the medical man, but on the coöperation with him of the patient and nurse. The training of nurses and midwives in asepsis is slowly improving, but much remains to be done, especially in private practice. To quote Dr. Paget: the adoption of asepsis in surgery took 15 years, and the training of the nurses who had not learned it originally was done by surgeons in actual practice. The training of maternity nurses in asepsis can, he says, only be done in a reasonable time, when every medical practitioner feels it his duty to see that it is completely carried out. The patient must be made to recognise its importance, and be advised to choose a nurse who understands it, and to provide a sterilised maternity outfit. The antenatal clinics supply these outfits, yet only 515 of a possible 1900 patients confined in private took the opportunity of obtaining them. Dr. Paget is urging their provision in all centres of maternal welfare; they cost about £1 5s. each if made of towelling (convertible after use into babies' napkins), and 10s. if made from old sheets. He sees the key to the problem of maternal welfare in coöperation between the expectant mother and her husband, a well-trained antenatal clinic nurse, an alert and efficiently trained medical attendant, and a well-trained maternity nurse or midwife on the one hand, and the services of the hospital board, which can provide hospital accommodation for patients who need it, and services for sterilising outfits for all patients on the other. If the Dominion Government and people attack the problem on these lines under the energetic leadership of obstetricians like Drs. Jellett and Paget, there is no doubt of their success, but a great awakening of public interest is obviously necessary. The recent inauguration by Mr. Victor Bonney of the New Zealand Obstetrical Society marked a definite step forward by the profession; the entire frankness of the Director-General's report indicates that the Dominion Government is willing to play its part. The education of the general public lies with the Minister of Health and the lay press.

Annotations.

"Ne quid nimis."

INTERNATIONAL VISIT TO BRITISH SPAS.

MEDICAL hydrology has had its meetings at continental health resorts whether in France, Italy, or Czecho-Slovakia, but until now no international medical party has visited British spas. This is to be put right when the International Society of Medical Hydrology holds its annual meeting from the 9th–17th of next month. The rendezvous will be London, where a reception will take place at the house of the Royal Society of Medicine on Tuesday night, Oct. 9th, and conferences have been arranged for the two following days, under the presidency of Lord Dawson. The first of these discussions, to be introduced by Dr. C. W. Buckley (Buxton), will deal with the organisation of the spas in various countries, especially for the treatment of insured persons, and the second with the humoral factor in disease, with particular reference to the action of waters. After this the party, numbering over 100 individuals of 17 nationalities, will make a tour of the spas, where they will see at first-hand the whole development of the native waters of Britain. At Harrogate opportunity will be given for considering specially the treatment of children by waters and baths, and at Buxton there will be a conference on rheumatism as a national problem. Visits will also be paid to Droitwich and Bath. Places are still available for a limited number of members of the medical profession who would like to make the tour of spas under such stimulating conditions and to take part in the discussions. A programme of arrangements in three languages is available, and particulars may be obtained from the Hon. Secs. of the Society, 139, Marylebone-road, London, N.W. 1.

LOCAL ANÆSTHESIA IN THE REDUCTION OF FRACTURES.

LOCAL anæsthesia is making rapid advances and is being used more and more for surgical conditions which formerly could be treated only under general anæsthesia. English surgeons are perhaps more conservative in their attitude towards local anæsthesia than their American and Continental contemporaries, and, while this is a tribute to the excellence of our anæsthetists, the use of local anæsthesia might with advantage be extended. A useful application has recently been described in two American medical papers—namely, the reduction of fractures of the forearm after infiltration anæsthesia with novocaine or procaine. The shorter article of the two describes two cases of fracture of the forearm which were reduced at the Boston Dispensary after infiltration with 1 per cent. novocaine solution.[1] In the other article[2] Dr. Carl O. Rice, of the Minneapolis General Hospital, gives a more detailed description of this method of reduction, a method he has used with success in a series of more than 50 cases treated during eight months in the receiving ward of his hospital. In no case did the manipulations cause pain, and the greatest discomfort that was ever noticed was a feeling of pressure or a painless grating during reduction. The reduction itself was always easy, and it was never necessary to use much force owing to the perfect muscular relaxation. The only two failures reported were in cases in which the deformity recurred and further infiltration was tried on the next day. The use of a second infiltration is now considered unwise, and general anæsthesia is recommended for the second attempt. Dr. Rice uses a 1 per cent. solution of procaine hydrochloride and the method he employs for the induction of anæsthesia has the merit of great simplicity as no very accurate visualisation of the important structures round the wrist-joint is necessary. After sterilisation of the field of operation with alcohol and iodine two subcutaneous wheals are raised about one inch above the line of fracture in the radius, one opposite to the dorsal border and the other opposite to the lateral border. A needle 2½ in. long is now inserted through the wheal opposite the dorsal border, and the dorsal and lateral surfaces of the radius are infiltrated in turn without withdrawing the needle. The ventral surface is infiltrated from the second wheal, the radial artery and the median nerve being avoided by keeping the needle close to the bone, so that it passes posterior to these structures. If no blood appears in the syringe during the injection the needle must be pushed in the direction of the fracture until blood appears and then about 5 c.cm. of the anæsthetic solution are injected into the effused blood at the site of the fracture. The total amount of anæsthetic used is 15 to 60 c.cm., and manipulations may be started about half an hour after the injection. Obviously this method cannot be used in the presence of infection or in compound fractures, and the risk of infection in uncomplicated cases must be considered. The author, however, considers this to be negligible when reasonable precautions are taken, and no case of accidental infection has occurred in his experience. The fact that the anæsthesia lasts for some time makes it possible to have a radiological examination after reduction; and if necessary further manipulation may be undertaken at once to improve the position of the fragments. It may be stated, therefore, that this method is one to be considered carefully, as it has many applications, even if it is not adopted as a routine in cases in which nitrous oxide anæsthesia would be adequate. The problem of a fracture of the lower forearm, with slight deformity, in the aged, the plethoric, and the alcoholic need no longer exist to worry the busy out-patient surgeon.

THE CHEMICAL COMPOSITION OF DENTAL ENAMEL.

PROBABLY the technical difficulties attendant on both the chemical and microscopical examination of the enamel of teeth have served to stimulate investigation of a tissue which forms so small a part of the body. But the interest has not been purely academic, for as the external calcified covering of the teeth, enamel represents the first line of defence against caries; when it is destroyed the tooth is left almost, though not entirely, unprotected against destruction. Much of the work on enamel has been histological, but various chemical analyses of this tissue have been made. In this country Sir Charles Tomes's findings in 1896 were that though a trace of organic matter might be present it was not enough to amount to a weighable quantity. Lovatt Evans in 1913 published an analysis and concluded that enamel contained at least from 1 to 2 per cent. of organic matter. Since then no further chemical analyses have been recorded in this country until E. Sprawson and F. W. Bury communicated a paper recently published in the Proceedings[1] of the Royal Society. The specimens of enamel examined were obtained by filing with a metal file. To remove any contamination from the file each specimen was exposed to a powerful electro-magnet such as is used in ophthalmic surgery. The nitrogen content was estimated by Kjeldahl's method, but the ammonia content was determined colorimetrically by means of Nessler's solution. The carbon content was estimated by means of a special apparatus devised by Dr. W. H. Patterson. As a result of a series of 20 analyses Sprawson and Bury find that the maximum organic content of enamel calculated from the highest nitrogen content is 0·15 per cent. The amount of protein calculated from the carbon present is a little higher. Samples of enamel from young persons, from adults, and from the deciduous teeth showed practically no difference in the organic content. Sprawson and Bury appear to have taken careful precautions to avoid fallacies which might vitiate the analyses and to have used very delicate methods. Their results, if they are confirmed, will have a definite bearing on some of the hypotheses of the causes of dental caries and its prevention which are being widely and increasingly championed in many quarters. During the last decade as a result of the microscopical study of enamel there has been an increasing tendency to believe that enamel, far from being practically an inorganic tissue, contains a definite amount of protein and that it is thus a vital tissue, capable of reacting to injury like other tissues so long as the dental pulp remains vital. The evidence for this hypothesis is of a cumulative character and drawn from a variety of observations. Enamel can be stained not only by the treatment of sections, but also by diffusion through the dentine in whole teeth. This would suggest that calcification is incomplete and by inference that the stained areas contain protoplasm. H. Malleson, by means of a delicate technique, was able to decalcify enamel and to demonstrate that the residue showed a definite structure. By analogy with other calcified tissues this would suggest that it contains a distinct organic basis, sufficient to show the character of its structure after decalcification. Although there is a definite line of demarcation between the dentine and enamel, yet the dentinal tubules may extend a short way into the enamel. The late Howard Mummery demonstrated the presence of what he termed fibrous bundles extending from the dentine into the enamel. A. Livingstone attempted to widen this conception and described certain experiments which gave some support to the suggestion that the enamel might act as an osmotic membrane. An observation of much interest was made by Mummery when he described the occurrence of translucency in enamel in cases of early caries of enamel. These closely resembled the translucent zones seen in dentine in the early stages of caries, which zones are known to be caused by the reaction of the pulp producing hypercalcification of the contents of the dentinal tubules. Mummery suggested that the translucent zones in enamel might be caused in the same way—a view which postulates the vitality of enamel. Each or any of these various observations made from different angles might be susceptible of some other interpretation, but their cumulative effect certainly suggests that enamel is not an inert tissue incapable of any change after formation except that of destruction by caries or abrasion. The high degree of immunity to caries in some individuals and the equally high susceptibility in others and also the alternations of susceptibility and immunity often found in the same person at different times might reasonably be explained by changes occurring in enamel after the eruption of the teeth. From this it was an easy step to suppose that it might be possible to influence the resistance of the enamel in various ways, as implied by M. Mellanby in her later work. But whatever inferences might reasonably be based on staining appearances in enamel as to the presence of organic matter, such inferences should be capable of confirmation by chemical analysis and without such confirmation they are deprived of much of their force. In a recent book reviewed on another page Mr. F. W. Broderick refers to Tomes's dictum, that enamel is an inert tissue, as a damper (on the development of the doctrine of the vitality of enamel) which was removed by the work of Lovatt Evans. He makes no mention of the results of Sprawson and Bury. The importance of the discrepancy in results in the view of some dentists is that while the percentage of organic matter found by Lovatt Evans might be sufficient to allow of metabolic changes in the enamel, the percentage found by Sprawson and Bury, confirming Tomes, is considered to be almost negligible. But the discrepancy is not really so very great, and probably none of the experiments here described shows whether the enamel is alive or not. That depends on its reactions to conditions rather than on its chemical composition. And in any case it is probably only a small part of it which *can* be alive. Pending further work no decision can be taken as to whether enamel once formed is incapable of change or whether it remains within the pale of nutrition.

SWIMMING BATH WATER.

THE Wheatley Memorial, as we pointed out last week, lays very just stress on the desirability of running water for public bathing. Even the watercress refuses to use a stagnant pool. Nevertheless it must not be forgotten that it is possible to disinfect the water of public swimming baths so as to make it safe for bathing or even safe (if not appetising) for drinking. Dr. G. K. Bowes in the current *Journal* of the Royal Institute of Public Health regards it desirable to adopt as stringent a standard for bathing water as for drinking water. To do so, however, requires a disinfecting agent continuously present in the water, the simplest and cheapest being free chlorine in the proportion of 0·2 to 0·5 parts per million. Dr. Bowes bases his recommendations on the examination of the water of public baths in Birmingham during two consecutive summers. In America, it appears, use is made of a standard frankly called "the index of stagnation," which consists of the number of bathers divided by the amount of clean water added, measured in thousands of gallons. It will readily be admitted that under a controlled water régime of this kind the incidence of conjunctivitis is likely to be small and any possible risk of the spread of poliomyelitis in this way disappears altogether. The occurrence of suppurative otitis after bathing is on rather a different footing, for this is presumably due simply to the careless admission of water to an infected middle ear whose safety lies in remaining dry. The use of natural running water remains the obvious course for bathers who dislike the accumulation of bacterial and human detritus, and we have little doubt that the memorial to be raised to Dr. James Wheatley will produce a good response.

THE LIMITATIONS OF PLASMOQUINE.

THE Hamburg School of Tropical Medicine, and foremost amongst them Dr. Otto Fischer,[1] have been energetically investigating the action of plasmoquine in human malaria; nor have they neglected the less favourable side of their subject, careful records being kept of the toxic symptoms occasionally caused by the drug's administration. Of these, methæmoglobinæmia is the most alarming, resulting as it does, in cyanosis. Experiments on otherwise normal cats have shown that daily doses of 0·1 to 0·15 g. plasmoquine invariably produce methæmoglobinæmia, but that the intimate mixture of quinine sulphate with plasmoquine seems largely to mitigate this and other toxic phenomena. Thus it has been shown in clinical practice that, if quinine be combined with plasmoquine in a dose of 1·0 g. daily, either no methæmoglobinæmia results or the amount is negligible. Subcutaneous injection of plasmoquine has been attempted at Hamburg, and in doses of 0·02 g. daily was not attended by any ill-effects; but this quantity is too small to have any permanent effects in eradicating the infection, although it may control multiplication of the parasites. On an average the minimal therapeutic dose of plasmoquine is 0·06 g. daily, or 0·01 g. to every 10 kg. of body-weight in benign tertian malaria. In subtertian malaria a total amount of 0·15 g. injected, or a total amount 0·2 g. by the mouth, suffices, whether spread over several days or given more massively within 24–36 hours, to eradicate crescents from the peripheral blood within a period of five days. Failure to banish crescents only occurs when the schizonts are not sufficiently exterminated and can undergo transformation into gametocytes. According to Fischer's observations, plasmoquine-resistant forms of malaria are extremely rare. This is specially true of the benign tertian parasite, in which Fischer has not seen a single failure, but in subtertian malaria three instances have been noted, in which crescents persisted in the blood stream while the patient was taking full doses of plasmoquine. Then it has already been claimed that plasmoquine exerts a selective effect upon the crescents, and his statement appears somewhat paradoxical, but the anomalous effect can be explained by failure of the drug to cause rapid death of the younger schizonts in the earlier stage of the infection. When plasmoquine is combined with quinine there is no such failure, which is a further argument in favour of combining these two drugs and of administering the plasmoquine component in a subminimal therapeutic dose.

SELF-KNOWLEDGE AND MENTAL HEALTH.

IN a paper read before the British Association Dr. William Brown stressed a point of great importance in the application of the method which he prefers to call "deep analysis" to the cure of psychoneuroses or symptoms referable to faulty adjustment of the mind. That is, the necessity, if a real and lasting cure is to follow, of ensuring not only that the patient shall acquire adequate knowledge of himself, his real needs and his errors, but also that he shall apply that knowledge to setting himself in order, correcting his faulty tendencies and habits, and developing an enlightened self-command. It seems that the more devoted followers of Freud are inclined to neglect this constructive aspect of analysis. Dr. Brown criticises the use of the term "psycho-analysis" for both of two distinct concepts that should have distinct names—first the Freudian method of deep analysis by free association; and, secondly, the Freudian theory of mental function and the manner in which it is modified by this method. This ambiguity is probably not so much a cause of the Freudian tendency to underrate the value of constructive re-education as the expression of an attitude of mind, not confined to the Freudians, that considers the method more than the result. It is a pity that this attitude should exist, but that it does is shown by the divergencies which are so evident between the various schools of psychological thought and impose such a handicap on progress. Dr. Brown therefore uses the term "deep analysis" for the method, reserving "psycho-analysis" for the body of doctrine.

The Freudian system lays what many, including Dr. Brown, consider a disproportionate stress on self-knowledge. Deep analysis is a process by which, in the course of many months and sometimes years of passive re-living of infantile experience and of the "transference" to the analyst of the emotional reactions which have been insufficiently related to the parents and to other persons who have partially replaced them, the patient acquires a knowledge of the primitive layers of his mind. In discussing his experiences with his analyst, who for the time being stands to him for an immensely superior personality, on whom he is extremely dependent and by whom he is highly suggestible, he inevitably adopts, often wholesale, the theory by which the analyst directs his method. Obviously the more rigid this theory is the less will the patient's own personality be able to evolve its own theories and shape the course of its own re-education. And if one thing is held by the leaders of analytical thought to be more important than any other it is that the patient must be led to think for himself, to work out his own salvation. It is for the analyst to provide the material and to indicate the ways from which the patient shall choose, but ultimately the patient himself must decide which way he shall go and what use he shall make of the material. It is of no use reducing the patient to a state of entire dependence and then turning him loose. After the analysis has been completed and the deepest emotional complexes and their ramifications are laid bare, there comes what many workers consider even a harder task—the education of the patient up to the point where he can free himself of this dependence and become an autonomous being. This is where many analysts, and among them many Freudians, fall short; they do not finish their job, and the patient has either to go elsewhere or remain almost as imperfectly adapted as he was in the beginning.

---

[1] Münch. med. Woch., August 10th, p. 1369; and August 17th, p. 1417.

It is obvious, therefore, that the constructive analyst will exercise great discrimination in the material he provides. It is no good spending weeks in working out infantile phantasies if the resulting knowledge is not going to be usefully employed in the reconstruction by which the patient hopes to adapt himself to the world. The analyst who adheres too closely to a preconceived method will almost inevitably allow his patient to pursue his way through many weary and overgrown by-paths which lead nowhere but into an impenetrable jungle and from which the return may be difficult and painful. The good analyst, like the good artist, knows what to eliminate and where to stop. Dr. Brown speaks of the great resistance which patients sometimes manifest to the process of analysis—" I wish I had not come. I ought not to have come to-day." Some degree of resistance is inseparable from an experience which must at certain crises be extremely unpleasant, but there are almost certainly resistances which arise from the real conviction of the patient's own creative personality that the way ahead of him is one that he would do better to avoid. An experienced man will often oppose his patient's resistances, but he will always respect them; some kinds of broken resistance may mar an analysis as badly as an unnecessarily cut nerve or tendon may mar a surgical operation. It is undoubtedly possible to have too much, even of such a good thing as self-knowledge. Mental analysis has long established itself as an indispensable weapon against the storms and stresses with which life assaults the mind, and the need to-day is, as Dr. Brown says, for analysts with independent and vigorous minds and a determination to think hard for themselves and evolve their own methods and theories. As is the master, so is the pupil, and the more completely an analyst has worked out his own transference on the master of his school and become self-directing, the more completely will he enable his patients to work out their transferences on himself.

X RAYS AND WHITE BLOOD CELLS.

That in the treatment of blood conditions repeated divided doses of X rays are more effective than a single massive dose is a principle generally accepted by radiologists, though up to the present it has lacked experimental proof. Such proof is in some measure supplied by the recent work of W. V. Mayneord and A. Piney[1] carried out at the Cancer Hospital. Using a carefully standardised technique, these observers in the course of an investigation into the effect of X rays upon the blood and blood-forming organs, found that a much greater result was produced in rabbits by a dose of approximately 500 R spread over 24 days than by the administration of the same dose at one sitting. As criteria of the effect of radiation upon the blood, these observers used the changes brought about in the three orders of white cells—lymphocytes, neutrophiles, and monocytes. They confirmed the old observation of Heinke[2] that the first and most striking effect of radiation is a progressive diminution in the number of lymphocytes, to be followed by an increase in the neutrophiles and, if the dosage is pushed to extremes, by a rise in the monocytes. At the Cancer Hospital it was found that a persistent increase in the monocytes usually served as an indication of irreparable damage and was followed by the death of the animal. Whether or not the monocyte of the rabbit is to be regarded as the strict homologue of the same cell in the human being remains to be decided; in any case this observation obviously calls for similar investigations in the case of human beings receiving X ray treatment. Typical lymphopenia was found as an early manifestation in the blood of the women affected by the radio-active substances in luminous paint, to whom Sir Thomas Oliver refers (see p. 634); it would be of interest to know if in the cases which proved fatal the monocytes were found to be greater in number than the lymphocytes. Mr. Mayneord and Dr. Piney found in the case of rabbits that death inevitably ensued if the monocytes in the blood came to exceed the lymphocytes in numbers. Working on the spleens of radiated animals Dr. Piney was able to demonstrate a selective action on the part of the rays for the lymphoid tissue of the Malpighian corpuscles, and he suggests that a generalised selective action upon lymphadenoid tissue is the explanation of the lymphopenia induced by radiation. That lymphadenoid tissue is peculiarly susceptible to X rays is shown by a number of clinical observations, notably the susceptibility of the glands in Hodgkin's disease and of the tumour masses in lymphosarcoma to the action of these rays.

"THERAPEUTIC-MINDEDNESS: A PEDAGOGIC PROBLEM."

Under this heading Dr. Paul Reznikoff, of New York, attacks[1] the doctrine that in medical practice treatment is less important than diagnosis. Whilst strenuously opposed to a return to "the enormous number of drugs and methods that preceded the age of therapeutic nihilism," he maintains that present methods of instruction fail to develop a correct mental habit, which he calls therapeutic-mindedness, a desire to heal. On analysing the treatment given in different diseases at a certain hospital, he found much support for his view that therapeutic-mindedness is at a low ebb. In lobar pneumonia, for instance, good or questionable treatment was started in the first eight hours of treatment in only 64 per cent. of cases. Generally speaking, the less dramatic the disease the lower was the percentage of effective treatment. Whereas all the patients in coma at once received good treatment, the percentage of cases in which it was given immediately was only 50 for meningitis, 70 in broncho-pneumonia, and 28 in colitis, and the unfortunate sufferers from sciatica were none of them efficiently treated during their first eight hours. Dr. Reznikoff is well aware that it is largely fatigue that causes the intern who has completed history-taking and physical examination to omit much thought of treatment, and he thinks that the remedy for this faulty attitude is not so much to provide separate courses for the teaching of therapy as to combine the teaching of diagnosis and treatment in such a way that in the mind of a physician failure to alleviate a headache or insomnia shall rankle as much as failure to diagnose an aneurysm. In order, therefore, that the clinical clerk shall give proper attention to his therapeutics, he should attend not only a course in pharmacology and theoretical therapeutics, but also medication conferences and "diet conferences," and—perhaps most important of all—demonstrations of such procedures as colon irrigation, steam inhalation, throat irrigation, hot packs, and bed-making. After each procedure or demonstration the uses of the measure should be discussed, and Dr. Reznikoff finds that the students become so interested in these conferences that many express their desire to spend some time as orderlies in the wards in order to master the methods.

[1] Jour. Amer. Med. Assoc., August 18th, p. 450.

With such a course of instruction and with the objects that underly it none can fail to sympathise. Many practitioners must wish that they were more in touch with the actual drugs they prescribe and with the methods they order nurses to carry out; it is more than likely, for example, that a large proportion of medical men have neither administered nor observed the administration of the simple soap enema. To correct such defects in experience is obviously desirable, and the attempt is made with more or less success at many of our hospitals. The reader, therefore, may be left wondering whether there is any reason for a cleavage between those who advocate treatment and diagnosis respectively; both wish the patient well, and both are supposed to be making intelligent use of the known facts. But undoubtedly there is some such cleavage. The conservative physician is especially impressed by the fact that all forms of treatment are but mild adjuvants to Nature, and consequently places most highly the need for an estimation of the diagnosis and course of the disease; the enthusiastic "progressive" physician is anxious at all costs to see some improvement or alleviation by whatever methods are available. Both schools are liable to fall into serious error, and whilst agreeing with Dr. Reznikoff in condemning diagnosis without treatment we must admit that treatment without diagnosis is apt to be the more dangerous. And even in Dr. Reznikoff's excellent paper it is possible to detect pitfalls into which the enthusiastic therapeutist may plunge unawares. In the opening paragraph we read that "everyone connected even remotely with the profession agrees that, whatever else the physician may be, he is above all a healer"—a sweeping statement with which many will flatly disagree. And when he goes on to say that "in the matter of therapeutics the future physician must . . . develop an emotional habit" besides a mental habit, he is inserting a line of divorcement between the departments of diagnosis and therapeutics which he has been elsewhere so anxious to weld into a consistent whole.

THE SELF-SUPPORTING HOSPITAL.

WILL the voluntary hospital continue to be voluntary, in the sense most of us at present attach to the word—that is to say, will it remain an institution, supported mainly by voluntary contributions, which gives free treatment to patients—or will it be replaced by the self-supporting hospital? This is the question which Dr. R. J. A. Berry, Professor of Anatomy and Dean of the Medical Faculty in the University of Melbourne, recently put to an audience in that city. Prof. Berry is well-equipped for discussing the subject, since last year he travelled 30,000 miles on a mission of inquiry into hospital and medical problems. The result of his investigations, as detailed in his address, was a strong conviction that the future is to "the medical centre devoted to community health" and its associated self-supporting hospital. He was "profoundly impressed" with this centre, as seen at work in the United States and Canada, and almost as profoundly dissatisfied with the voluntary hospital system of Great Britain which in the main he found, like the hospitals of Melbourne, to be "totally divorced from the pre-clinical and scientific laboratories of a medical school." Prof. Berry laid stress upon the right of the patient, whatever his means, to the benefits of institutional coöperation, coördinated medical knowledge, and individual service, benefits which, so far at all events as Melbourne is concerned, cannot be obtained to the full "in the present isolated hospitals, laboratories, and incomplete medical school" of the city. No one will quarrel with this claim, nor is there any expert at home who fails to recognise that the voluntary hospital is in a state of transition. That our hospitals are all so destitute of immediate association with medical education and laboratory research as he suggests cannot however, so readily be conceded. The connexion between university, medical school, and hospital is by no means unfamiliar, and the advantages of that connexion are so patent that the movement towards the medical centre, where it does not exist, has already begun. Such centres can be planted only in great towns, yet it should always be possible to affiliate to them those smaller local hospitals which often stand seriously in need of the practical experience and scientific help of the great institutions which exist as much for research and prevention as for curative purposes. The isolated individualism of our voluntary hospitals is a drawback which cannot but have an inimical influence upon their usefulness, and it seems inevitable that, sooner or later, we shall have something in the nature of hospital circles radiating from great scientific centres. The self-supporting hospital, which Prof. Berry found so frequently on the North American Continent, is really the voluntary hospital with a difference. It acquires self-respect by being relieved from the necessity of making constant appeals for money, and instils self-respect into those of its patients who are not actually indigent, by teaching them the unworthiness of expecting "something for nothing," an expectation which Prof. Berry has found widespread and resents. He enumerates the sources of revenue of the trans-Atlantic self-supporting hospitals as receipts from endowments which are sometimes considerable, since "no wealthy man dare die in the States without leaving something to his university, home-town, or favourite hospital"; payments for hospital services from middle-class and wealthy patients; payments from local authorities for patients unable to pay for themselves. Thus the occupant of every bed pays, or is paid for. The system is, in effect, a fusion between the voluntary hospital, as we know it (with or without "pay-beds"), and the poor-law infirmary, maintained out of public funds, with this important difference, that nobody is called by the absurd name of pauper. The bill, whether presented to the patient or the authority responsible for him, includes the medical fees which are paid over by the hospital to the medical consultant in charge of the case. If hospitals are to be open, as they already in considerable measure are open, to patients of all classes, that part of the voluntary system which implies the free services of the medical profession goes by the board. The institution of "pay beds" which is becoming so common is a recognition of the changed situation that has been forced upon hospital managers, but it may be found, in the end, to be no more than a palliative.

TRANSMISSION OF DISEASE BY AEROPLANES.

AN Australian correspondent draws our attention to some of the implications of the flight made by Kingsford Smith and his associates from San Francisco to Brisbane. New standards of rapidity in communication must have the effect, he points out, of bringing "the endemic centres of hitherto exotic disease" into dangerous proximity to Australia. Separated by long sea voyages from the primitive sanitation of the East, the Commonwealth has, up to the present, kept fairly free from Oriental infections: thus there has been no case of small-pox since August, 1921, and plague has not occurred since June, 1923. Cholera and yellow fever, indeed, have never penetrated Australia's quarantine barrier, an important factor in this happy state of affairs being the length of time that must elapse on the journey from an infected port. Plague and cholera are prevalent at Rangoon and Bombay, but during the voyage t Australia from these cities any infection is sure t manifest itself on board the vessel, as the incubatio period is less than a week. By fast air transport, however, Rangoon is only 62 hours' journey from Australia. Small-pox, moreover, may not develop until 16 days after exposure to infection, within which time, as Hinkler showed, it is possible to travel the whole way from England. The solution of the problem, our correspondent considers, cannot be quarantine; for who would travel 6000 miles in 84 hours in order to spend the following two or three weeks in a quarantine station? The only possible control, he believes, is by a scheme of quarantine surveillance, whilst vaccination and similar means of mass-immunisation will again have to be utilised to protect a community freshly exposed to risks which it has almost forgotten.

DEATHS UNDER ANÆSTHETICS FOR DENTAL OPERATIONS.

The percentage of deaths occurring under anæsthesia for dental operations is extremely low, far lower indeed than for general operations; yet fatalities do occur and the number in any year is by no means negligible. The fact that the operation of dental extraction for which the anæsthetic is usually given is of a relatively trivial character, makes the occurrence of death from the anæsthetic employed peculiarly tragic. Our contemporary, the *Dental Surgeon*, has devised a questionaire which it is intended to circulate to those doctors and dentists unfortunate enough to have a fatal case, with a view to eliciting a body of information which may in time become large enough to provide valuable information. As the *Dental Surgeon* truly points out, the reports of such cases are usually of a meagre character and provide little material for forming a judgment as to the best general anæsthetic for dental operations and the conditions favourable or unfavourable to the patient's safety. The idea of such an inquiry is a good one, and we hope that the questionaire will be fully and carefully filled up. It has been so framed as to cover all the essential points, and there can be no doubt that if it should prove possible to collect enough data, knowledge would be gained which might be the means of reducing still further the number of deaths during dental operations.

EFFECTS OF A HIGH CARBOHYDRATE DIET ON LACTATION.

The claim has frequently been made that starchy foods have a stimulating effect upon lactation, but no systematic study of the influence on breast-milk of supplementary nourishment by one particular starchy food being available, it was decided by three American workers to carry out a thorough investigation of this nature, and their findings were reported in a recent issue of the *American Journal of Obstetrics and Gynecology*.[1] The substances chosen were rice and tapioca, because of their similarity, because both are inexpensive, familiar in the ordinary home, and capable of being prepared in a great variety of ways, and because it has been asserted that tapioca is a galactagogue. A series of 130 lactating mothers in a hospital were divided into three groups, each patient being placed in rotation on her admission and all grossly abnormal cases being eliminated. Group I. received the regular hospital ward diet, and Groups II. and III. this same diet, except that the noon-day dessert was omitted and 60 g. of rice and tapioca respectively were added. A little later a fourth group was started, to whom fat in the form of cream of the same caloric value as the starchy foods was added to the ordinary diet. The hospital dietary had a caloric content of about 2600, the others being brought up to a total of about 3000 calories. The diet was begun 24 hours after delivery, under careful supervision. On the fifth and ninth days, as nearly as possible at the same time, one breast of each patient was completely emptied by electric breast-pump, and the milk analysed, and the babies were weighed for test feeds at the same hour each day.

The most important feature of the results seems to be that the quantity of milk obtained by the baby was definitely higher in the two carbohydrate groups, the average intake being 2·40 oz. in the rice group, 2·47 in the tapioca group, 2·01 in the cream group, and 1·84 oz. among those whose mothers were receiving the hospital diet. The differences are comparatively small, but the most rapid growth after the fifth day was found in the rice and cream groups, and all three classes with additional feeding regained their birth-weights during the time in hospital in greater proportion than the control series. The conclusions drawn from the investigation are these: In all four groups the appearance of milk in the mother's breasts occurred about the third day, and in all there was a tendency for the protein to decrease and the sugar and fat to increase from the fifth to the ninth day; on the fifth day the sugar content was lowest in Group I. and highest in Groups III. and IV. (tapioca and cream), and by the ninth day the rice group also had milk containing a high percentage of sugar; the largest quantities of milk, as tested both by the breast-pump and by the weighing of infants before and after feeding, were secreted by the rice and tapioca-fed mothers; the cream diet was the only one resulting in an increased fat content of the milk on the fifth day, but by the ninth day all groups showed about the same percentage of fat. The practical result would seem to be that, by yielding a slightly larger volume and a higher lactose content, the increased carbohydrate diet supplies the baby with a greater fuel value than the ordinary diet.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

IV.—THE INTERPRETATION OF REPORTS ON SPUTUM.

By S. Roodhouse Gloyne, M.D. Leeds, D.P.H. Lond.,
PATHOLOGIST TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS.

(1) Collection of Material: Physical and Chemical Characteristics.

Obtaining a Specimen.

A patient who has sputum cannot be considered to have a normal respiratory tract, and it may be just as important to examine the sputum as it is to apply a stethoscope to his chest. For practical purposes sputum may be regarded as secretion which comes from the respiratory tract, the ciliated epithelium being assisted in their action by coughing or "clearing the throat." It is not uncommon, however, for saliva and stomach contents to be sent to the laboratory as sputum.

Sputum expectorated in the early morning before food is best for bacteriological examination, and the patient should be asked to rinse out the mouth with sterile water before expectorating the sample. Blood-clot, although complying with the definition of sputum given above, does not as a rule give helpful information on bacteriological examination, except in the relatively rare cases of broncho-pulmonary spirochætosis in which disease hæmoptysis may be a prominent symptom. In cases of early pulmonary tuberculosis with hæmoptysis it often happens that the patient has no sputum except for a few hours, or perhaps a day, following the cessation of the hæmoptysis, when he may expectorate a few drachms. This small quantity of sputum generally contains tubercle bacilli, and the opportunity of sending it to the laboratory should never be missed. Such an opportunity may not occur again. Only a small quantity—a few drachms—of sputum is necessary for bacteriological examination. A small fresh specimen sent to the laboratory as soon as possible after expectoration is better than a large accumulation of stale sputum collected for a whole day. Autolysis takes place in sputum allowed to stand, during the process of which cells soon degenerate and some pathogenic organisms die out. Tubercle bacilli, however, survive many days after autolysis is complete If a laboratory outfit be not available the ordinary flat-sided bottle commonly sed for tablets and throat lozenges makes a suitable ubstitute. The bottle should, of course, be sterilised efore use and in sending by post should be carefully cked and marked "pathological specimen." These rections may seem superfluous, but it is surprising w often they are neglected by the patient.

---

[1] The Influence of Supplementary Feeding of Carbohydrate upon Lactation. By Israel S. Kleiner, Ph.D., John E. Tritsch, M.D., and Lulu G. Graves, B.E., New York City.

Children generally do not expectorate readily, and it may be necessary to instruct them how to clear the throat and bring up sputum. This is best done by an adult demonstrating the process for them. Sometimes a small particle of sputum may be picked off the pharyngeal wall by means of a throat swab. When children with pulmonary tuberculosis swallow heir sputum the bacilli can frequently be found in the eces. Probably all patients swallow a certain amount f sputum during sleep. Post-nasal secretion can be btained also by clearing the throat; failing that naceous secretion can be removed from the post-nasal space by means of a swab and the whole sent to the laboratory. When an examination of pus from an accessory sinus is required the "wash out" may be sent for examination, saline being used for the occasion instead of the usual antiseptic.

A full report on a sputum examination would give a description of :—

(1) Physical characters, whether foul smelling, mucoid, mucopurulent, purulent, or blood-stained.

(2) Chemical—the presence of albumin, bile, &c.

(3) The character of the cells, those found in different kinds of sputum being large squamous epithelial cells from the oro- and laryngo-pharynx, epiglottis, and vocal cords, ciliated columnar cells from bronchial epithelium, alveolar cells from lung substance proper, neutrophil leucocytes, eosinophils and lymphocytes. Malignant cells, pigment and fat containing cells are less commonly recorded.

(4) The bacterial flora.

(5) Any unusual substances, such as fibrin, amœbæ, spirochætes, Charcot-Leyden crystals, or Curschmann's spirals.

(6) Virulence tests in suitable animals—the guinea-pig for the tubercle bacillus, the mouse for the pneumococcus and some strains of streptococcus.

A complete examination of this kind is, however, rarely needed, and as a rule the pathologist presents a report only on (1), (3), and (4).

Physical Character.

Mucoid sputum, often greyish in colour from admixture with atmospheric dust, is generally found in post-nasal catarrh, chronic pharyngitis, and bronchitis. The chief characteristics of this kind of sputum are the presence of large squamous and ciliated epithelial cells together with the so-called catarrhal organisms, amongst which the Gram-negative *M. catarrhalis* is usually conspicuous. Pneumococci are generally of the unclassified group IV. type and streptococci of the "salivarius" class. Growth is usually luxuriant and virulence for animals low. Mouth organisms are common.

Mucopurulent sputum of the typical "nummular" type is the common concomitant of pulmonary tuberculosis. The cells are mostly of the pulmonary alveolar type, but the significance of these is rarely emphasised in face of the much more important tubercle bacillus.

Purulent sputum suggests septic bronchitis, broncho-pneumonia, pulmonary abscess, and gangrene, and bronchiectasis. In the last three conditions mentioned it is usually very foul smelling. The bacterial flora is generally very mixed; virulent types of pneumococci and streptococci predominate, but in the fœtid sputum of bronchiectasis and abscess all kinds of unidentified Gram-positive and negative organisms, often anaerobic, crowd the specimen, and mouth spirochætes are common. A report of large numbers of organisms of different kinds in a foul-smelling sputum is very significant of bronchiectasis.

The typical *sputum* of lobar pneumonia is "rusty" looking and sticky, and generally yields the pneumococcus in nearly pure culture. It must be borne in mind, however, that there are many aberrant forms of pneumonia, especially during an influenza epidemic, and these are often characterised by a mixed bacterial flora. In this case, however, the sputum is not typically "rusty" looking.

Blood-stained sputum may be traced to a variety of causes. In pulmonary tuberculosis the finding of the tubercle bacillus, and in broncho-pulmonary spirochætosis the presence of large numbers of spirochætes decide the diagnosis, but there are many cases where the examination of sputum will only yield indirect evidence in support of a diagnosis. In the first place, it is important to ascertain that the blood comes from the respiratory tract. Blood-stained sputum is generally frothy and has an alkaline reaction, blood from the stomach is usually not frothy and is darkened in colour from action of gastric juice, and if mixed with gastric contents the material is likely to be acid. Post-nasal bleeding may be associated with mucus or with muco-pus, or it may consist of pure blood, in which case there will be but very few cells except red blood cells. Post-nasal blood may be swallowed and then vomited. A microscopical examination of the cells in blood-stained sputum may help in showing bronchial epithelium, alveolar cells, pus, squamous pharyngeal cells, and the like. The presence of starch granules or particles of food may also assist in deciding on the source of specimen. In suppurative lung diseases such as bronchiectasis, abscess, and gangrene, blood-stained sputum and hæmoptysis are not uncommon. The great predominance of pus cells, the enormous number of bacteria, of mixed and often unidentified species, and the foul smell, are usually sufficient to clinch the laboratory diagnosis. In mitral disease with failing compensation the capillary oozing into the mucoid secretion often gives a characteristic pink tinge to the sputum. Later, streaks of blood may be present in the mucoid sputum. Infarct produces a much larger amount of blood and of a darker colour, but this is not sufficiently characteristic for diagnosis. Blood-stained sputum may follow operation or the administration of a general anæsthetic, and may be due to trauma, embolus, secondary infection, or the lighting up of quiescent pulmonary tuberculosis. A bacteriological examination for the tubercle bacillus and other organisms is important. Malignant disease of the lung is often described as producing prune juice sputum, but it is neither a helpful nor characteristic description. It should not be forgotten that the malingerer—especially if he has had experience in a sanatorium—can produce a very good imitation of blood-stained sputum from a small abrasion of the gum. Generally it is a more or less homogeneously coloured pink frothy saliva which contains practically no cells but red blood corpuscles. The malingerer will sometimes borrow sputum from another patient, especially if compensation or a pension claim be pending. When suspicion is aroused, the specimen sent for examination should be coughed up in the presence of doctor or nurse.

Chemical Tests.

The presence of *albumin* used to be considered indicative of pulmonary tuberculosis, but it is found in other inflammatory conditions and is not really very helpful as a diagnostic sign. *Bile* is found occasionally when liver substance communicates with lung by ulceration through the diaphragm, but it is more commonly due to the accidental admixture of stomach contents and sputum.

SPORADIC DYSENTERY IN A LARGE CITY.

BY J. A. CHARLES, M.B. DURH., M.R.C.P. LOND., D.P.H.,
ASSISTANT MEDICAL OFFICER OF HEALTH, NEWCASTLE-UPON-TYNE.

DYSENTERY is no novelty in Newcastle. It was a frequent visitor in the eighteenth century, when its signs and symptoms were known and adequately recorded. In comparison with the carefully worded and meticulously studied description given by one of the city's physicians, Dr. Andrew Wilson, in his "Essay on the Autumnal Dysentery" in 1760, the accounts of the disease to be found in modern text-books are but colourless epitomes.[1]

One has only to read the graphic descriptions of those days to realise that the old-time clinician had a very definite conception of the cardinal features of the "bloody-flux," and of its existence as a separate entity, altogether different from cholera on the one hand and the simple diarrhœas on the other. From the fact that mention of hepatic signs and sequelæ is lacking, it is obvious that the condition then prevalent was a bacillary and not an amœbic dysentery. Later records are to be found in the Annual Reports of the Newcastle Dispensary,[2] and every year from its opening in 1771 until 1900 a number of cases passed through the books of that institution. In some years the disease was apparently epidemic—for example, in 1783 and 1785 when 329 cases with 17 deaths find record, but more generally the numbers are small. In some of the city's death returns during the nineteenth century dysentery can be separated from its companions—diarrhœa, zymotic enteritis, and intestinal catarrh—and during the ten years, 1874–83, 60 deaths were attributed to it. From 1901 until the war years the record, both of the dispensary books and the death returns is blank.

Under the regulations of 1919 dysentery became a notifiable condition and in that year ten cases, with one death, were so notified. The numbers gradually diminished until in 1924 there were none. In 1925 a group of cases, due to the para-Shiga organism mentioned later in this article, came to notice. These were followed in July of 1926 by a definite outbreak of six cases of so-called "food poisoning," from five of which a Flexner bacillus was isolated.[3]

History of the Present Series of Outbreaks.

In the first week of March of the present year three cases of a mild dysentery due to *Bacillus dysenteriæ* Flexner occurred in two related families, which, though normally residing apart, had been temporarily sharing the same home in Cowgate, one of Newcastle's newer suburbs. Recovery was uneventful in all these cases. During the last week of the same month and the first fortnight of April four sudden deaths in children, aged from 7 to 9, were reported, and each of these was subjected to post-mortem and bacteriological examination. In two of these cases the bacteriological findings were negative, and the deaths were recorded from the pathological evidence as being due to gastro-enteritis; in the other two cases it was ascertained that a bacillary dysentery had been the cause.

In view of this sequence of dysenteric infections, a circular was issued on April 18th by the medical officer of health for the city, requesting practitioners to notify any severe cases of acute enteritis which they might encounter in their practices. All cases notified were carefully investigated, and any with signs or symptoms suggestive of dysentery were removed to the City Hospital for Infectious Diseases. Stools, &c., were bacteriologically examined, not as a routine, but wherever the history of the case seemed to indicate its advisability. Up to June 30th, 64 notifications from all sources had yielded 17 cases of bacillary dysentery with two deaths. Of the 47 non-dysenteric cases notified, four died, but only one was brought to post-mortem examination. In this, as in the other three, death was returned under the omnibus term of gastro-enteritis. For the period March 1st to June 30th there are thus records of 22 cases of dysentery, all bacteriologically proven, four of which have terminated fatally. These 22 cases have been found in 15 separate households. The sex and age-distribution of the cases were as follows:—

Thirteen, or 59 per cent., were in females, with one death, representing a female case mortality-rate of 7·7 per cent. The remaining nine cases were males. Three died—a male case mortality-rate of 33·3 per cent. There were no cases under the age of 12 months, two were under 2 years, three in the age-period 2–5, ten from 6–10, one from 11–15, and six above the age of 20. Three deaths occurred in the age-period 6–10, and one from 11–15.

Clinical Features.

Two very different types of the infection were encountered, the one mild from the beginning—a simple dysentery—the other fulminant and fatal, suggesting the form of the disease known as entero-dysentery.

Mild Cases.—The average length of stay in hospital of ten non-fatal cases was 18 days, and this period was sufficient to cure symptoms, establish convalescence, and prove the disappearance of the infecting organisms from the stools. The ordinary clinical history is as follows: The onset is gradual with headache, occasionally associated with vomiting. Within a few hours diarrhœa commences, and generally the first motions are loose and fæcal. The bowel is soon emptied of fæcal contents, and thereafter the motions are almost pure mucus with varying quantities of blood. "Jelly and blood" is a graphic description of the motion frequently obtained by the history-taker, though the true red-currant jelly stool of dysentery has been seen only on one or two occasions. The diarrhœa is very frequent—every 20 or 30 minutes—40 to 60 stools in the 24 hours, and this stage may last for four or five days, unless treatment has been adopted. Even after treatment has been commenced the cessation of diarrhœa is gradual, and there is generally some looseness of the bowels with brown and grumous motions up to about the tenth day. Throughout the diarrhœic stage colicky pains are invariably present in greater or less degree, and are relieved by the passage of stools. Tenesmus has been complained of in the majority of cases. Abnormal abdominal distension was not observed in any case. Some indefinite tenderness over the pelvis is frequently elicited, but pain on pressure over the descending colon was never obtained. Enlargement of the spleen was only found in one patient. Slight furring of the tongue is generally present.

The bronchitic signs described in Sonne infection by the Aberdeen observers were absent in the few cases concerned.[4] The temperature is elevated—generally from 99°–100° F. in the evening, and about ½° less in the morning. There is a progressive defervescence, and about the tenth day, coincident with the improvement in the intestinal condition, the temperature is usually normal, and convalescence is assumed to have begun. About two days after this the bacteriological examination of another stool is commenced, and by the time the report on this is available (i.e., five to seven days) the patient is generally fit for discharge.

The latest date on which dysentery bacilli have been found in the stools was the tenth day of the disease, but this only happened in one case, and as a rule they have rarely been obtained later than the sixth day—the first three days being the most favourable for their isolation. On two occasions when multiple clinical cases have occurred in a household, the stool has only been positive in one case, but the blood serum of another taken at a later date has agglutinated the organism from the stool of the positive case in high dilution. There have been no relapses in hospital, nor, as far as could be ascertained by routine inquiry, after discharge. Treatment has been largely symptomatic, and sodium sulphate in doses of from grs. 40–60 three times a day has been adopted as a routine in the first four or five days.

Fulminant Cases.—In this type of the disease, the onset, development of symptoms, and death have followed one another so swiftly that the average duration of such a case has been less than 24 hours. The onset is extremely sudden, and as in the mild type headache has been common; vomiting, moreover, has been an invariable symptom. Colicky pains and diarrhœa with mucus and blood have followed. The number of such stools has usually been relatively few—perhaps about ten or a dozen—and their appearance was that of a mixture of fæcal material, blood, and mucus, rather than the "jelly and blood" characteristic of the mild type of the disease. Abdominal distension, tenderness, and rigidity of the muscles on palpation were not present in any of the cases. The spleen was never found to be enlarged on clinical examination.

In two cases only have temperature records been obtainable, and in these the pyrexial reaction was higher (101°–102°) than in the milder type. Drowsiness, passing into coma, has preceded the fatal issue. In general it may be said that these fatal cases have been associated with a degree of toxic infection altogether out of proportion to the symptoms.

Post-mortem Appearances.

Post-mortem examinations which were made in all the fatal cases showed the same general pathological appearances in every case.

In every case there has been an enteritis and a colitis—the former condition predominating. The inflammatory changes have been most marked in the lower one-third of the ileum, though in one case it was the upper part of the jejunum which appeared to be chiefly affected. Engorgement of the blood-vessels in the wall of the gut has been the principal external sign, and the peritoneal reaction has never gone beyond this hyperæmic stage. Internally there has been evidence of a folliculitis, passing on to follicular ulceration. The Peyer's patches in the main have not been affected.

There have been no signs of chronic thickening of the bowel wall, but recent œdematous changes have been constant. The condition of the colon has generally been similar to that of the intestine though in a minor degree. A slight gastritis was present in some of the cases. A presumably acute lymphadenitis of the mesenteric glands was found in one case, and the spleen was definitely enlarged in another. Toxic changes were invariably present in the heart, kidneys, and liver.

The results of the bacteriological examinations of fæces, blood, and post-mortem specimens will be considered later.

Epidemiological Features and Spread of the Disease.

Distribution and Chronology of the Outbreaks.—The 22 cases recorded occurred in 15 separate domiciliary outbreaks. There were ten outbreaks made up of single cases; three multiple groups of two cases each; and two where three patients were affected. The chronological order and date of commencement of each of the outbreaks is given in Table II. Cases and outbreaks occurred in nine of the 19 wards of the city (population 288,500), but although there has been a multiple incidence in certain wards, in no instance have there been two outbreaks in one street. In fact, after the closest investigation and interrogation of all facts and persons concerned, it may be said quite definitely that there has never been any known contact between one affected family and another, either domestically, scholastically, or otherwise.

Water.—The water common to all these cases for the purposes of drinking and ablution was that of the Newcastle and Gateshead Water Company, a supply obtained from upland sources, stored, filtered, and chlorinated. It is usually of high quality judged both by chemical and bacteriological standards. Samples of water taken from each house without sterilisation of the tap were satisfactory in all but five. In three of these *B. coli* were present in 1 c.cm.; in two specimens in 10 c.cm. In no case were streptococci present. Neither the series of outbreaks as a whole, nor any individual focus presented the features of a water-borne epidemic, and in view of this and the known feeble viability of *B. dysenteriæ* under saprophytic conditions, little significance is attached to these findings of dirty waters, though to a certain extent they act as an index of the general hygienic standard of the dwelling.

Milk.—Only in five cases was fresh milk an article of diet in the household. In four cow's milk was used, in the remaining one goat's milk. The milk had been boiled in only one instance. The purveyors of these milks were all different, and as far as could be ascertained the sources of supply were entirely independent. In the remaining cases tinned milks were in regular daily use, and the patronage of the various brands appears to have been very catholic, no fewer than ten different varieties being consumed.

Milk products, &c.—In view of the variety of brands of butter and margarine used there is nothing to suggest their relationship to the outbreaks.

Ice cream.—A history of eating ice-cream was only given in two of the outbreaks. In each of these cases—one of which proved fatal—it had been consumed the day before the sickness commenced, and had been obtained from diverse sources.

Prepared meats.—Brawn, potted meat, galantine, &c., were not eaten by any of the patients affected. Two patients in separate outbreaks gave a history of eating respectively corned beef and tinned tongue. These meats came from different shops, and in both instances were partaken of by others who suffered no ill-effects.

Shell-fish.—One fatal case had a few whelks on the day of the onset of illness. Others similarly indulging in the same and adjacent houses were unaffected.

Watercress, salads, unwashed fruits were not implicated in any of the outbreaks.

Flies were a negligible feature of both domestic and outdoor life during the period under review.

Epizoötics.—Careful inquiry was made as to the degree of rodent infestation of the affected houses. This was negligible, nor was there any evidence of any epizoötic, such as might be shown by the presence of dead rats or mice, or diarrhœic indications of an intestinal complaint.

Sanitary conditions were fairly good. Water-closets were fitted on all the premises, and dry refuse was removed periodically under corporation arrangements.

Contact with other cases or carriers.—As has been stated above, there has been no evidence of any contact between one infected household and another, either directly or through intermediaries. In two instances an apparently healthy member of the household gave a history of a previous attack of dysentery, one in South America in 1913, the other while serving in France in 1916. Neither of these persons had anything to do with the preparation of the family's food, and their stools when examined were negative for the dysentery group.

One incident remains to be recorded for what it is worth. From a small domiciliary group of three cases an agglutinable Sonne dysentery bacillus was isolated. One patient—a boy of 11—died, and the other two, though attacked at the same time, manifested only the very slightest symptoms. About six weeks prior to this a playmate of the boy had died suddenly in the flat above, with symptoms suggestive of dysentery. The macroscopic appearances at post-mortem examination were those of entero-dysentery, but unfortunately the specimens obtained were useless for bacteriological purposes, and accordingly this case has not been included in the present series. The only suggestive facts are that the father of this latter boy had suffered from diarrhœa on the day of his son's death, and that he had but recently returned from Glasgow—a Sonne infected area. His stools when tested at a later date were negative.

Overcrowding.—The houses affected were a rather less than average sample of the dwellings occupied by the working classes of the city. Some were tenement property in comparatively poor neighbourhoods, others were modern habitations recently constructed under corporation town-planning schemes. On a standard of two persons per room, 51 of the total number of 94 inhabitants were overcrowded, a percentage of 54, compared with the average overcrowding of 33·6 per cent., which held in Newcastle at the time of the 1921 census. The relation between overcrowding and the incidence of diseases of the diarrhœa type does not require to be emphasised here.

Climatic conditions.—There was nothing exceptional in the climatic conditions for the time of the year.

Up to this point these cases of bacillary dysentery have been treated as if one, and only one member of that group of organisms had been the cause of the whole series of focal outbreaks. The bacteriological evidence, however, shows that no fewer than five types of dysentery bacilli, or of organisms so closely allied as to be grouped with them, have acted as the "materies morbi" in these cases.

Bacteriological Data.

Only the essential features of these laboratory findings will be recorded here, as they form the material for a bacteriological review of the outbreaks, which is in course of preparation by the investigators concerned.

A brief statement of the standards adopted as diagnostic, and an enumeration and distribution of the organisms implicated, are, however, necessary for the purpose of this article. All examinations of clinical and post-mortem material were carried out in the Routine Department of the University of Durham College of Medicine Bacteriological Laboratory by or under the direction of Dr. F. H. A. Clayton.

1. Every case of dysentery in this series was a positive bacillary case in the sense that (*a*) an undisputed dysentery-causing bacillus was obtained from

its stools, or (*b*) its blood-serum agglutinated not only a standardised emulsion of a dysentery organism, but also an identically similar organism found in the stools of another patient in the same household.

2. As a result of these investigations the following five organisms have been discovered amongst the 22 cases of dysentery :—

(*a*) Three out of the five commonly accepted serological types of *B. dysenteriæ* Flexner—namely, W, Z, and one which agglutinated X and Y strains equally and is in consequence referred to as XY. Type V was not found in the present series.

(*b*) A Sonne bacillus, and an inagglutinable variant of the same.

(*c*) A so-called para-Shiga organism. This designation was applied because it is not agglutinated by Shiga serum, although it shows the fermentation reactions of that organism, causes dysenteric symptoms, and has been isolated from a fatal case. A very similar, if not identical, bacillus was isolated from a case of clinical dysentery in Newcastle in September, 1925, and in May of this year from an outbreak of about 20 mild cases of the disease in the Cripples Home at Gosforth, one mile outside the boundaries of the city. A description of this organism is being published by Dr. Clayton and Dr. S. H. Warren, of the University Laboratory. Neither of these other foci could be associated in any way with the two cases in the present series.

It is important to note that wherever multiple infections have occurred in a household, the type of the causal organism has remained the same for all the cases therein.

TABLE I.

Type of organism.	Flexner.				Para-Shiga.	Sonne.
	V.	W.	XY.	Z.		
Organism isolated from stools	—	3	2	4	—	3*
As above, and agglutinated by patient's own serum ..	—	—	—	2	—	—
Blood-serum, tested against standard Oxford emulsion, and/or organism from case in same household	—	—	—	3	1	—
Organism isolated from P.-M. material	—	1	1	—	1	1
Totals	—	4	3	9	2	4

GRAND TOTAL .. 22 cases in 15 outbreaks.

* 1 inagglutinable.

Flexner W caused 4 outbreaks, XY 2, Z 6, para-Shiga 1, Sonne 2.

Table I. gives the distribution of the five organisms amongst the 22 cases, and also shows the sources from which they were obtained.

Table II. is included as a matter of interest. It shows the chronological order of the 15 outbreaks, their dates, neighbourhood, and the type of the infecting bacilli. It demonstrates, amongst other things, that the first seven outbreaks sprang up in different wards ; that there were never two consecutive outbreaks in the same ward, and where one type of organism was implicated in successive outbreaks the infected localities were, of course, not the same.

The interrelations of the various dysentery bacilli are still somewhat ill-defined. It would appear to be generally accepted that Shiga and Sonne are distinct organisms, with well-marked serological and biological properties which they hand on through many generations. On the other hand, the fermentation reactions of the Flexner group, though of considerable importance, are not quite reliable enough to be used alone for purposes of differentiation. Accordingly, bacteriologists have developed their already considerable knowledge of the more stable distinguishing features of these several organisms, which could be found in their reactions to immune sera. These agglutination tests do not invariably yield clear-cut and definite lines of demarcation between the five or more strains—V, W, X, Y, Z, &c.—into which the Flexner group has been subdivided serologically, but they are sufficient for most practical purposes.

Whether in course of time these serological types alter and change one into another is not known. At any rate in the present investigation wherever multiple cases have occurred in houses there has been no evidence of such transmutation of type. Nor is there any reason to believe that what holds good for these multiple cases does not similarly apply to the single cases throughout the series.

Discussion.

In considering these 22 cases an attempt was first made to regard them simply as " bacillary dysenteries " without differentiating the type of causal bacillus. For a time it was convenient to imagine them as arising from one source, and following in one sequence. But on further scrutiny not only was it necessary to recognise the diversity of the infecting organisms, but also that there was no definable factor common to all the cases, and that there was nothing wherewith one could connect them together in a consecutive series. Arranged in five groups corresponding to their causal organisms, these outbreaks still failed on the most careful investigation to divulge any other common feature which might facilitate an understanding of the incidence and spread of the disease. And, finally, the attempts made to link up any individual outbreak with another have proved unsuccessful.

Relying on the evidence available, and allowing as auxiliary predisposing factors the obvious overcrowding, and the proved facilities for easy contamination of water and food which arise under these conditions, one is reluctantly compelled to admit that apart from the thesis that these outbreaks of dysentery are certainly a sporadic, and possibly an endemic manifestation of the disease, there is no other explanation easily acceptable at the moment. How exactly the disease arises, and what part intermittent carriers and the even more dangerous latent case, as described by Cunningham, have played in the spread of the disease it is impossible to say. The amount of material at one's disposal is not sufficient. It would appear an entirely feasible hypothesis that in certain cases following upon some dietetic indiscretion, the quiet " carrier " has become actively dangerous, perhaps even personally ill, and that other cases in the same household, some of acute dysentery, others of transient diarrhœa, have been the result. Sporadic dysentery in itself is nothing new ; it has been described in this country by many observers, amongst others by Saundby in Birmingham (1906),[5] Bainbridge and Dudfield in Paddington (1911),[6] and Severn and Evans in Smethwick (1928).[7] The interest of the present series lies in the variety of organisms at work, and in the way in which the sporadic elements have become so frequent as to attain the dimensions of an endemic.

Several questions arise—many of which cannot be answered at the present moment. They are, nevertheless, stimulating in their suggestion of fresh avenues of inquiry. It will be remembered how Creighton pursued the records of dysentery across a century, and found cases which were at one time well and truly recorded as " griping of the guts," later masquerading as "convulsions."[1] And probably in a measure the same is true to-day. Diarrhœa, the "omnibus" diagnosis, has no doubt regained the allegiance of many of the dysenteries, and ulcerative colitis, a comparative newcomer, may have acquired some of the remainder. A search of the death returns for the last six years, under the headings of dysentery, diarrhœa, and the allied diseases, has given for Newcastle a limited amount of "data," which on strict statistical inquiry and analysis may show whether this sporadic or endemic dysentery is a normal feature of life and death in Newcastle. But apart from these retrospective inquiries, extensive observations on normal living material are necessary. What percentage of the ordinary population intermittently excrete dysentery bacilli in their stools? How many people are there with well-marked agglutinins for the dysentery group in their blood? The former percentage would give us some idea of the number and significance of the dysentery carrier; the latter figure should show the extent of past infection. These data have been obtained before but separately, or from communities (e.g., mental hospitals) which cannot be accepted as normal. The work of Schorer,[8] Ritchie,[9] and Pickworth[10] along these lines urgently requires to be extended.

Other questions, not so important perhaps, but equally fascinating come to mind. If this is not a true endemic, is it the beginning of an epidemic? Are these sporadic foci due to five types of bacillus, the first potential centres of an epidemic outbreak? Why should five types of organisms have simultaneously made their presence so manifest? Have these organisms been with us all the time, and is there now some failure of the natural immunity of certain members of the population? Have the protective properties of the bacteriophage become enfeebled? Has there been some transmutation of certain forms of bacterial life? The main object, however, of this article has been to draw attention to the series of cases of dysentery which have occurred in Newcastle, in the hope that other observers may inquire whether such a condition of affairs is present elsewhere.

My acknowledgments and thanks are due to Prof. Harold Kerr, medical officer of health of Newcastle-upon-Tyne, for permission to publish this report, and for much interest and assistance in its preparation.

BUXTON MEDICAL RESEARCH SOCIETY.—At a meeting held on Sept. 7th at the Devonshire Hospital Mr. J. Race, biochemist to the hospital, communicated the result of an analysis, made by Dr. Judd Lewis, of the gases issuing from St. Anne's Well, showing the rare gases to be 1·20 per cent. of the total volume, made up of argon 96·6 per cent. and helium 3·4 per cent. The absence of neon is an interesting feature of the analysis, as it appeared to exclude atmospheric air as a source of the helium and afforded a sharp contrast with the gas at Bath which, like atmospheric air, contained considerably more neon than helium. The output of radium emanation in the gas had been estimated at 3000 milli-micro curies per hour. Seeds soaked in the radio-active Buxton water germinated quicker and grew more rapidly than in either tap water or in a natural water practically identical in composition with the Buxton water but free from radium. The waters, he said, were all adjusted to the same pH before use.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Unequal Distribution of Doctors.

A RECENT publication shows how many medical men there are in the six central European States which derive all or part of their territory from the old Austro-Hungarian Empire. From the data given, which were compiled for other purposes, the following figures may be quoted as indicating the unequal distribution of practitioners in these countries:—

—	Population.	Practitioners.	No. of inhabitants per practitioner.
Jugoslavia	12,000,000	2100	5700
Roumania.. ..	16,000,000	3000	5300
Poland	7,000,000	2200	3200
Czecho-Slovakia ..	13,500,000	6800	1970
Hungary	8,000,000	5400	1480
Austria	6,500,000	7300	900

This makes it painfully clear that the situation of the medical profession in Austria is worse than in any of the other States; even wealthy Czecho-Slovakia, with more than double our population, has far fewer doctors to compete with one another than there are here. Austria's poverty and economic depression obviously justify the authorities in their endeavour to prevent or diminish the matriculation of medical students.

The Principal Causes of Deaths in Vienna.

From the report of the Vienna Board of Health for the first half of this year it appears that tuberculosis no longer holds first place among the causes of mortality. Pulmonary tubercle—the other forms do not play a significant part in these statistics—was responsible in 1918 for 22·5 per cent. of all deaths in the city, and in 1920 for 18·6; but by 1926 the percentage had fallen to 13·7, and in the past six months it has been only 12·3, which is very gratifying. No doubt the decline is due to the remarkable improvement in housing effected by the present municipal government, and also to instruction of the public concerning the hygienic importance of light and air, and the necessity for isolating phthisical patients. Further, the increase of tuberculosis centres and sanatoriums has a very beneficial effect upon "open" cases. Thus it comes that diseases of the heart and circulation now take precedence over tuberculosis as causes of death. Whilst it is by no means certain that these pathological conditions have absolutely increased in Vienna, their prevalence may be an after-effect of the war, now becoming more distinctly manifest. This is probably true of wear-and-tear diseases such as arterio-sclerosis.

Doppler's Method of Reactivating Viscera.

For some three years, as I have already mentioned,[1] Dr. Karl Doppler has been making extensive use of a method of reorganising visceral blood-supply, based on a technique devised by Leriche for increasing the circulation in paralysed legs. On dividing the sympathetic nerves accompanying the blood-vessels of the limbs, and thus destroying the vaso-constrictor branches, Leriche obtained improvement, albeit temporary, in the circulation, and Doppler's technique is based on his observation that a similar result can be got by painting the adventitia of the blood-vessels with a 7 per cent. solution of phenol. He first tried this method in a case of badly healing gastric ulcer and the result was promptly satisfactory. Then he used it wherever it seemed desirable to stimulate a too sluggish blood-supply, and it is true that he—and many other surgeons who used his carbolic solution—got very good results. Encouraged by these experiments, Doppler started using the method for increasing the blood-supply, and thus promoting the functional activity, of the testes and ovaries. For this process he strictly repudiates any use of the term rejuvenation. He calls it a "regenerative" method, and together with Prof. Hans Lorenz—not the orthopædic surgeon—he has used it in a large number of cases, in which the effect has undoubtedly been very beneficial in certain respects, whilst the operation itself is very simple and easily performed. A distinct return of muscular strength and mental activity, with growth of hair and even return of its normal colour, has been observed by many surgeons. The duration of the effect is not yet known; as a rule, it seems to be two years at least, although sometimes repetition of the operation has been required within that period. There are also, of course, refractory cases, and the treatment cannot be expected to do much good if the organ under stimulation has been irreparably damaged so that its glandular tissue has atrophied. Attempts have so far been made to reactivate the liver, the kidneys, the ovary, and the testes; experiments are now going on with regard to the thyroid and suprarenal glands. The physiological basis of the method is now thoroughly understood. The carbolic solution destroys—much better than a knife—certain nerve-tissues, and at the same time sets up a process which prevents the formation of new nerves after the original destruction, at any rate for two or three years. The 7 per cent. solution acts chiefly on the vaso-constrictors, the vaso-dilators being much more resistant. The method is now being widely tried all over Vienna, but results are not being given to the public as Dr. Doppler wishes to make certain of his facts as far as possible before making further claims.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

A Medical Register for India.

NEWSPAPER reports that the Government of India intend to bring before the forthcoming session of the Central Legislature a Bill to regulate medical education in India by the establishment of a Medical Council and the maintenance of a Medical Register have evoked mild protest from the Bengal Medical Association and one or two other quarters. More than one medical circle has declared that the time has not yet come for the establishment of an Indian Medical Council, and that it would not be easy to control provincial medical councils by a centrally constituted organisation.

The question whether there is need for setting up a central organisation has been engaging the attention of medical faculties and other such associations for at least a decade. Indeed, it has been revived and pressed upon the Government more than once since 1919, but apparently the Government have hitherto not been kindly disposed to the demand. Possibly their want of sympathy was due to the fact that all provincial governments were not of one mind on the question. It has, in fact, been stated in a well-informed quarter that three of the local governments were against the proposal. This, and perhaps the usual financial difficulties, might have stood in the way of the Central Government taking any bold step, but events since then have been distinctly in favour of a definite forward move.

The Bill which has now been prepared by the Government of India can be said to be a comprehensive measure which aims at making India autonomous in regard to medical qualifications based on the Western system. Its object is said to be the creation of a Central Council which will establish a uniform standard of qualification in medicine for all provinces so that holders thereof may be empowered to practise throughout British India, and it will be the sole authority to regulate, on a footing of reciprocity, the conditions on which qualifications acquired abroad are to be recognised in India.

Bengal's Poor Health.

The deterioration of the public health of Bengal is emphasised in a recent address by the Director of Public Health of the province. For this state of affairs improper and inadequate food is largely responsible. The annual mortality for the province is about a million and a half, and deaths of children under the age of 15 make up no less than 50 per cent. of the total. In 1927 no fewer than 120,000 people died of cholera in Bengal; the mortality from malaria was 350,000; reported deaths from enteric vary annually between 50,000 and 100,000, while deaths from tuberculosis total about 100,000. In all probability there are at least half a million sufferers from tuberculosis in the province. The infantile death-rate is appalling, and on the average 55,000 newly-born children die of tetanus every year.

Dangerous Drugs.

There is every likelihood of the Government of India introducing a Bill in the autumn session of the Central Legislature regarding dangerous drugs. This Bill is rendered necessary in view of certain obligations undertaken by the Government under the Geneva Dangerous Drugs Convention of 1925. It is not known at what stage the Bill is now, but it will be published in the *Gazette* shortly before the commencement of the September session. As, however, the measure in its application will concern a large number of provinces in India, it is likely that soon after the introduction in the Legislature a motion will be made for circulating the Bill to local governments for opinion. This means that further progress will not be made till the next winter session in Delhi.

Wild Animals.

The total number of persons returned as killed by wild animals (other than snakes) in British India during the year was 2285, as against 1955 in the previous year and 1962 in 1925. Tigers were responsible for 1033 of these deaths, leopards for 218, wolves for 465, bears for 78, elephants for 56, and hyenas for 12. Deaths were highest from tigers and leopards in Madras, from wolves in the United Provinces, from bears in Bihar and Orissa, and from elephants in Assam. Of 423 deaths from "other animals" about 136 are assigned to crocodiles, 85 to wild boars and pigs, and 41 to jackals. The highest number of deaths from all wild animals occurred in the Madras Presidency (579), the United Provinces, Bihar and Orissa, and the Central Provinces and Berar coming next in order. During the year 25,612 wild animals were reported as having been destroyed, including 1368 tigers, 4390 leopards, 2739 bears, and 2430 wolves.

Deaths from snake-bite decreased from 19,724 to 19,069, the number of snakes destroyed in India proper increasing during the same period from 46,012 to 57,116.

MEDICINE AND THE LAW.

Dangerous Drugs Regulations.

ATTENTION was recently drawn[1] to the Order in Council which at last brought into operation the Dangerous Drugs Act, 1925. That Act provided a new definition of the drugs to which Part III. of the 1920 legislation applied, and another Order in Council of the same date applied Part III. to certain specified preparations. The Home Secretary has now made two sets of regulations dealing with these preparations. The first set regulates the manufacture, supply, possession, &c., of benzoyl-morphine under licence. The other extends the Dangerous Drugs Regulations of 1921 to dihydro-oxycodeinone and dihydrocodeinone and their respective salts, and requires that separate registers (or separate parts of the register) be kept in respect of these preparations. These two recent sets of regulations are what is called Provisional

---

[1] THE LANCET, Sept. 1st, p. 475.

Regulations. This name merely implies that, on certified grounds of urgency, the Home Office is entitled to make the regulations without giving the usual 40 days' notice of his intention under Section 1 of the Rules Publication Act of 1893, and without waiting to collect the observations of persons interested upon his proposals. The Provisional Regulations have meanwhile (and until the Regulations are made, after the full preliminaries of notifying intention and collecting criticisms. as Statutory Rules and Orders) just as complete validity as if they were "Statutory" and not "Provisional."

A Promising Advertisement.

A cutting from a Malayan newspaper contains an advertisement (with portrait) of a "Burmese specialist," giving an address in Kuala Lumpur, who, having had 35 years' practice at Rangoon, begs to notify the public that he is able to cure a number of specified diseases. The list ranges from hiccough, hoarseness, and indigestion to madness, paralysis, asthma, and leprosy. "Persons affected with evil spirits or charms could be released; guarantee to cure diabetes within two months." The announcement may not be taken seriously by western readers, but can we say that similar advertisements have entirely disappeared from the columns of English newspapers? Parliament has prohibited them so far as they relate to venereal disease; they might be, though they seldom are, the subject of criminal proceedings in so far as they incite to or abet abortion. Otherwise there is nothing—except the general spread of education—to restrict the advertisement of promised cures. The vendors' descriptions of patent medicines seldom understate their claims.

An Osteopath Prosecuted.

But while an eastern journal publishes such an advertisement, the eastern courts may be found taking proceedings against a development which is entirely western. A Kuala Lumpur newspaper of July 30th records the prosecution and conviction at Colombo of Mrs. Starr for practising osteopathy—or, to be exact, for having during April and May last, practised medicine and surgery for gain without having registered herself as a practitioner under Ordinance 2 of 1905. Mrs. Starr, described as a manipulative therapist, had, it appears, given treatment of a kind associated with the practice of osteopathy. Her counsel argued that the treatment was a sort of massage, neither medicine nor surgery, that massage is not a branch of surgery but an aid to surgery, and that consequently the manipulative treatment given (in the case charged a manipulative treatment of the spine) did not offend against the Ordinance. The magistrate examined various dictionary definitions of osteopathy. He observed that massage was undoubtedly an aid to medicine and surgery, but remarked that osteopaths worked on a different plane. They claimed to diagnose and remedy disease: their methods were more drastic and far-reaching than those of the masseur. The osteopath is not so much a humble auxiliary of the qualified practitioner as a substitute and sometimes even a rival: he is not an assistant but a principal. Osteopathy, said the magistrate, is a particular branch of manipulative surgery: Mrs. Starr practised surgery in administering manipulative treatment. He fined her the nominal sum of 25 rupees, having taken into account the facts that she had practised her profession openly for some years in Colombo and elsewhere without interference or objection, that she was stated to have given relief to certain patients where qualified doctors had failed, and that she might have been legally entitled to practise in other parts of the world, and therefore possibly was unaware of the Ordinance under which she was being prosecuted. The magistrate then added certain general observations of considerable interest. The legal position, he said, seemed to be that the practice of osteopathy was not proscribed in Ceylon, but that only practitioners qualified and registered as physicians and surgeons could practise osteopathy. "I think it would be true to say that the medical profession admits in theory the great value of osteopathy, a branch of manipulative surgery, in the treatment of certain injuries in carefully selected cases: but it is probably also true that no members of the medical profession in Ceylon are qualified osteopaths." The practical result was that, at the moment, if any patient in Ceylon had an ailment which could only be remedied by osteopathic treatment, he or she could not obtain such treatment. There was, however, another important consideration. It had been alleged that Mrs. Starr was treating her patient for infantile paralysis when in fact the ailment was malaria. The judicial medical officer had attested that the patient died of heart failure from excessively high temperature due to malaria. His final pronouncement summed up the position clearly. "What in any event is obvious, is the great danger that exists in allowing a person, unqualified save in one particular branch of surgery, to attempt to diagnose every type of disease and ailment; it is unreasonable to suppose that the one remedy of manipulative surgery is a suitable prescription for every type of disease, and the great danger that lies in the prescription of such a remedy where it is unsuitable is patent."

The Services.

ROYAL NAVAL MEDICAL SERVICE.

H. L. Pridham to be Surg. Lt.

The following appointments have been notified:—Surg. Comdrs.: H. B. Padwick to *President* for post-graduate course; and R. A. W. Ford and J. C. Sinclair to *President* for R.N. Medical Store Depôt, Deptford, for survey of stores. Surg. Lts.: E. J. K. Weeks to *Victory* for R.N. Barracks, Portsmouth; and H. W. Strong to *Fisgard*.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Lt. D. A. Imrie to *Victory* for R.N. Hospital, Haslar, for training.

Surg. Lt. (D.) E. D. Collins to *Virid* for R.N. Barracks, addl. for training.

Surg. Sub-Lt. D. S. Buchanan promoted to Surg. Lt.

Proby. Surg. Sub-Lt. H. E. Holling and R. H. Wheeler to *Victory* for R.N. Hospital, Haslar, for training.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. R. L. V. Foster retires on retd. pay.

Majs. to be Lt.-Cols.: G. S. Wallace, vice Lt.-Col. B. B. Burke, promoted; C. J. Coppinger, vice Lt.-Col. R. L. V. Foster.

W. D. Hughes to be Lt. on prob.

TERRITORIAL ARMY.

Lts. W. S. C. Copeman and K. V. Milburn to be Capts.

ROYAL AIR FORCE.

Flying Officer J. Hutchieson is granted a permanent commission in this rank.

Flight Lt. (Hon. Squadron Leader) G. S. Ware relinquishes his temporary commission on completion of service, and is permitted to retain the honorary rank of Squadron Leader.

DEATHS IN THE SERVICES.

Col. LLEWELLYN THOMAS MANLY NASH, C.M.G., R.A.M.C., retd., who died on Sept. 9th at the Queen Alexandra Military Hospital, Milbank, London, aged 67 years, received his medical education at the Royal College of Surgeons, Ireland, and at the Rotunda Hospital. He was appointed surgeon in the R.A.M.C. in 1885, and served with the Miranzai Expedition in India (mentioned in despatches and medal with clasp) and also with the Hazara Expedition (clasp). He reached the rank of major in 1897, and that of Lt.-Colonel in 1905. In the late war he took command of No. 8 General Hospital at Rouen in August, 1914, and was later A.D.M.S. of the 8th Division (twice mentioned in despatches and created C.M.G.). In 1915 he returned to England, owing to ill-health, and was subsequently appointed to headquarters in the Eastern Command. At the end of 1916 he organised the R.A.M.C. centre at Blackpool with marked success. In 1917 he was appointed A.D.M.S. in Sussex. His genial disposition and tactful manner brought him many friends in civil as well as military life who will deeply regret his death. Col. Nash married in 1901 Edith Gertrude, daughter of the Rev. Charles Sloggett.

BRITISH MEDICAL ASSOCIATION.

ANNUAL MEETING AT CARDIFF.

(Continued from p. 578.)

SECTION OF LARYNGOLOGY AND OTOLOGY.

CHRONIC ETHMOIDITIS.

Dr. ROSS SKILLERN (Philadelphia), in his opening paper, said that chronic infections of the ethmoid could be broadly divided into suppurative and non-suppurative. With regard to the suppurative variety, the exudate varied from a thin watery to a thick yellow discharge, and this variation occurring in the same case, while the patient attributed it to the acquisition of fresh colds, was really due to exacerbations of his chronic condition. The discharge at times became so thin and scanty as to lead the patient to believe that a cure was in process. The final result, however, was a constant purulent secretion.

The *non-suppurative type* was characterised by polypoid formations unaccompanied by true leucocytic pus. This hyperplastic ethmoiditis, while distinct pathologically from the suppurative variety, did not preclude a combination of both types. In fact, the probability of suppuration was in direct proportion to the extent of hyperplasia. Saprophytes were more likely to find a suitable growth medium when polyposis was present. The *suppurative type* might be subdivided into suppuration affecting the anterior cells or the posterior or a combined suppuration of anterior and posterior. Suppuration of the anterior cells as an individual entity did not exist save with one exception. He had not seen this condition apart from accompanying affection of the frontal sinus. The exception referred to was infection of the bulla ethmoidalis, and even then an abscessed bulla was often associated with infection of other cells. Infection of the posterior cells was more frequent, because they were larger and more numerous, and they were so situated as to be less amenable to aeration. Their drainage could easily be interfered with by a slight swelling of the mucosa and their situation prevented easy exact diagnostic instrumentation. So slightly were they disturbed by inspiratory air currents that they offered an excellent medium for microbic growth. The combined anterior and posterior infection was usually an acute infection in contra-distinction to the gradual insidious infection of the separate anterior or posterior cell types. The *hyperplastic types* varied from a slight degeneration of the lower border of the middle turbinate, to the formation of large sessile polypi. Actual polypi appeared to originate from the body of the ethmoid or the uncinate process. He had never seen a large polyp originating from the lower border of the middle turbinate. The anterior labyrinth was the seat of large extracellular hypertrophies, while in the posterior labyrinth the intracellular variety was the rule. The so-called choanal polyp sprang from the mucosa of the maxillary antrum. In old chronic cases the entire ethmoid became converted into one mass of polypoid degeneration. In such cases there was a profuse watery secretion, which did not stain linen. Staphylococcic infections appearing in cycles produced thick yellow secretions. The true combined form only became permanent when the organisms found lodgment deep in the mucosa.

Treatment had for its basic principles aeration and drainage. Complete removal of all infected tissue was unnecessary. At one time he was prone to overdo the removal. Drainage was the duty, while ventilation, although desirable, was not indispensable. Ofttimes haphazard procedures only left an area of debris, which degenerated into a disorganised suppurating mass. In simple catarrhal infection, removal of the middle turbinate was almost a sine qua non; first, to permit thorough aeration, and secondly to make possible the application of medicaments. In some cases he had found it necessary to resect part of the septum, so that the middle turbinate could no longer swell and compress the ethmoid. Five days after removal of the turbinate tampon treatment was instituted. Cotton tampons saturated with a 10 to 20 per cent. silver preparation, dissolved in equal parts of water and glycerine, were used and allowed to remain in situ at least five hours. The solution should be warm and freshly made. The tampons at first were used every other day, and later with decreasing frequency. Suppuration in the anterior cells often required that the frontal sinus should be cleared of infection. An abscessed bulla could be treated by opening its floor. Suppuration in the posterior cells was difficult to detect even with the nasopharyngoscope, but one clue was always at hand and that was the hypertrophied and mottled appearance of the middle turbinate. In treatment the middle turbinate should be removed, and obviously diseased cells should be opened up, following which the tampon treatment should be carried out. Suppuration of the entire labyrinth required a complete exenteration. In doing so, the preliminary removal of the uncinate process with a flat chisel was advisable. After this had been done the posterior cells could be methodically resected. It was well to leave that part of the inner wall of the ethmoid which housed the olfactory nerve filaments. This was done rather to preserve the sense of smell than to obviate the development of meningitis via the cut filaments. Silver tampons as an after-treatment were admirable.

Treatment of Hyperplastic Ethmoiditis.—Localised hyperplasia (polypi) was treated with a snare, and it was strongly advisable to resect the bony attachment of the polyp. In generalised hyperplasia of the anterior and posterior labyrinths, complete removal, as far as possible, of the degenerated tissue was called for. Here the Mosher and Sluder operations were indicated. Intranasal operations demanded an intimate knowledge of anatomy, but even so there was no anatomical configuration of the ethmoid cells to constitute a normal model. In consequence of these variations, certain deep-lying cells often escaped attention, and that was why the ultimate results were not all good. Nevertheless, he was convinced that the intranasal operation offered the least dangerous, if not the most facile, opportunity to the patient for relieving him of his distressing and ofttimes dangerous infection.

Mr. W. G. HOWARTH (London) classified chronic ethmoiditis into catarrhal and suppurative varieties. He was of opinion that the catarrhal type in its early stages might respond to treatment by simple lavage and hygienic measures, but these were of little use if there was deep infection. He emphasised the importance of aeration and drainage and strongly advised the removal of the middle turbinate. The suppurative variety might be treated by morcellement of the cells after preliminary removal of the turbinate, but he thought the labyrinth could not thoroughly be cleared out by an intranasal operation. He preferred to approach it via the extranasal route, which he had used for 15 years. It gave a better approach to the ethmoid and was not dangerous. Even this method, however, did not expose all the ethmoid cells in certain cases.

The PRESIDENT (Dr. D. R. Paterson, Cardiff) made a plea for conservative treatment. He mentioned cases in which, for various reasons, radical measures had not been attempted. These cases had been treated along conservative lines, such as the periodic removal of polypi for many years. Looking back on these cases he had no reason to be dissatisfied with the results.

Mr. E. B. WAGGETT (London) thought that antritis usually coexisted with ethmoiditis, and that failure to cure the antral trouble was due, in many cases, to an infected bulla. Snipping off the bulla was always worth while.

Mr. HERBERT TILLEY (London) stressed the importance of the use of the endoscope as a means of diagnosis. The antra should be explored in every case of chronic catarrh. He thought there were cases of ethmoiditis in which neither suppuration nor polypoid formation occurred.

Dr. WILLIAM HILL (London) spoke of the difficulty of complete exenteration of the labyrinth, and pointed out the difficulty of dealing with cells extending into the wings of the sphenoid. He did not advocate the routine use of multiple exploration punctures.

Dr. P. WATSON-WILLIAMS (Bristol) said that while the suppurative and non-suppurative varieties were clinical entities, they were but expressions of the same pathological process. The variations depended upon the virulence of the infecting organisms and the patient's own resistance. He suggested the use of vaccines on tampons, and to this end specimens of pus should be obtained by means of suitable cannulæ. With regard to operative measures, he favoured intranasal methods. The middle turbinate should be conserved as far as possible. It at least served as a guide for the removal of the ethmoid cells.

Mr. W. S. SYME (Glasgow) believed that ethmoidal disease was often more extensive than it at first sight appeared. Exploration of the antra was essential, and in most cases an intranasal operation sufficed.

Mr. C. A. SCOTT RIDOUT (Portsmouth) advocated the external nasal operation. He pointed out the frequency of pain between the eyes in infection of the posterior ethmoid cells.

Mr. J. B. HORGAN (Cork) believed in mutiple explorations, and recommended approach to the ethmoid cells via the antrum. He had found iodised phenol of service in cases where the capsule of the ethmoid had been broken into during operations.

Dr. G. M. COATES (Philadelphia) referred to the use of vaccines in chronic infection. American practice did not place any great reliance on their virtues.

Dr. LOGAN TURNER (Edinburgh) expressed the opinion that the external operation was based on sound surgical principles. While meningitis resulting from infection conveyed along the olfactory nerve filaments could not be very common, it did undoubtedly occur. Specimens illustrating it could be seen in the Edinburgh Museum.

Dr. SKILLERN, in reply to a question, stated his preference for local anæsthesia.

Dr. WATSON-WILLIAMS read a paper on a case of Optic Neuritis due to Sphenoidal Sinusitis, which was treated by differential exploration. He pointed out that anatomical variations of the sinuses frequently made diagnosis difficult. In his case the patient had a true undeveloped left sphenoidal sinus. This had become infected and the patient had developed optic neuritis. The infected sinus was found by a process of differential diagnosis, in which cannulæ were used. The method of use was demonstrated by lantern slides. He mentioned that the patient's optic neuritis had much improved when he was subsequently examined by Dr. D. Leighton Davies.

DRAINAGE OF BRAIN ABSCESS.

Sir PERCY SARGENT, in opening the discussion, referred to the special features of brain abscesses. These were the type of tissue involved, the presence of cerebro-spinal fluid, and the pressure conditions within the cranial cavity. There was also the frequent coexistence of other conditions to be considered—e.g., meningitis, ventricular ependymitis, and sinus phlebitis. Four types of abscesses could be recognised: (1) diffuse septic softening; (2) a pus-containing cavity with a ragged wall; (3) a cavity with a thin capsule of young fibrous tissue; (4) a cavity contained by dense fibrous tissue perhaps an inch in thickness. In the first variety, which was really not an abscess at all, no surgical treatment was likely to be of any use, save perhaps simple decompression. In the second class drainage might be successful. The third and fourth types differing only in the thickness of the capsule, merged imperceptibly into one another. Around the thin-walled abscess there was an area of œdematous brain along which extension might take place and by which route the ventricle might become involved. In the thick-walled abscess the changes in the surrounding brain were insignificant. Their proper treatment was complete enucleation followed by closure of the wound without drainage.

The commonest type of abscess was probably that represented by Type 3. Most of these were of otitic origin and situated in the temporal lobe or cerebellum. Cerebellar cases, because they usually gave earlier indications of their presence, were more likely to be operated upon at an earlier stage. He commented upon Macewen's series of cases and his astonishingly low mortality-rate. This latter, he thought, was due to the fact that Macewen's cases consisted of definitely encapsulated abscesses with a long history. These cases did not lend any support for early operation, but in the speaker's opinion early operation ought to be undertaken as soon as an abscess was diagnosed. The dangers of delay were: rupture into the ventricle, acute spreading œdema, and, especially in cerebellar abscess, sudden respiratory failure.

If an abscess were imperfectly drained, the ventricle which contained fluid under pressure might rupture into the abscess and lead to the escape of cerebro-spinal fluid from the wound. If properly drained, the intracranial pressure fell. The appearance of a fungus cerebri—i.e., a protruding mass of strangulated necrotic tissue—was indicative of unrelieved pressure. The route of approach and the method of drainage were of prime importance. The "stalk" of the abscess, representing the inward track of infection, was the ideal route of approach. In otitic cases during a mastoid operation the "stalk" might fortunately be found, and it was possible that the drainage thereby established might be adequate.

Failing the finding of the "stalk" a transarachnoid route must be used. After the skull had been opened the subarachnoid space should be packed off with gauze before the pus was evacuated. This guarding plug might be left in for two or three days.

A subcortical abscess was usually indicated by bulging of the brain with pallor and broadening of the convolutions. These appearances were lacking in deep-seated abscess, and exploration with the trocar and cannula was to be deprecated. He was accustomed to use a small flat seeker, with which the resistance of an abscess wall could be felt. Having located the abscess he tied off all necessary cortical vessels, and then he incised the abscess with a knife. The material of the drainage-tube was of little importance provided it was sufficiently rigid. He had used aluminium and celluloid tubes. The tube should be sutured to the dura or skin and kept clean by syringing. It should be shortened very gradually, and there was always a tendency for some œdema to push it out. This could be tided over by lumbar puncture.

Mr. SYDNEY R. SCOTT (London) spoke of the routes of infection in brain abscesses of otogenic origin. A cerebral abscess might develop via the tegmental, the labyrinthine, or the venous route, and cerebellar abscesses originated from the antrum, the sigmoid sinus, or the labyrinth. Regarding methods of opening the skull, he preferred the use of a broad sharp gouge and a heavy hammer. The gouge should be used parallel to the surface. He deprecated the use of blunt probes in the case of acute abscess. A short pointed knife was advisable. If thick pus was present a dilating forceps was useful. For enucleation purposes he used a spoon and forceps. Drainage was not always necessary as in the case of a small superficial abscess. He said that the use of a suction apparatus was sometimes desirable, but demanded great care. In concluding, he spoke of the value of manometric records as an aid in controlling pressure.

Dr. E. D. D. DAVIES (Stonehouse) pointed out that drains might sometimes be harmful. They might be a source of trauma or secondary infection.

Mr. E. B. WAGGETT (London) suggested exploration with the finger. Once the abscess had been located by an instrument, the latter should not be removed until the drain had been inserted.

Dr. **William Hill** asked why the prognosis of frontal abscess was so bad compared with that of temporo-sphenoidal abscess.

Mr. **Hugh E. Jones** (Liverpool) thought that possibly the close relationship of the anterior horn of the ventricle to a frontal abscess was the explanation. He raised the question of ventricular drainage, where drainage of the abscess was not enough.

Mr. T. R. **Rodger** (Hull) suggested that it might be advisable to delay operation on a cerebral abscess so as to permit of encapsulation.

Dr. **Coates** (Philadelphia) said that the mortality-rates in his country were approximately equal to those in this. He disliked rapid drainage.

Sir **Percy Sargent**, in reply, spoke of the size of the cranial opening. It should always be of sufficient size, a mere trephine opening was not sufficient. A contralateral decompression was of use for the relief of pressure. Ventricular puncture, while useful, was transient in its effects. Hypertonic saline injections were efficacious, but their effects should be carefully watched, for there was a danger of the brain falling away and thereby opening up adhesions. He had no experience of a two-stage operation, nor of gauze drainage, and the latter might be harmful.

Injuries of the Ear arising from Fracture of the Skull.

Dr. E. D. D. **Davies** remarked that in view of the increasing frequency of motor and street accidents, the aurist's point of view was of particular importance. The aurist was usually called in some weeks after the accident to treat deafness, or in connexion with compensation matters. He would be able to give a more accurate estimation of the damage, and treatment might be facilitated, if he were called in soon after the occurrence. Most fractures of the base involved the middle fossa, and this was to be expected, since a line of weakness extended through both Glaserian fissures and the Eustachian tubes to the foramina lacera media, between which was the sphenoidal sinus. The halves of the skull were more or less cemented together by the basi-occipital and the basi-sphenoid, and the fracture usually followed this weak line. The roof of the tensor tympani canal and Eustachian tube and that of the tympanum and antrum were usually involved in fractures along this line.

The extent of the injury varied with the violence, and the site where the blow was applied. Spicules of bone from the tegmen were sometimes found in the auditory meatus. The middle ear was almost always damaged in surviving cases, while the internal ear was rarely fractured. The external meatus was often fractured when the line was through the Glaserian fissure. It appeared to split longitudinally into an upper and lower half. (A specimen showing this was exhibited.) A crack in the roof of the meatus was more common. Where great force was applied, the fracture might extend from the upper or anterior surface of the petrous bone into the internal meatus. A smashing blow might knock off the mastoid and injure the lateral sinus. Fractures of the posterior fossa began in the cerebellar fossa, radiated into the sinus groove of the same side, and then passed either along the inferior petrosal sinus groove or across the petrous pyramid, through the cancellous bone surrounding the antrum and semicircular canals and behind and external to the internal meatus. A blow on the temporal fossa had cracked the roof of the middle ear, and blood had escaped into the tympanum without rupturing the drum. No blood was found in the meatus, but the drum had a bluish appearance. In four such cases the only indication was deafness, and the injury would not have been detected without an aural examination. In such cases posterior rhinoscopy would occasionally show blood in the orifice of the Eustachian tube. Hearing was completely recovered in these four cases in three weeks. Usually, however, the upper half of the drum was ruptured, and blood escaped into the auditory meatus. Leaking of cerebro-spinal fluid indicated the opening-up of the subarachnoid space, and all such cases he had seen had been fatal. Cerebro-spinal fluid also escaped in fractures involving the internal ear.

Profuse and prolonged bleeding from the ear pointed to rupture of the middle meningeal artery or the lateral sinus, and urgent operation was called for. The meatus was sometimes a vent for extradural hæmorrhage and ought never to be firmly plugged. The lateral sinus was rarely ruptured, and the increased intracranial pressure sufficed to arrest bleeding. Hæmorrhage from both ears had a mortality of 66 per cent., while from one ear it was 39 per cent. The average mortality of all cases of fractured base was about 40 per cent.

The presence of pre-existing middle-ear suppuration made meningeal infection very probable. Local suppuration sometimes followed the injury, and materially added to the damage. Mastoid suppuration occasionally followed a fracture, and was liable to lead to meningitis. Some cases of local suppuration, if seen late, could not be distinguished from ordinary chronic middle-ear suppuration, hence the importance of examination soon after the accident. In compensation cases the history of absence of deafness and ear disease previous to the injury should be carefully verified.

Facial paralysis occurred in abour 46 per cent. of fractures of the middle fossa. In a few cases the eighth nerve was involved as well. The facial nerve was injured in the facial canal, particularly near the geniculate ganglion. Paralysis set in almost immediately, save in some cases where it was due to hæmorrhage into the canal. Recovery in these latter cases was more rapid. All cases he had seen had recovered, even after long intervals.

The degree of deafness arising from fractures was very variable. Some showed no deafness. A case seen 12 months after injury, in which the sixth, the seventh, and part of the third nerve had been paralysed, revealed only slight middle-ear deafness. Suppurative cases suffered most loss of hearing, and this loss became permanent. Any improvement which occurred usually took place within eight weeks of the injury. He had not seen genuine ear deafness arising from concussion alone, or from a fracture showing the signs he had described. Probably all subjects of injury to the internal ear died.

The treatment was not always masterly inactivity, and a watch should be kept for the onset of suppuration. Absolute rest in bed for a long period was essential, and the less done to the ear the better. The head should be raised. The meatus should be gently cleansed with spirit, and sterile wool frequently changed should be placed lightly in the orifice. If there was a discharge of cerebro-spinal fluid, the skin should be dried and smeared with antiseptic ointment. Packing with gauze, syringing, and the use of drops were to be deprecated. If suppuration arose, free drainage should be established. The drum should be incised if necessary, and a simple mastoid operation should be carried out at the slightest indication. The operation should be done gently, and preferably by burr or drill to avoid the jarring of the mallet and chisel. Early recognition and treatment of suppuration were essential, to prevent meningeal or intracranial infection.

SECTION OF HISTORY OF MEDICINE.

Nature and Treatment of Dropsy.

Mr. **Walter G. Spencer** presiding, Dr. J. D. **Comrie** (Edinburgh) discussed the historical aspect of ideas regarding the nature and treatment of dropsy. From the earliest times, he said, dropsy was recognised as a morbid condition and was for long regarded as a disease sui generis due to liquefaction of the tissues. The ancient Greek physicians attributed it chiefly to a disorder of the liver, and hardening of the organ was regarded as the principal cause by the Alexandrian school of medicine. Galen regarded the defective action of the heart which was often an accompaniment of dropsy as an effect rather than a cause. In the eighteenth century Morgagni drew attention to the frequency with which the heart was found to show valvular defects and other disorders in cases of dropsy, but did not carry the matter further. Withering, who introduced the use of digitalis in 1775, recognised that only certain cases of dropsy were amenable to treatment by the drug. He described as the type of case in which the dropsy was chiefly benefited persons showing symptoms which were now recognisable as being those of advanced cardiac disease, although the means of diagnosing valvular disorder were not at the time available to Withering. In the beginning of the nineteenth century Corvisart followed by Laënnec placed the diagnosis of cardiac disease on a sure foundation and showed that dropsy was frequently simply a sequel of this type of disease. The recognition of kidney disease as a cause of dropsy was first made early in the nineteenth century when Wells, Blackall, and others pointed out the fact that the presence of albumin in the urine was a prominent feature in certain dropsical cases, and these observations were placed on a sure footing by Bright in 1827. A further group of cases in which neither the heart nor the kidney was found to be at fault was demonstrated by Gull and Ord in the seventies of last century to be due to atrophy of the thyroid gland and to be of a different nature from simple watery œdema.

The PRESIDENT dealt with the surgical aspects of dropsy, particularly omentopexy.—Prof. J. A. NIXON sketched the history of war œdema or famine œdema, the first reference to which was to be found in Hesiod's "Works and Days."

WELSH PHYSICIANS AND THE RENAISSANCE.

Dr. E. ROLAND WILLIAMS (Maenchochog) gave an account of those Welsh physicians of the sixteenth century who had claims to be remembered not only as physicians but also as pioneers of the new learning in other fields of knowledge. The earliest and greatest of these was Robert Recorde, of Tenby (1510–58), who was not only a physician of repute but also one of the great mathematicians of the sixteenth century. To him was due the invention of the sign of equality (=) and the popularisation of the signs plus (+) and minus (–). He was the author of a treatise on anatomy and of "The Urinal of Physick," which laid down the classical canon of uroscopy. Humphrey Llwyd, of Denbigh (1527–68), was another physician notable for the breadth of his culture and his pioneer work in new fields of knowledge. He was the author of "The Judgment of Urine," published posthumously in 1553, which was a kind of therapeutic index and guide to dispensing. Llwyd was devoted to music and was an industrious and erudite writer on Welsh history and antiquities, but his work on geography formed his chief contribution to the new learning. Many prints of his maps were still extant. One of the early translators of the classics into English was the physician. Thomas Phaer, who rendered nine books of the Æneid into English verse and was also the author of two medical works. "A Goodly Brief Treatise of the Pestilence" and the "Regimen of Health." Several of the contemporary Welsh grammarians were physicians who sought relaxations from the cares of practice in what one of them called "the anatomy of language." The most picturesque, typical, and learned of these was John Dafydd Rhys, of Llanfaethlu, in Anglesey, who graduated as doctor of physic at Sienna and wrote two grammatical treatises in Italian, one being an "Introduction to the Study of Latin" and the other a "Guide to the Pronunciation of Italian." He subsequently returned to Wales and practised in Brecknockshire where he died in 1609. During the last period of his life he wrote a Latin treatise on Welsh grammar and prosody, and published a Welsh translation of Aristotle's metaphysics.

Dr. J. D. ROLLESTON (London) emphasised the importance of Thomas Phaer whom Prof. J. Ruhräh had called "the father of British pediatrics."

HISTORY OF SCARLET FEVER.

Dr. Rolleston said that not only in the remote past but until comparatively recent times it was often almost impossible to disentangle the history of scarlet fever from that of other acute exanthemata, especially measles and erysipelas on the one hand, and diphtheria on the other. An attempt had been made by some writers to trace back the history of scarlet fever to classical antiquity and even to identify it with the pestilence at Athens in 430 B.C. Some passages in Hippocrates had given rise to the belief that the father of medicine was familiar with scarlet fever, as he described an illness accompanied by a severe sore-throat though he made no mention of a rash. The mere existence of ulcers on the tonsils, however, did not justify the diagnosis of non-eruptive scarlet fever. The same objection applied to passages in Celsus, Caelius Aurelianus, Aretæus of Cappadocia, and Aetius of Amida supposed to refer to scarlet fever, whereas diphtheria was probably the disease in question.

The Arabian physicians such as Avicenna, Ali Abbas, and Rhazes had also been credited with allusions to scarlet fever, but their descriptions were too vague to be interpreted as such. The first undoubted reference to scarlet fever in medical literature was made by Ingrassias (1510–80), who, in a work published at Naples in 1553, described a disease popularly known as Rossalia, or Rosania, which he distinguished from measles. The next most important writer on scarlet fever was Baillou (Ballonius) who, under the title of Rubiolae, described the principal varieties of the disease from his observations on a severe epidemic in Paris in the winter of 1574–75. Jean Cottyar, of Poitiers, a contemporary of Baillou, also gave an account of the disease under the name of "febris purpura epidemialis et contagiosa." A much more important writer was Daniel Sennert (1572–1637), who was the first to describe scarlatinal desquamation, the early arthritis, and post-scarlatinal dropsy and ascites. The epidemic which he observed at Wittenburg was severe and often fatal, and convalescence was protracted. Sennert's son-in-law, Michael Doering, observed an epidemic in Poland in 1625 and also noted the desquamation, rheumatoid pain, and anasarca as well as the inflammation of the tonsils and surrounding parts.

The term scarlatina was generally supposed to have been first introduced into medical literature by Sydenham, who published his brief account of the disease in 1683, six years before his death. The mild character of scarlet fever at that time was shown not only by his statement that it was hardly worthy the name of a disease, but also by his omitting any mention of the sore-throat or of the complications of rheumatism and dropsy described by his predecessors. In spite of his inadequate description. Sydenham was to be credited with having established the autonomy of the disease and given it a name to distinguish it from the other acute exanthemata, especially measles. His contemporary, Richard Morton, however, maintained that scarlet fever and measles were exactly the same, although unlike Sydenham he described a malignant as well as a mild form and expressly mentioned inflammation of the fauces in the acute stage and alluded to dropsy and ascites as sequelæ. He was also the first writer to mention the occurrence of scarlatinal otitis. In spite of Morton, Sydenham's distinction of scarlet fever from measles was accepted by subsequent writers.

The occurrence of scarlet fever in Scotland was first described by Sir Robert Sibbald, physician to Charles II. and President of the Royal College of Physicians of Edinburgh, in his work "Scotia Illustrata," published in 1684. During the eighteenth century numerous epidemics occurred throughout Europe and the United States and were described by Huxham, Fothergill, and Withering in England, Storch and Zimmermann in Germany, Plenciz in Austria, De Haen in Holland, Rosen von Rosenstein in Sweden, Tissot in Switzerland, and Benjamin

Rush in the United States, where the disease first appeared in 1735. During the eighteenth century there was a tendency to confuse scarlet fever with angina maligna, which was not finally established as a distinct disease until 1821 when Bretonneau gave it the name of "diphthérite." During the last 30 years of the eighteenth century there was a considerable increase in the incidence of scarlet fever, epidemics of which occurred in England, France, Germany, Italy, Holland, Sweden, Denmark, and North America. The epidemics were mostly mild, but one in central Germany, which lasted from 1795 to 1805, was attended by an unusually high mortality.

At the commencement of the nineteenth century malignant and extensive epidemics were followed by periods of lesser prevalence and low mortality, as shown by the experience of Graves in Dublin and Bretonneau in Tours, who differentiated scarlatinal angina from diphtheria. His doctrines were developed by Trousseau, who drew attention to the characteristic tachycardia and frequent occurrence of miliaria, and gave an account of the "formes frustes" (defaced types) of the disease. In the course of the nineteenth century several parts of the world which had hitherto escaped received their first visitation of the disease, such as Madeira (1806), South America (1829), Greenland (1847), Australia and New Zealand (1848), and California (1849). The mortality from scarlet fever in England was very high for at least 50 years after the introduction of registration in 1838, the maximum being reached in 1863. During the last 50 years the mortality had shown a steady decline in England in striking contrast with that in Eastern Europe, especially Poland, Bulgaria, and Roumania.

In conclusion Dr. Rolleston alluded to the advances in our knowledge of the ætiology, prophylaxis, and treatment of scarlet fever since the war.

Welsh Physicians in the Middle Ages.

Dr. P. **Diverres** (Swansea) said that the first medical treatise in Welsh known as the Meddygon Myddfai (the physicians of Myddfai) was probably composed in the thirteenth century. The compiler did not make use of folk medicine, but borrowed freely from Latin authors of repute in that line and in particular from the Secretum Secretorum. With the exception of the Welsh Laws references to physicians were very scanty in mediæval Welsh literature. There were, he said, no allusions to a school of medicine such as existed in the Middle Ages on the continent, but he believed that each physician trained some pupils who were often, perhaps in most cases, his sons or near relations. It was noteworthy that Gerald, the Welshman whose work was so full of interesting details, made no mention of physicians—an omission not likely to have occurred if medical practitioners had been numerous in his time. The Welsh Laws, which in their present state dated from the thirteenth century, only mentioned the Court Physician who was one of the 24 officers of the Court. He was one of the three persons allowed to have private intercourse with the King without the presence of the judge of the palace. He was never allowed to leave the palace without the King's permission. He was expected to give his professional attendance gratuitously to all the officers of the palace, receiving only by way of fees the blood-stained clothes of the patient. If, however, he had to attend to one of the three deadly wounds (blow on the head penetrating the brain, stab in the body penetrating the intestines, and fracture of one of the four limbs) he was to receive one pound without his food or nine score pence with his victuals. In war time the Court Physician was obliged to accompany the armies. According to contemporary medical texts most diseases were treated with remedies made of herbs, but in some cases other kinds of treatment were known such as ligatures, cauteries, and baths.

History and Lore of Cinchona.

Mr. C. J. S. **Thompson** (London) discussed the history of cinchona during the past 300 years from the traditional, the empirical, and the chemical aspects. He dismissed as unfounded the stories told by Geoffroy and La Condamine of the discovery of the febrifuge properties of cinchona by natives. The first authenticated record of the therapeutic value of cinchona bark was in 1638, when the wife of the fourth Count of Cinchon and Viceroy of Peru contracted intermittent fever and made a rapid and complete recovery after taking powdered bark which had been sent her by the Corregidor of Loxa who had himself been cured of an attack by this drug. When the Countess returned to Spain in 1640 she took with her a quantity of bark which she distributed among those suffering from fever on her husband's estates. In 1653 Chifflet, physician to the Archduke Leopold of Austria, wrote a report on the drug and its introduction into Europe. Contemporary physicians differed as to its value. Although many admitted that it palliated the fever, they insisted that it "fixed the humour," thus causing a relapse of some other dangerous disease. It was known at the time as *pulvis Jesuiticus* because the Jesuit fathers used to administer it, or more commonly as *pulvis Peruanus*. In 1670 the Jesuit fathers in Peru sent considerable supplies to Rome, where the methods for using it were explained to a congress of Jesuits. The bark was first known in England in 1655. Brady, then professor of physic at Cambridge, was one of the first to prescribe it, but its general introduction was largely due to Robert Talbor, who made his name and fortune by exploiting it as a secret remedy. In 1677 Peruvian bark first appeared officially in the London Pharmacopœia under the name of Cortex Peruanus. Until the beginning of the nineteenth century cinchona was still used in the crude state, and it was not until 1810 that Gomez, of Lisbon, obtained the acute principles of cinchona, the basic properties of which he called "cinchonino." In 1820 Pelletier and Caventou showed that cinchonino consisted of two distinct alkaloids, one of which they called quinine and the other cinchonine. In 1833 Henry and Delandre isolated quinidine, in 1844 Winckler discovered cinchonidine, and Pasteur produced the alkaloidal derivatives, cinchonicine and quinicine. Since the discovery of quinine 30 alkaloids have been found to occur naturally in cinchona bark, and from these there had been many derivatives.

SECTION OF TROPICAL MEDICINE.

Human Helminthiasis.

Dr. P. H. **Manson-Bahr** presiding, Lieut.-Colonel **Clayton Lane** read a paper on recent advances in the diagnosis and treatment of human helminthiasis. He dealt with the various fæcal egg-counting methods which, for estimating the output of helminth eggs, dated from 1885, and for the control of diagnostic techniques and the estimation of the extent and degree of individual infection in a community from 1918. The means used, he said, should fit the end in view; the diagnostic technique of direct centrifugal floatation (D.C.F.) could detect the presence of a single female hookworm normally ovipositing, was the only technique capable of mass usage, and was the simplest, most rapid, and most accurate available for hookworm, and probably for other common nematode infections where eggs appear in a host's fæces. It fulfilled an aim he had set before himself over ten years ago and since steadily pursued. Diagnosis by culture and extraction of hookworm larvæ was untrustworthy and might well miss the most active, and therefore most dangerous, larvæ. Trapped cultures must be used. "Creeping eruption" probably indicated intradermal wandering of a larva in an uncongenial host.

The principle of the Casoni skin sensitisation reaction for hydatid had, said Dr. Lane, been applied by Fülleborn to strongyloides infection, where it was invariably positive if the infection had lasted more than 18 months. Positive reactions with ascaris antigen appeared to be independent of ascaris infection. Hamilton Fairley had shown that complement deviation had marked value as a test for hydatid and schistosome infections. In appraising the damage done by infection arbitrary selection of tests was worthless. Tests must be such as really measured any disability produced. The most promising and controllable were those which dealt with the same persons before and after disinfestation, and there was reassuring evidence that such tests, dealing with general mortality, morbidity, and wage-earning capacity, were coming into their own again.

In treatment the perfect anthelminthic was yet to seek. The value of intravenous emetine and tartar emetic in schistosomiasis was established; yet Hamilton Fairley had shown that they were not parasiticidal in themselves, but were changed in the body into something which was; similarly, santonin appeared not to be toxic to ascaris, but to become so under the action of bile. Allusion was made to the persisting and lethal error which confused Schüffner's advocated dosage for oil of chenopodium of 48 drops from the international dropper, or 1·2 c.cm., with 48 minims or 3 c.cm. As to carbon tetrachloride, the drug with "no lethal dose," which was claimed to cause, in every million, but a few deaths, "and those among the ones who could best be spared," it was pointed out that, while 3 c.cm. was the advocated dose, death had followed 1·5 c.cm. of the pure drug, and sometimes many deaths. The precautions now advocated as possibly effective in preventing these deaths precluded the employment of the drug on a mass scale.

Dr. Lane drew a sharp contrast between mass treatment, which implied previous individual diagnosis, and herd treatment which "drenched" men promiscuously like cattle, and it was urged that since D.C.F. permitted four men to make an individual diagnosis regarding hookworm infection at the rate of a quarter of a million specimens or more yearly, herd treatment had no justification in morality, science, or expediency. If for the purposes of herd treatment there were adopted a drug, unforeseeably deadly in less than the advocated dosage, the advocated precautions against whose lethalness were inapplicable in herd conditions, then such adoption must in future imply disregard of professional obligations to those treated and deliberate pursuance of a course devoid alike of reason and humanity.

Discussion.

The President said he had found in the long-needed accuracy of diagnosis now afforded by D.C.F. a valuable clinical advance, for his clinical experience was positive that no infection with ankylostomes, however small, should be neglected on its own account or as an important because] harmful complication in other diseases. In his own hands, under conditions obtaining in hospital in England, carbon tetrachloride had proved a safe and effective drug in scores of cases of hookworm infection. There was, however, great need of standardisation of anthelminthics.

Prof. E. Hindle had noted, as a result of periodical examination of fæces of unselected patients in Cairo, that many got rid naturally of their hookworm infestation without any treatment. Prevention of reinfection was therefore of chief importance.

Dr. C. M. Wenyon thought that the main objection to herd treatment without diagnosis appeared to lie in the unforeseeable lethalness of one of the drugs used. Discovery of a safer, yet effective, anthelminthic would remove that objection.

Dr. B. M. Wilson described the anti-hookworm campaign in Jamaica. There a sanitary unit dealing with village sanitation in general and latrines in particular took charge of the selected area, and after their work was well established the treatment unit began theirs. This plan was based on the fact that treatment was largely wasted unless reinfection could be prevented. Deaths after carbon tetrachloride had occurred in Jamaica, and there thymol was now the drug of choice—an effective one—against hookworms.

Dr. H. M. Hanschell recounted his experience of the success of D.C.F. in revealing very small ankylostome infections where other not more time- or labour-saving technique had failed to do so. In certain of his cases of secondary syphilis proving unexpectedly resistant to treatment discovery by D.C.F. and expulsion by thymol of the small number of hookworms present had been followed by rapid clinical and serological response to the same antisyphilitic treatment. Carbon tetrachloride was a proved potent liver poison. It should not, therefore, be given to a purged and fasting patient unless sufficient glucose were given at the same time. For the same reason, to protect the liver, glucose should be given with antimony drugs also.

Dr. J. B. Christopherson held that antimony acted directly on the schistosome, though possibly not as antimony tartrate, but perhaps in an organic combination. There was no evidence that action of the drug on body tissues produced an "antibody."

Dr. Manson-Bahr read a communication from Dr. F. G. Cawston, of Natal, reporting success in treating "creeping eruption" with intramuscular colloidal antimony, or intravenous tartar emetic injections, and also with carbon tetrachloride by mouth in human schistosomiasis and in distoma infestation of cattle.

Transmission of Kala-azar.

Dr. C. M. Wenyon began by pointing out that development of kala-azar and oriental sore parasites into *leptomonas* forms was strong evidence for an insect host. *Leptomonas* were essentially intestinal parasites of insects or other invertebrates. The flea had such an infection, which spread from flea to flea as small rounded bodies, resembling *leishmania* of kala-azar and oriental sore. They escaped in the flea's fæces, were ingested by flea larvæ, and appeared as *leptomonas* in the hind gut of adult flea. All insect *leptomonas* had that simple life-history. A sand fly which ingested parasites of kala-azar, or oriental sore, acquired *leptomonas* infection, but in stomach, œsophagus, and even buccal cavity, not in hind gut. If such sand fly fed through a membrane into a fluid it injected the *leptomonas*, it must therefore inject these also into wound it inflicted in skin. That no one had actually transmitted kala-azar, or oriental sore, by its bite was not due to lack of infectivity, for if the flagellates were removed by dissection from sand fly and injected into man's skin (oriental sore), or into hamster's peritoneum, a kala-azar infection occurred. Perhaps "receptive" condition was necessary to ensure infection from small dose injected through proboscis. *Leishmania* parasites would develop in the bed bug, but that could not be host for distribution of bug and disease differed, and if few *leishmania* were ingested by bug only few flagellates developed. In the natural host there was progressive increase of flagellates which attached themselves to cells of the intestine. No attachment occurred in bug. Association of canine with human kala-azar in Mediterranean region gave rise to theory of flea transmission, but careful experiments had failed to incriminate that insect. Kala-azar parasites in intestinal villi of man indicated possible escape in fæces, and they had been demonstrated in the urine. Contamination infection was unlikely for the parasites could not withstand drying and would not survive in water. Ankylostomes were possible ingestors of the parasites, but these helminths from cases of kala-azar had not revealed trace of infection. In the sand fly from small dose of *leishmania* there developed large numbers of flagellates attached to cells of stomach and persisting for life of fly; thus the parasite behaved as in a natural insect host. Probably site of infection, originally in hind gut, had changed; or perhaps sand fly was not original insect host. Man having become infected from original insect host, which might or might not now function, the sand fly might have become secondarily infected from man. A similar problem was presented by tsetse fly transmitted trypanosomes, where development in tsetse was also an anterior one. It was a posterior one in the primitive *Trypanosoma lewisi* in the flea. This spread from flea to rat by the latter's ingesting flea fæces containing infective trypanosomes. If the sand fly were the vector there were several possible modes of infection of man. Flagellates might be occasionally ejected from the fly's rectum on to the skin, but dose deposited would be even smaller than that injected from probocis. Crushing of sand fly gave larger dose which might be inoculable by scratching or by conveyance on fingers to mouth or conjunctiva.

In India the distribution of kala-azar corresponded with that of the sand fly *Phlebotomus argentipes*. In China the disease was found only north of the Yangtse. There was no information regarding existence of sand flies south of it. In India *argentipes* was most suspected, though development occurred also in *papatasii*. In North China *P. major* var. *chinensis* and *P. sergenti* var. became infected, but former was the better host. With oriental sore, *P. papatasii* in Palestine and Biskra had been infected, and in Bagdad *P. sergenti*. In Palestine and Biskra *P. papatasii* had been found infected in natives. In India a single infected *P. argentipes* had been captured in a kala-azar house. With South American cutaneous leishmaniasis a single experiment suggested that *P. intermedias* might be the vector. There were infections of animals—e.g., gecko and chameleon—and plants, with *leptomonas*, but nothing was known as to the relations these might have to the human diseases. At present, therefore, transmission problem of kala-azar and oriental sore centred around sand flies. The extraordinary flagellate development of *leishmania* parasites in them was convincing evidence that they were the vectors.

Discussion.

Prof. HINDLE gave an account of recent work supporting the view that sand flies were mainly responsible for the transmission of *leishmania*. He pointed out: (1) The *specific nature of the development in the sand fly*. The sand fly stomach did not serve merely as a favourable culture tube, for, if so, different strains of *leishmania* should develop equally well in any one species of phlebotomus. Yet, though four different strains of *leishmania* all developed into flagellate stage in the Chinese sand fly *P. major* var. *chinensis*, only the local strain of *leishmania* showed attachment of flagellates to stomach wall, and subsequent incursion of pharynx and buccal cavity. This presence of flagellates in anterior gut occurred only in the species of sand fly and with the particular strain of *leishmania* that seemed to be transmitted by it. (2) The *virulence of the flagellates in the sand fly*, proved by inoculation of contents of infected flies into susceptible hosts. As corollary, since these flagellates were present in the infected fly's proboscis and must therefore be inoculated into skin when that fly fed, that fly's bites would sooner or later produce infection. (3) The *geographical evidence*. In both India and China there was close agreement between distribution of kala-azar and that of sand fly presumably responsible for transmission of the disease. He criticised the transmission experiments up to date, and showed that with kala-azar they were inadequate in number to prove or disprove infectivity of the sand fly. In China kala-azar occurred in infants who, by reason of age, could not have been exposed to sand fly bites. Low and Cooke's case of kala-azar in an infant born in England, whose mother had contracted kala-azar in India, demonstrated that the disease might be congenitally acquired. The infant cases in China were doubtless of that kind. Referring to possibility of a second insect host in the cases of *leishmania* and *trypanosoma* in which flagellate stage occurred only in anterior gut of insect vector, here the parasite had merely lost hind gut flagellate stage in becoming closer adapted for life in the vertebrate host. Suppression of development in insect host reached its limit in the disease "dourine," where the trypanosome had become a parasite of the vertebrate host only, and transmission was only by direct contact in coitus.

Colonel A. G. MCKENDRICK quoted results of his statistical inquiry in support of the theory of sand fly transmission of kala-azar.

Sir FRANK CONNOR described his cases in Bagdad and in India of familial and of multiple oriental sore. His clinical observations of these and other cases, their personal habits and circumstances, favoured the theory of the frequent occurrence of direct contact transmission of oriental sore.

Dr. CHRISTOPHERSON pointed out the profound biological difference between the morphologically indistinguishable parasites of trivial oriental sore and fatal kala-azar. Parasites of oriental sore experimentally inoculated into human beings always produced only oriental sore. Clinical evidence suggested that oriental sore was the result of skin infection with insect flagellate, and kala-azar resulted after the flagellate had been further pathogenically modified by additional developmental cycle in another host. His own experience of naso-oral and dermal leishmaniasis in Sudan showed that lesions could be the result of inoculation by insect, and also by direct contact infection.

Dr. MANSON-BAHR said he had observed oriental sore appearing in one parent in India, and six months after the family of four had returned to England the sore appearing in the other parent and the two children before the lesion in the first parent had healed. This suggested direct contact infection. He pointed out that to Dr. Wenyon we owed valuable and indispensable pioneer work on the transmission of oriental sore.

ACUTE DISSEMINATED ENCEPHALOMYELITIS.

To the Editor of THE LANCET.

SIR,—Attention should be directed to the frequency with which cases of acute disseminated encephalomyelitis are being encountered in certain parts of London. A number of cases more or less similar have been met with during the last few years in association with vaccination or with measles, but otherwise, until recently, they have been rare. In June last, however, Drs. Hunter and Brain[1] were able to report that they had seen six cases within a period of two months. In Germany and Austria such cases have been recorded in moderate numbers during the last two years, and there they seem to have occurred in circumscribed epidemics. Redlich[2] in March, 1927, reported that he had seen numerous cases in Austria; Pette[3] saw 25 at Hamburg in 1926, and the early part of 1927, Muntzka[4] in a paper just published records five cases at Dölling.

Now that these cases are occurring more commonly in London it is desirable that their clinical features should be made widely known in order that as many as possible of the cases may be recognised. The more severe of the cases which I have seen are characterised clinically by the facts that the symptoms are referable to widely separated, or, at any rate, discrete parts of the central nervous system, and, secondly, that they come on in a series of attacks, different parts of the cerebro-spinal axis becoming involved suddenly at different times.

The first case I saw was that of a man of 70 who was under the care of Dr. C. E. Sundell at the Seamen's Hospital in January of this year. His illness began with pains in both legs, and within a day or two the legs became weak and numb; subsequent examination showed that this paralysis was of the flaccid type. During the next week there was considerable recovery and then paralysis of the

hands came on abruptly in the course of a few hours; the extensor muscles in the forearms were as a whole more affected than the flexor, and in the right arm partial paralysis extended as high as the deltoid. Accompanying this paralysis was a sensory loss corresponding to the fifth and sixth cervical segments of the cord. These symptoms remained almost stationary for 14 days, and then acute bulbar symptoms came on and the patient died within a few hours from respiratory failure. In this case there was evidence of invasion at different times of three portions of the nervous system—lumbar enlargement, cervical enlargement, and medulla.

In the next case—a man of 32, admitted under the care of Dr. S. Wyard at the Bolingbroke Hospital on the last day of June—the patient had felt indefinitely ill for a few days and had severe headache; then he gradually lost the power of his legs in the course of four or five days, and the paralysis was accompanied by a feeling of numbness both in the legs and in the arms. During the next five or six days he was semi-conscious all the time. A fortnight after the beginning of the illness the left side of the face became paralysed, but it recovered rapidly after four days. In the limbs, at this stage, the tendon-jerks were all weak, the knee-jerks being unobtainable; the plantar reflexes were indefinitely extensor. The abdominal reflexes were absent. The patient complained for many days of severe pains in the arms. The cerebro-spinal fluid contained an excess of protein (0·10 per cent.) but no excess of cells. In the course of five or six weeks this patient made a complete recovery.

A third case was that of a man of 55, admitted under my care at the Bolingbroke Hospital on August 27th, 1928. He had not felt well for some months, and four days before admission on awakening in the morning he found that both his arms were weak and shaky. Within the next four days the hands became almost useless, and then recovered considerably. Two days after admission both hands had fair power, but they were still tremulous. By that time both sides of the face had become completely paralysed. The tendon-jerks were all brisk, and the plantar reflexes indefinite. There was no sensory loss. The patient was slightly delirious, but could be recalled to consciousness. He answered questions, but was very irritable. The cerebro-spinal fluid showed an excess of protein (0·085 per cent.). but no increase of cells. During the next 13 days his condition was almost stationary, but towards the end of that time his face showed great recovery. Then on Sept. 9th his temperature, which had hitherto been normal, rose to 100° F., and at the same time the patient began to have difficulty in swallowing and in talking. During the next 48 hours the temperature rose steadily to 102·4° F., and the paralysis of larynx and pharynx and tongue became absolute. The patient died from respiratory failure on Sept. 14th.

A fourth case was that of a little girl of 8 whom I saw at the National Hospital, Queen-square, on August 23rd. After a period of indefinite malaise she had suffered from pains in the lower limbs; then her legs became weak and she had difficulty in micturition, amounting almost to retention of urine. At that time she was considered to be suffering from poliomyelitis, but she had a high temperature. After three weeks the power of the legs had in great measure returned, but then the patient began to have difficulty in talking. (The precise nature of this difficulty cannot be determined.) She became very drowsy, and lay constantly with her head and eyes turned to the right. About the time of this aggravation her sight became dim. When admitted to the hospital she had extensor plantar responses on both sides, absent tendon-jerks in the right leg and arm, intention tremor in both hands, conjugate deviation of the eyes to the right, without any single ocular palsy, and partial atrophy of both optic discs. She is now recovering well, but it is too early to say how far recovery will go.

It is to be expected that in less severe cases of the same disease, the malady would not get beyond the stage of one more or less localised lesion, and most of the German cases have been of this type. Many of them presented the picture of a transverse myelitis of sudden onset and rapid recovery. Others at certain stages closely resembled poliomyelitis. In the last few weeks I have seen one case, similar to the foregoing as regards onset, but in which only spinal symptoms have appeared, and another case in which the diagnosis remains in doubt between this disease and poliomyelitis.

The prognosis generally seems to be more favourable than the record of these few cases implies. In Redlich's cases complete recovery was the rule and fatalities were few. In Pette's series of 25 cases most of the patients made good recoveries and there were only two deaths. Hunter and Brain reported four complete recoveries and one death among their six cases. Recovery may be incomplete and permanent defect remain, but no "after-effects" in the sense of disabilities developing after apparent recovery have, to my knowledge, been described.

I am, Sir, yours faithfully,

J. PURDON MARTIN.

Harley-street, W., Sept. 17th, 1928.

THE LATER RESULTS OF PARTIAL GASTRECTOMY FOR GASTRIC AND DUODENAL ULCER.

To the Editor of THE LANCET.

SIR,—Dr. Arthur Hurst's letter in THE LANCET of Sept. 1st cannot be allowed to pass without comment. He says: "Our experience shows that gastro-enterostomy is the commonest gastric disorder to-day, and undoing gastro-enterostomies is the operation we now most frequently recommend." This emphatic opinion from so eminent an authority might cause considerable confusion in the mind of the profession, if he had not spoilt the first part of this terse paragraph by figures cited immediately before it—viz., since 1921 there had been at the New Lodge Clinic 37 patients suffering from gastric ulcer, 165 from duodenal ulcer, and 67 from the ill-results of gastro-enterostomy or partial gastrectomy. So on his own showing gastro-enterostomy is not the commonest gastric disorder of to-day. Moreover, he does not indicate a very obvious point, which is that his clinic naturally collects failures.

Against Dr. Hurst's statement that the undoing of gastro-enterostomy is the operation he now most frequently recommends I put this one—of the hundreds of gastro-enterostomies I have done myself for duodenal ulcer and of the thousands I know which have been done by my colleagues, I cannot recall a single case in which the gastro-enterostomy has been subsequently undone, except where a jejunal ulcer has developed, and then, of course, it is the jejunal ulcer which is the disorder and not the gastro-enterostomy. But I suppose all of us have undone gastro-enterostomies performed where there was no sign of ulcer, past or present, and possibly Dr. Hurst has this class of case in mind when he makes the sweeping statement quoted above. In Leeds we have put this kind of surgery behind us long ago.

I am, Sir, yours faithfully,

Park-square, Leeds, Sept. 17th, 1928. E. R. FLINT.

To the Editor of THE LANCET.

SIR,—I find it a little difficult to reply, at one and the same time, to Dr. Hurst and Mr. Flint, for while the one ironically suggests that all operative procedures on the stomach are doomed to ultimate failure and that the commonest gastric operation of to-day is the undoing of gastro-enterostomies, the other tells us that the unsatisfactory results of gastro-enterostomy, far from reaching the 36 per cent. suggested in my article, are not more than 10 per cent., and that in many of these the symptoms are so slight that the cases could be considered satisfactory. Were I not very deeply impressed by the fact that in the present state of our knowledge of gastric and duodenal ulceration it is impossible to be categorical (even that surgical treatment is useless) I should find it impossible to reconcile these two opinions. Without reopening the whole question, however, there are certain explanatory points to which I should like to refer.

Both Dr. Hurst and Mr. Flint appear to be unfavourably impressed by the fact that I use the ability to take all kinds of food without restriction as one of my criteria of cure. But could any test be more appropriate, especially from the patient's point of view? If he has to continue upon a special restricted diet for the rest of his life he can scarcely regard himself as cured in the truest sense of that word, whether such a dietary be the sole treatment or merely the complementary treatment of a gastro-enterostomy. Unfortunately the cases of gastro-enterostomy included in my unsatisfactory group have had perforce to continue with such treatment for much longer periods than the three to six months which I claim should be sufficient if an operation is really curative. That a comparatively large ulcer will heal in such time if placed under the best conditions has been amply proved both by subsequent operations and radiographically. If operative or other treatment has brought about complete cure there should be no need for further dietetic restriction beyond this period, and it is in this respect particularly that the results of partial gastrectomy have turned out much more satisfactory than those of gastro-enterostomy, as indeed Mr. Flint's experience of the necessity for medical treatment "long afterwards" in the latter operation suggests.

It has been my ill-fortune, too, to meet several cases where following gastro-enterostomy for duodenal ulcer the patient remained completely free of digestive symptoms, but hæmorrhage or perforation many years later showed that the ulcer was still active, or, what is more probable, that fresh ulceration had occurred owing to the fact that the operation had not dealt satisfactorily with the cause, even although it had relieved the symptoms. This, indeed, is the crux of the argument—the relief of symptoms as opposed to the removal of the cause—and as far as the evidence of my cases goes it would appear that we are approaching the latter more closely by the performance of a partial gastrectomy than either by medical treatment or gastro-enterostomy. My attitude is, however, not a dogmatic one (the curtailment of the article to render it of suitable length for publication may perhaps have conveyed a wrong impression) and I realise to the full that the last word has not been said; yet the results in the cases of this series cannot be gainsaid, and in the absence of further knowledge they justify the recommendation of an operation which, in view of its mortality, any surgeon might otherwise hesitate to perform.

It would be interesting to learn what Dr. Hurst has to suggest, as an alternative, for those cases in acute agony who have already had a succession of medical treatments with almost immediate recurrence, and what prospects he has to offer them of returning to their former livelihood, often of an arduous nature, with little opportunity, either financial or otherwise, for carrying out any strict dietetic régime. The majority of the gastrectomy cases quoted in my article are men and women of the labouring classes who have returned to their former occupations without dietetic restrictions. But perhaps patients of this type do not find their way to the New Lodge Clinic. I am, Sir, yours faithfully,

NORMAN C. LAKE.

Welbeck-street, W., Sept. 17th, 1928.

BLEPHARITIS SUCCESSFULLY TREATED BY AN AUTOGENOUS ANTIVIRUS.

To the Editor of THE LANCET.

SIR,—It will be interesting to hear if Dr. Armstrong's case of blepharitis treated by bacteriological methods maintains freedom from relapse. During the last year every case of severe blepharitis seen by me in private practice, and in the out-patient departments of two London hospitals, has been found to be associated with gross focal sepsis. When the origin of the focal sepsis has been dealt with, usually either by the dental surgeon or the throat surgeon, combined with mild local treatment, the blepharitis has been permanently cured.

I am, Sir, yours faithfully,

A. F. MACCALLAN.

Welbeck-street, W., Sept. 15th, 1928.

INSOLATION IN PULMONARY TUBERCLE.

To the Editor of THE LANCET.

SIR,—I am glad to see attention called to the danger of rest in hot sunshine for those who are suffering from pulmonary tuberculosis. Verandas on the south side are commonly provided in sanatoria; but medical officers of experience know that it is unwise to use them in hot weather. All such structures should have ample gaps in the roof for ventilation or a discontinuous double roof. At Pinewood Sanatorium, Wokingham, a northerly veranda is provided as an alternative; in other institutions, rest shelters in shady situations. Even an open tiled terrace with awning next the building may be undesirably hot in summer. On the other hand, in dull or cold weather in this country we need all the sunlight available, so that permanent verandas in front of bedrooms have their drawbacks. At the Crooksbury Sanatorium awnings which can be furled are provided instead, and covered places not in front of the bedrooms; but in hot weather, for non-febrile patients, rest under the pine trees has often been preferred. To clear away all the trees from the vicinity of a sanatorium is a great mistake. Asphalted paths may be undesirably hot in summer for phthisical patients; dry walks, carpeted with pine-needles, are preferable. Sunshine treatment in "surgical" tuberculosis needs caution; in the pulmonary varieties it is dangerous to the febrile, and in some other cases.

I am, Sir, yours faithfully,

Farnham, Surrey, Sept. 14th, 1928. F. R. WALTERS.

BRITISH SOCIAL HYGIENE COUNCIL.

To the Editor of THE LANCET.

SIR,—Owing to the growing work of the British Social Hygiene Council it has been found necessary to obtain the services of a whole-time salaried medical secretary who is able to undertake medical educational work in connexion with the general organisation of the Council in all parts of the country. The medical secretary would also give assistance in the general work of the Council. As this entails a considerable amount of public speaking preference will be given to those accustomed to handling both medical and lay audiences. The post would give scope for anyone interested in research on venereal subjects and would probably be suitable for a younger man retired from one of the services. The work of the medical department is under the direction of the honorary medical secretaries and the medical advisory board. Further particulars are given in your advertisement columns.—We are, Sirs, yours faithfully,

KENNETH M. WALKER.
A. H. HARKNESS.
Hon. Medical Secretaries.

Carteret House, Carteret-street, London, S.W.
Sept. 15th, 1928.

B.M., B.Ch. Oxon. has omitted to enclose his card.

SUCCESS OF BIRMINGHAM CONTRIBUTORY SCHEME.—This scheme, which was started only eight months ago, already has 306,000 members and £61,000 has been paid to the hospital. *This result is mainly* due to the development of the Hospital Saturday Fund, which last year distributed £44,000. One of the conditions upon which the scheme was established was the abolition of notes and tickets.

TUBERCULOSIS DISPENSARY IN MANCHESTER.—The Ministry of Health has given notice that a public inquiry *into the proposal of the* Manchester Corporation to build a dispensary for the treatment of tuberculosis *upon* the vacant plot of land at the corner of Oxford-road and Denmark-road, opposite the Royal Infirmary, will be held in Manchester Town Hall on Oct. *11th.* During the debate in the city council the recommendations of the public health committee were approved, being opposed by only *one* member.

Obituary.

JOSEPH JOHN PERKINS, M.B. CAMB., F.R.C.P. LOND.

THE death on Sept. 13th of Dr. J. J. Perkins, at the age of 65 years, has come as a grievous blow to his large circle of friends. Affectionately known as "J. J." to most of his contemporaries, he was held in high esteem by his colleagues and former clerks, and was beloved by his patients, the secret of his genius for friendship being unselfish sympathy and generosity.

Born in 1863, Perkins started his career with a wide knowledge of the classics and of history acquired at Manchester University; it was not until he went up to Cambridge as an exhibitioner to Emmanuel College that his thoughts turned towards medicine. He became a scholar of his College and took a first-class in 1888 in the Natural Science Tripos before entering St. Thomas's Hospital at a slightly older age than the average medical student. Gifted with a retentive memory and with a keen incisive mind, he came early under the influence of the late Dr. J. S. Bristowe, who profoundly impressed him and for whom he entertained always the deepest admiration and esteem.

DR. PERKINS.

On qualifying in 1891 Perkins held house appointments at St. Thomas's and Brompton, taking every opportunity of increasing his experience, and in his long association with these two hospitals developing a clinical acumen and a deep knowledge of treatment which made his opinion much sought after, with the result that he acquired a very considerable consulting practice, not only in regard to diseases of the chest, his more immediate specialty, but also in regard to difficult cases in general. He would listen keenly to the history; then, after a quick but thorough examination, he not infrequently made a diagnosis in difficult cases surprising in its accuracy and brilliance. Although keenly impressed with the value of the older methods of physical examination he was quick to adopt new methods and applied them with a due sense of perspective. His ability, sympathy, and the practical helpfulness of his suggestions combined to secure for him the special professional distinction of being a doctor's doctor. He was for many years secretary of the National Council for the Prevention of Tuberculosis, devoting his time unstintingly to this work, so that his place will be hard to fill.

After an attack of rheumatic fever in early youth he was never robust, and in the later years of his life his health was far from good. In spite of this he worked extremely hard until a serious illness some ten years ago when he was away from work for many months. On returning, though he continued to practise, he restricted his private work, and about four years ago he decided to give up all professional activities. From this time onwards he devoted himself to his numerous interests, and was apparently happy in his keen enjoyment of them. He read deeply in the classics, took long motor drives to distant churches, where he indulged his love of architecture and increased his profound knowledge of monumental brasses and of old stained glass.

In congenial circumstances Perkins was a brilliant conversationalist and a witty companion with a keen sense of humour. His hearty appreciation of an apt reply or an amusing anecdote will long remain as a pleasant memory to his friends. But in spite of his large sympathies and of his wide circle of friends, there was even to those who knew him best a strange reticence, due to a sensitive nature and a modesty amounting almost to diffidence. It was this that prevented him from writing much in the medical journals and from producing books—a real loss to medicine, since he had garnered much medical wisdom which he was only able to impart to those coming immediately under his personal influence.

Of Perkins's genius for friendship we have received remarkable testimony of which only fragments can be quoted. The colleague who supplied the biographical notes writes: "I owe much to his stimulus, criticism, and wisdom, and find it hard to realise that the friend and counsellor of the whole of my medical life has departed. Perkins will be missed also, not least, by the young sons of his friends, to whom he was ever ready with sympathy, stimulus, and help." Another colleague says: "The beginning of my friendship with Perkins dates back to the time when I was a clinical clerk, and though as house physician he would of course possess what to the student seemed a profound knowledge of medicine, yet the main impression he left on me was not only that of a remarkably good house physician. Much more did he impress me even then with his kindly thoughtfulness and shrewd humour and above all with what I now realise was the early maturity of his outlook. The soul of loyalty to his hospital and a staunch colleague, his attachments were deep and enduring and he was never happier than when spending a week-end with some sanatorium friend. He was a good conversationalist, but in his long talks by the fireside, interesting, amusing, and stimulating as they were, he studiously avoided any reference to himself. Sociable he was and a delightful companion, but he viewed the world in a detached and impersonal fashion and held himself rather aloof from the rough and tumble of life. Good health he lacked, but as far as he could he hid this from the world and in his outward bearing he showed little evidence of the recurring outbreaks of tuberculosis which dogged his footsteps throughout life. The picture which I think Perkins will leave in the minds of most of us is that of a man of distinguished bearing, thin, fastidious in his dress, cheerful and often gay, mildly sardonic at times, but eminently courteous and considerate and always with a rather proud reserve concerning himself."

J. G. E. writes: "It was 32 years ago that I first met Perkins when I was house physician at the City of London Hospital, and to-day I mourn one of the best friends a man ever had. He was a man of many friends and he made us all realise the fullest meaning of that word, for with absolute obliteration of self he entered wholeheartedly into our lives and made our interests his own. He was always ready to encourage and help when we were in doubt, and many of us have reason to be profoundly thankful for his sound judgment and wise counsel."

ALBERT WILSON, M.D. EDIN.

DR. WILSON, who died at Fairwarp, near Uckfield, on Sept. 9th, was in his seventy-fifth year. He was born at Newcastle-on-Tyne, educated at the Friends' School, York, where he developed a marked taste for natural science, and went on to Edinburgh University, taking the gold medal in his M.D. for a thesis on heart diseases and, later on, visiting the Universities of Paris, Vienna, Berlin, and St. Petersburg. After qualifying in 1878 he was house surgeon at the Royal Infirmary, Edinburgh, and resident physician to the Cowgate Dispensary, playing a prominent part at the Royal Medical Society, of which he was president in 1879. Moving to London he had at first a City practice, but his interests tended more and more in the direction of the study of psychology, especially criminal psychology, and he became medical officer to the Walthamstow Branch of the Essex Asylum, doing much unostentatious work among poor folk in the East End. His varied publications included books on Education, Personality and Crime (1908), Unfinished Man (1910), and papers on multiple personality. At the time of his death he had just corrected the final proofs of a book entitled The Child of Circumstance, being a sociological study of the criminal couched in simple non-technical language and embodying the author's faith in the possibility of physical and mental improvement for the most degraded class of humanity. Dr. Wilson served with the French Red Cross in the early part of the war, and made a contribution on war wounds. All his life a keen traveller, his holidays were generally spent in some foreign clinic, where he added to his store of curious knowledge. Latterly he confined himself to consulting work. Dr. Wilson married, in 1881, Amy, daughter of Surg.-Capt. J. C. Minto, M.D., who survives him with two daughters.

Colonel Sir JOHN HEWAT, who died at Port Elizabeth on August 20th, took a prominent part in South African affairs in the intervals of a busy professional life spent in practice at Woodstock, a suburb of Cape Town. Born in Sarawak in 1863, he was a son of the late Captain John Hewat, of Cape Town, and was educated at George Watson's College, Edinburgh, and at the South African College, Cape Town. After graduating in medicine at Edinburgh University in 1887, he settled at Woodstock and became one of the leading practitioners there. He entered the old Cape House of Assembly as Progressive Member for Woodstock in 1904, and was re-elected in 1915 to sit in the Union Assembly. Under the leadership of the late Sir Starr Jameson he was for some years Chief Whip of the Unionist Party. Joining the Cape Garrison Artillery as a young man, he enjoyed long service as an officer of the corps, from which he retired with the rank of captain. At the Coronation of the present King he was one of the delegates chosen to represent South Africa and he was also one of a delegation from the Union which visited the war zone in 1915. He served in the brief German South-West campaign in 1915 as lieutenant-colonel in the South African Medical Corps, being mentioned in despatches, and was promoted to the rank of full colonel in 1917. He was knighted in 1919. A keen sportsman, Sir John was a steward of the South African Turf Club, and also president of the Cape Colony Athletic and Cycling Union.

Dr. F. J. NICHOLLS, who died at Eastbourne on Sept. 1st after a month's illness at the age of 58, was well known throughout the locality not only as a practitioner but as a sportsman. The son of Mr. E. W. Nicholls, of Eastbourne, he was sent to Rugby School, where he played in the XI. in 1888 and 1889. Thence he went up to St. John's College, Cambridge, and he studied medicine both there and at Guy's Hospital, qualifying as M.R.C.S. in 1899, and as M.B. in the following year. After special experience at the City of London Hospital for Diseases of the Chest, Victoria Park, and elsewhere, he settled in practice at Eltham, moving to Eastbourne some 19 years ago. During the war he did valuable work as anæsthetist to the war hospitals in the vicinity, and held a commission with the Sussex Volunteers. Outside his professional work he was an enthusiastic tennis player and golfer, and in former years played for the Eastbourne Cricket Club. His widow, the daughter of Mr. H. Simpson Gee, survives him with three sons and a daughter.

The death of Dr. OWEN PRITCHARD, at the age of 75, removes a distinguished member of the Welsh community in London. Educated at St. Bartholomew's Hospital he graduated as L.S.A. in 1880 and as M.D. in the University of Brussels three years later. Entering practice in London he became physician and later surgeon to St. Saviour's Hospital for Cancer and Diseases of Women, and made a number of contributions to professional journals. He was also associated with several other charitable institutions. In 1906 he was appointed High Sheriff for the county of Anglesey, and for the later years of his life was closely connected with the University of Bangor, which last year conferred upon him the degree of LL.D. in recognition of his services. Dr. Pritchard, who was unmarried, was a collector of books and china, and it is stated that some of his valuable furniture has been left to the National Museum of Wales. The funeral took place on Sept. 3rd.

Dr. WILLIAM MACFIE CAMPBELL, who died on Sept. 13th in his eightieth year, was a graduate of the University of Edinburgh, where he took the M.B. degree in 1869 and won the gold medal for his doctor's thesis in 1873. After post-graduate experience at Paris and Vienna, he went to Liverpool as house surgeon to the Northern Hospital, and it was not long before he was appointed to its consulting staff, as well as to that of other institutions in the neighbourhood, including the Liverpool South Dispensary. Interested especially in gynæcology, he published a considerable number of papers, chiefly in the *Liverpool Medico-Chirurgical Journal*, and won a high reputation among his colleagues, who elected him to various offices in the Liverpool Medical Institution, the most important centre of medical activity and interest in the city. Dr. John Hay, as president of this society, writes of him as follows: "I should like to put on record an appreciation of the valuable work done by him for the profession in Liverpool, and, more particularly, for the Medical Institution. In 1871 he became a member; from 1875 until 1901 he was continuously in office; and during 1898 and 1899 he was president of the Institution. But whether in office or out of office, he gave freely of his time and brains. He served the Medical Institution and the profession ungrudgingly, unselfishly, and wisely; and the vigorous health of our Society at the present time is in no small measure due to his sustained efforts. He has left us a noble tradition." Dr. Campbell had at one time probably the largest practice in the South End of Liverpool, and won the affectionate regard of his many patients. In his earlier days he was attached as surgeon to the 2nd Volunteer Battalion of the King's Liverpool Regiment, and in later life gave public service as a justice of the peace. His death will be regretted by a large circle in Liverpool.

Medical News.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The following demonstrations of specimens in the Museum will be given at 5 P.M. in the theatre of the College in Lincoln's Inn-fields. The demonstrations are open to advanced students and medical practitioners. On Oct. 19th Sir Arthur Keith will discuss problems in human anatomy which arise out of the identification of a skull attributed to Lord Darnley, showing illustrative specimens. On Oct. 26th he will trace the development, and on Nov. 2nd the evolution, of the human foot in relation to orthopædic disorders. On Oct. 22nd and 26th and Nov. 5th Mr. T. W. P. Lawrence will comment on surgical specimens.

POST-GRADUATE COURSES IN FRANCE.—A series of courses on the diagnosis and treatment of cancer will be held at Strasbourg from Oct. 16th–31st, under the direction of Prof. Gunsett, to whom application may be made at the Centre Anticancéreux, Hôpital Civil, Strasbourg, Alsace. Dr. C. Laubry has arranged a course on diseases of the heart and circulation and of the blood, to be given at the Hôpital Broussais, 96 rue Didot, Paris XVI., from Oct. 8th to 20th. Particulars may be had from Dr. Moussoir at the hospital.

University College Hospital Medical School. The winter session of this school will open on Monday, Oct. 1st, when an introductory address will be given in the Library, at 4.30 P.M., by Sir Thomas Barlow, F.R.S.

Westminster Hospital Medical School.—The annual dinner of past and present students will take place in the Royal Adelaide Galleries, Gatti's Restaurant, Strand, on Monday, Oct. 1st, at 7 P.M. for 7.30, Sir James Purves-Stewart in the chair.

Chelsea Clinical Society.—The annual dinner will take place at the Hotel Rembrandt, Thurloe-place, London, S.W., on Oct. 23rd, at 7.30 P.M. Those intending to be present are requested to communicate with Mr. L. A. Harwood, 90, Sloane-street, London, S.W. 1, as early as possible.

Cancer Campaign in the North.—The campaign against cancer in Lancashire, Cheshire, and North Wales will now be resumed energetically, and the Council hopes that before the end of the year the sum of £200,000 will have been collected in this area, another £90,000 being required to this end.

St. Bartholomew's Hospital, Rochester.—The inadequate pathological department of this institution has been removed to an adapted water-tower, formerly part of a brewery, at the back of the buildings. St. Bartholomew's was the first general hospital in Kent to possess such a department. The staff deal with some 6000 cases per annum.

Extension of Rugby Hospital.—A new out-patient department and casualty wards are being erected at Rugby Hospital. Mrs. Arthur James, who recently laid the foundation-stone, has contributed £8000 towards the cost, as a memorial of her late husband. The penny-in-the-pound scheme in aid of this hospital, which was started only two years ago, has 11,400 contributors.

Blackpool Victoria Hospital.—The board of management have decided to build an entirely new hospital of 150 beds on a fresh site at a cost of about £100,000. The existing buildings are officially described as "absolutely out of date." The children's ward is a temporary wooden building, there are no separate medical and surgical wards, the nurses live away from the hospital, an annexe of 20 beds is separate from the other buildings, the administrative block is "totally inadequate," and the out-patient department is "unsatisfactory."

German Congress of Urology.—The eighth annual session of the Deutsche Gesellschaft für Urologie takes place at the Langenbeck-Virchow-Haus in Berlin from Wednesday, Sept. 26th, to Saturday, the 29th, under the presidency of Prof. Alex. v. Lichtenberg (Berlin). At the opening sitting on Wednesday Prof. C. Posner (Berlin) will deliver an oration on Max Nitze in memory of the jubilee of the invention of the cystoscope. On the same day Dr. Viktor Blum (Vienna) will open a discussion on hypertrophy of the prostate and diverticula of the bladder, and Dr. Rudolf Paschkis (Vienna) on chronic non-specific ulcers of the bladder. On Thursday will come up for discussion the pathology and treatment of malformations of the kidney and ureter, on Friday strictures of the urinary passages, and on Saturday the relations of urology to social legislation. There will be an exhibition of instruments, apparatus, and books during the Congress. Further information from Dr. Arthur Lewin, Berlin, W.50, Tauentzienstrasse 13.

Post-graduate Studies in Manchester.—Post-graduate work for the coming year in Manchester will follow the lines of previous years. Besides the teaching which leads to diplomas in special subjects, such as public health and psychological medicine, the University is undertaking set courses in special subjects. A whole-time intensive course in general medicine and surgery is at present in progress and will be followed by a short similar course in obstetrics and gynæcology, beginning on Sept. 29th. Part-time courses in ophthalmology will start in October, and in radiological work, diseases of the skin, and clinical pathology in the new year. Clinical assistantships are obtainable at several of the general and special hospitals. The hospitals also give courses in different parts of the year. The first part of the Royal Infirmary course lasts from Sept. 25th to Dec. 11th, and consists of individual lectures on independent subjects. The lectures are on Tuesday and Friday afternoons. On Oct. 23rd Sir Berkeley Moynihan will give the Lloyd Roberts lecture, his subject being Some Problems in Gastric Surgery. At Ancoats Hospital short courses will be given on Thursday afternoons on the sympathetic nervous system, minor operations on the ear, nose and throat, and on advances in antiseptics.

Dr. Kinnier Wilson has been made an honorary corresponding member of the Gesellschaft Deutscher Nervenärzte.

New Hospital at Bakewell.—On Sept. 11th the Duke of Devonshire opened a new infectious diseases hospital at Bakewell, Derbyshire, which will meet the needs of six urban districts and one rural district. The hospital cost £9500 and includes three blocks of buildings.

Dudley Guest Hospital.—This hospital is about to be enlarged from 104 to 185 beds. The existing buildings are, to a certain extent, to be modernised, and the additions will include two ward units of two storeys each and eight single-bed observation wards.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.
  Monday, Sept. 24th to Saturday, Sept. 29th.—Royal Free Hospital, Gray's Inn-road, W.C. Course in Electro-Therapy by Dr. C. B. Heald. Four lecture-demonstrations on successive Wednesdays at 5.15 P.M. Westminster Hospital, S.W.—Special post-graduate Course in Medicine, Surgery and the Specialties. All day course.—Royal Eye Hospital, St. George's-circus, S.E.—Every afternoon. Course in Ophthalmology.
ROYAL NORTHERN HOSPITAL, Holloway-road, N.
  Tuesday, Sept. 25th.—3.15 P.M., Dr. E. H. Shaw: Demonstration of Immediate Microscopic Examination of Tumours.
CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.
  Monday, Sept. 24th.—1.30 P.M.: Hearing Tests.
  Wednesday.—1.30 P.M.: Examination of the Sinuses.
MANCHESTER ROYAL INFIRMARY.
  Tuesday, Sept. 25th.—4.15 P.M.: Mr. W. R. Douglas: Demonstration of Surgical Cases.
  Friday.—4.15 P.M.: Dr. P. B. Mumford: Some Problems in the Diagnosis and Treatment of Syphilis.

Appointments.

Barker, H. L., L.R.C.P. Lond., M.R.C.S., D.P.H., has been appointed Medical Officer of Health, Ilkeston.
Challans, F., M.D. Lond., Regional Medical Officer for the Ministry of Health in Devon, Cornwall, and Somerset.
Jones, E. H., M.D., C.M. Edin., Medical Officer of the Rhyl Medical Relief District of the St. Asaph Union.
Kennedy, A. D., M.D. Glasg., to be a Medical Referee under the Workmen's Compensation Act for Wick in the Sheriffdom of Caithness, Orkney, and Shetland.
Strachan, C. H., M.B., Ch.B. Aberd., Resident House Surgeon, *Batley Hospital.*
Certifying Surgeons under the Factory and Workshop Acts: Farrer, R. T., M.R.C.S. Eng., L.S.A. (Brighthouse, W. Riding); Mair, W. B. G., M.B., Ch.B. Glasg. (Carnwath); Roche, G. D., L.R.C.P. & S. Edin., L.R.F.P.S. Glasg. (Scalloway, Shetland); and Waterhouse, A. R. (Wirksworth).

Vacancies.

For further information refer to the advertisement columns.

Belgrave Hospital for Children, 1, Clapham-road, S.W.—H.S. Also Asst. H.P. Each at rate of £100.
Birmingham General Hospital.—Asst. S. £50.
Bridgetown, Barbados General Hospital, B.W.I.—Sen. Res. S. £300.
Brighton, Royal Alexandra Hospital for Sick Children.—H.P. £100.
British Medical Association, Tavistock-square, W.C.—Librarian. £400.
British Social Hygiene Council, Carteret House, Carteret-street, S.W.—Medical Secretary. £400.
Burnley, Victoria Hospital.—H.P. At rate of £125.
Cambridge, Addenbrooke's Hospital.—H.S. At rate of £130.
Carlisle, Cumberland Infirmary.—H.S. to Special Depts. At rate of £155.
Evelina Hospital for Children, Southwark, S.E.—H.P. At rate of £120. Also Hon. Asst. Aural Surg.
Exeter, Royal Devon and Exeter Hospital.—H.P. At rate of £130.
Gloucestershire County Council.—M.O. for Maternity and Child Welfare. £750.
Gloucester, Gloucestershire Royal Infirmary, &c.—H.P. At rate of £150.

Greenwich Metropolitan Borough.—M.O. for Maternity and Child Welfare Work. £600.

Guildford, Royal Surrey County Hospital.—H.S. £150.

Hospital for Sick Children, Great Ormond-street, W.C.—H.S. Also H.P. Each at rate of £100. Also Part-Time Jun. Cas. O. At rate of £150.

Hospital of St. John and St. Elizabeth, 60, Grove End-road, W.—Res. H.S. At rate of £75.

Huddersfield Royal Infirmary.—Pathologist. £750.

Infants Hospital, Vincent-square, Westminster.—Med. Reg. £120.

Jersey General Hospital and Poor-law Infirmary.—Res. M.O. £200.

Leeds, St. James' Hospital.—H.P. and S. £200.

Liverpool, Eye and Ear Infirmary, Myrtle-street.—H.S. £100. Also Hon. Asst. Surgeon to Ear, Nose and Throat Department.

Liverpool Sanatorium, Delamere Forest, Frodsham.—Asst. to Med. Supt. £250.

London Hospital, E.—First Asst. and Registrar to one of the five Surgical Firms. £300.

London Temperance Hospital, Hampstead-road, N.W.—Res. M.O. At rate of £175. Cas. O. At rate of £120. Also H.P. At rate of £100.

Macclesfield G [illegible] 180.

Macclesfield, [illegible] Clin. Asst. £75.

Maidstone, K [illegible] st. M.O. £300.

Manchester, [illegible] £600.

Mauritius, P [illegible]

Metropolitan Ear, Nose and Throat Hospital, 2, Fitzroy-square, W. Anæsthetist.

Middlesex Hospital, W., Feren's Institute of Oto-Laryngology.—Bernhard Baron Research Scholarship. £300.

National Hospital, Queen-square, W.C.—Asst. P.

Norwich, Norfolk and Norwich Hospital.—H.S. and Cas. O. Each £120.

Nuneaton Borough.—Asst. M.O.H. £600.

Prince of Wales's General Hospital, Tottenham, N.—H.S., Special H.S., and H.P. Each at rate of £120. Also Jun. H.S. and Jun. H.P. Each at rate of £90.

Public Dispensary, 122, Drury-lane, W.C.—Res. M.O. £120.

Queen's Hospital for Children, Hackney-road, E.—Physician-in-Charge Skin Department.

Royal [illegible] *Mall East.*—Milroy Lecturer.

Royal [illegible] *Circus, S.E.*—Clinical Assistants.

Royal [illegible] *-road, W.C.*—Cas. O. £150.

St. M [illegible] *&c., City-road, E.C.*—H.S. At ra[illegible]

Samaritan Free Hospital for Women, Marylebone-road, N.W.—Hon. S. to Out-patients.

Southampton, Borough Isolation Hospital.—Res. M.O. £360.

Southern Rhodesia Medical Service.—Govt. M.O. £500 to £600.

Swansea Hospital.—Two H.S.'s. £150.

Warrington, County Mental Hospital, Winwick.—Asst. M.O. £350.

Willesden General Hospital, Harlesden, N.W.—Res. H.S. At rate of £100.

The Chief Inspector of Factories announces a vacancy for a Certifying Factory Surgeon at Pangbourne (Berks.).

Births, Marriages, and Deaths.

BIRTHS.

Brooke.—On Sept. 13th, the wife of Ralph Brooke, M.B., F.R.C.S., of a daughter.

Cameron.—On Sept. 12th, in a nursing home, Belfast, the wife of Captain W. Moore Cameron, O.B.E., R.A.M.C., of a son.

Corner.—On Sept. 8th, in a nursing home, Bournemouth, the wife of Dr. H. W. Corner, of a daughter.

Gaussen.—On Sept. 7th, in a nursing home, Herne Bay, the wife of Surgeon Lieut.-Commander J. F. H. Gaussen, M.B., R.N., of a daughter.

Hardie.—On Sept. 11th, at King-street, Great Yarmouth, the wife of Ronald W. W. Hardie, M.B., Ch.B., of a daughter.

Liston.—On Sept. 15th, at Milner-street, Cadogan-square, S.W., the wife of Dr. R. Prosper Liston, of a son.

Porter.—On Sept. 13th, at Kidderminster, the wife of Dr. C. Petvin Porter, of a daughter.

MARRIAGES.

Lawrence—Batson.—On Sept. 7th, at Holy Trinity Church, Brompton, Robert Daniel Lawrence, M.D., to Doreen Nancy (Anne), only daughter of Mr. and Mrs. T. Batson, Overstrand-mansions, Battersea, S.W.

Murphy—Murphy.—On Sept. 1st, at Brompton Oratory, Major Denys Murphy, *M.C.*, F.R.C.S., I.M.S., to Vera, elder daughter of Mrs. Murphy, Greenleaze, Knowle, Bristol.

DEATHS.

Campbell.—On Sept. 13th, at his residence, Shrewsbury-road, Birkenhead, William Macfie Campbell, M.D., J.P., late of Liverpool, in his 80th year.

Edgelow.—On Sept. 14th, at Braddon Villa, Torquay, William Ford Edgelow, M.D., aged 75.

Forbes.—On Sept. 17th, at Cuminestown Turriff, Aberdeenshire, Hugh McGregor Forbes, L.R.C.S., L.R.C.P. Edin.

Perkins.—On Sept. 13th, Joseph John Perkins, M.A., M.B. Camb., F.R.C.P. Lond., aged 65.

Phillipps.—On Sept. 12th, suddenly at Seafield, Paignton, William Alfred Phillipps, M.D.

Wyndham.—On Sept. 7th, in London, Thomas Lancelot Wyndham, L.R.C.S. & P. Edin., aged 54.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE INFLUENCE OF INDUSTRIAL POISONS UPON THE DIFFERENT ORGANS.*

By Sir Thomas Oliver, M.D., F.R.C.P.

When a poison has been absorbed and has circulated in the blood, it might be expected that the whole body would more or less suffer simultaneously, but experience shows that certain organs and tissues exercise a selective influence upon some poisons and not upon others. A distinction must be made between acute and chronic forms of industrial poisoning. There is the opinion that those tissues of the body which are the last to be developed, and therefore the more delicately organised, are less resistant, hence the rapidity of the effects of alcohol upon the higher nerve centres in the brain. While the nervous system is not free from the harmful influences of lead, many research workers regard the blood and the hæmopoietic system as the anatomical elements earliest affected by lead, those bodily units, in fact, which are formed and function in the early stages of embryonic development, and which therefore ought to be the most stable. It is an interesting circumstance that while the blood and blood-making organs are readily influenced by lead, yet in the blood very little of the metal is found, even while the internal organs may contain it in considerable quantity. Although the blood may show physical and chemical changes due to the influence of lead, it has only slight retentive power upon the metal, possibly because the blood is ever changing and therefore rejuvenating itself, its corpuscles are short-lived, also that it is constantly eliminating the poison, while in the tissues generally, physico-chemical changes are less rapid, and there is therefore given greater opportunity for the metal to become more firmly linked to the cellular constituents.

The types of industrial poisoning which have the greatest interest for us are those where the amount of toxin received daily into the system is small, where elimination almost equals absorption, and where therefore poisoning is slowly induced. In many of these cases, symptoms of toxæmia may not arise for several years; so slowly, in fact, do the symptoms appear that the individual is not aware of his condition until some change occurs in his metabolism or he is attacked by some minor ailment.

Lead.

It is now several years since I remarked upon the storage of lead in a rather insoluble form in the body, also upon the absence of symptoms, until there have occurred chemical changes in the liquor sanguinis and the fluids bathing the tissues, whereby the deposited lead becomes soluble, thus favouring its reabsorption into the circulation. To this subject and the early harmful effects of lead upon the blood, Aub and his co-workers in Harvard University have given close attention, as also have Kehoe and Thamann, of the University of Cincinatti, and P. Schmidt, of Halle, who hold, like many other physicians, that, by a microscopical examination of the blood of lead-workers, plumbism may be detected before symptoms develop, and when, therefore, it is possible for further trouble to be averted. The relation of the blood to poisons passing through it are of a two-fold character; the blood may be little affected or physico-chemical changes are induced in it which affect its efficiency as an oxygenating and nutritive medium.

So far I have dealt mainly with lead, principally because, apart from iron and steel, lead is the metal which is most widely used in the industries, also because it has been the occasion of much ill-health among the workers. Most of its salts, too, have the power of precipitating proteins, as observed on mucous membranes, thereby exercising a protective influence compared with the corrosive effects produced by several other industrial poisons. Absorption of the metal is slow, so that time and opportunity are given for lengthened reaction to take place between the poison and the animal tissues.

Industrially, lead poisoning is seldom acute. When large doses of lead acetate have been swallowed by a healthy person, the symptoms which follow are less the result of absorption of the metal, than of the local effects of the lead compound upon the stomach and intestine. The intravenous injection of a neutral lead salt precipitates the proteins of the blood and may cause embolism. Harnack found in injecting lead-triethyl into the veins of animals that it became decomposed in the tissues and gave rise to symptoms of plumbism. Lead intravenously introduced into dogs causes paresis and paralysis, diarrhœa, colic, tremors, and convulsions. Harnack considered the diarrhœa to be the result of violent contraction of the intestinal wall, and that this persisted even when no peristaltic wave was passing. In my own experiments I found, after death, discontinuous portions of the small intestine, over lengths of 3 or 4 in., so firmly contracted as to have obliterated the intestinal canal, and which appeared to me to have been rather the cause and explanation of the colic.

---

* Abridged from an address delivered to the Fifth International Congress for Industrial Accidents and Occupations in Budapest on Sept. 3rd, 1928.

In order to ascertain the effects of lead upon the heart and blood pressure, Sir Robert Bolam and myself carried out a series of experiments in which we introduced a solution of a lead salt directly into the blood stream. Our experiments showed that the result of injections of lead in animals was a general fall of the blood pressure.

There is a general opinion that workers in the lead industries in course of time develop structural changes in their arteries and have a high blood pressure. The numerous deaths among them from cerebral hæmorrhage lend weight to this supposition (but as the kidneys are prone to become diseased, inefficiency of these organs as a contributory cause cannot be ignored). We cannot quite place patients in whom symptoms of plumbism appear early in the same category with those who are the subjects of chronic plumbism, for in the latter structural changes have probably developed in the internal organs. One dose alone of lead hardly ever gives rise to symptoms, but if small quantities are repeatedly passed into the system through the alimentary canal or the lungs, chronic plumbism develops, indicating that absorption has taken place, and that possibly some of the lead may have become locked up in the tissues and from which it will be only slowly eliminated. The internal organs in which, after death, the metal is found are the liver, kidneys, brain, and bones. Lead is eliminated by the kidneys, the intestinal epithelium, the mammary secretion, and the saliva. Any effect, therefore, produced by lead is not so much due to the amount of the poison circulating in the blood at a particular time, nor to its deposition in the tissues, but, as Straub suggested, to the summation of the injuries inflicted by its recurrent presence in the blood in infinitesimal quantities.

Arsenic.

In Great Britain, since harmless pigments have replaced those containing arsenic in wall-papers and paints, industrial arsenical poisoning has considerably declined. In 1900 there were reported to the Home Office 22 cases of industrial poisoning due to arsenic, with three deaths; in 1926, five cases with three deaths; and in 1927, three cases with one death. Pure arsenic is insoluble in water, so that if swallowed it passes through the gastro-intestinal canal practically unchanged, although very minute portions might be converted into arsenious acid in the stomach and intestines. The symptoms caused by its compounds are less due to the metal itself than to the ions of arsenious acid, which if swallowed in fairly large doses cause violent abdominal pain, vomiting, and watery diarrhœa, muscular cramps, feeble pulse, coma, and death. It matters little the channel by which arsenic gains entrance into the body for the same gastro-intestinal events arise, showing that the mucous membrane of the alimentary tract is the medium whereby it is eliminated, although the metal may be found in the hair and also be a cause of pigmentation of the skin, as has been observed in chorea patients treated by increasing doses of liquor arsenicalis. Taken in medium doses over a varying length of time, it produces peripheral neuritis; an epidemic occurred in England a few years ago in beer-drinkers, the poison being traced to the glucose in beer which was obtained by sulphuric acid methods from iron pyrites containing arsenic. Yet, even to such a dangerous metal as arsenic, tolerance can be established by taking graduated quantities, as was shown a few years ago by the arsenic-eating peasantry of Styria and the Tyrol. These hill-men, swallowing arsenic in small but increasing doses, stated that it enabled them to climb the mountains with less effort, and that it improved their respiratory powers, while their women-folk believed that it improved their complexion. The practice did not appear to exercise any harmful influence, for these people lived to a great age without exhibiting any signs of ill-health.

The worst effects of arsenic as an industrial poison which I have seen have been not so much upon the internal organs as upon the skin. This was especially so upon the hands and fingers, also upon the external reproductive organs of men engaged in mixing colours, of which Scheele's green formed a large constituent. The skin of the fingers and hands was ulcerated, often down to the bone; the ulcers were angry-looking and painful.

The presence of arsenic in soot is regarded as the cause of chimney-sweep's cancer, also of malignant growths upon the hands of gardeners who use soot for potting and other purposes.

Arseniuretted hydrogen, when inhaled, rapidly induces sickness and vomiting, followed several hours afterwards by jaundice and hæmoglobinuria or hæmaturia. The breaking-down of the red blood corpuscles is so complete that the hæmoglobin becomes incapable of carrying on its respiratory function, while the liver and kidneys are severely taxed in regard to the elimination of the disintegrated products.

Mercury.

In the industries subacute and chronic forms of mercurial poisoning may be met with. Of the organs primarily affected in the less acute forms of poisoning the salivary glands call for mention. They are stimulated to great activity, the gums are swollen, the teeth loose, the breath fetid, and on the buccal mucous membrane small ulcers may be observed. The submaxillary glands become enlarged, mastication is difficult and painful, there are diarrhœa and loss of appetite, followed by pains in joints and limbs. To the psychical troubles, of which a sense of timidity and loss of self-control before strangers are noticeable features, the term *Erithismus mercurialis* has been applied. Voluntary muscular movement becomes inhibited. In addition to the inordinate flow of saliva, there are muscular tremors, at first mainly of the muscles of the face and hands, but if the individual continues to follow his occupation the tremors become general and render the individual helpless. In the company of Dr. Giglioli, of Turin, I had the opportunity a few years ago of visiting the mercury mines on Mont Amiata, and of witnessing some unusual signs and symptoms. Several of the men were so much affected through inhaling the fumes of the metal that, if during the act of walking, and this generally with a staggering gait, they were called upon suddenly to stop, they could not immediately arrest their progress. In attempting to do so they were either precipitated forwards or swayed excitedly forward and backwards. There might be no tremor observable when the body was at rest, but tremors became immediately apparent, equal in range to those observed in disseminated sclerosis, when slight effort was made. So violent may the movements subsequently become, or so extreme the muscular paresis or paralysis, that many of the affected smelters are ultimately rendered completely helpless; they can neither feed nor dress themselves. Workers in mercurial compounds not infrequently have albuminuria. With their swollen gums, fetid breath, and muscular tremors, the men present a broken-down appearance and have an unhealthy, sallow look.

Phosphorus.

As far back as 1870 the sufferings of lucifer match-makers had attracted public attention. In 1872 Finland, in 1874 Denmark, in 1897 France, in 1898 Switzerland, and in 1901 the Netherlands had prohibited the use of white phosphorus, but the regulations had not the desired effect, nor was any united and organised effort made to secure this object until Switzerland, in 1906, invited the various countries to attend a meeting in Berne, known as the Berne Convention, and at which the countries represented unanimously agreed to the prohibition of the dangerous metalloid. French chemists had found in sesquisulphide of phosphorus a safe substitute for the dangerous form, and wherever it has been used phosphorus necrosis has disappeared as an industrial disease. To France, therefore, belongs the credit of having made possible the replacement of a harmful by a harmless chemical agent in this important industry. It was not, however, until 1919 that India and Japan joined the Convention, but even as late as 1923 China had not done so. In 1925, according to the *China Journal of Science and Arts* of February and March of that year, there were 15,000 persons employed in lucifer match factories using white phosphorus. In January, 1925, China definitely prohibited the use of the harmful material, so that with her entrance into the Berne Convention there is now the probability of the disappearance of a painful occupational malady in the Far East.

Radio-active Substances and the Health of the Workers.

Three years ago my attention was drawn by Dr. F. L. Hoffman to the occurrence of necrosis of the jaw-bone and of aplastic anæmia in young women engaged in painting numerals on illuminated watch and clock dials. There had occurred six deaths and there had been reported seven cases of serious disease.[2] Radium salts formed the basis of the luminous material: one of the manufacturing firms used mesothorium. In painting the numerals on the dials the girls were in the habit of pointing with their lips the camel's hair brushes, and although each of the workers was given a bottle of distilled water in which to wash the brush before putting it between the lips, they disregarded the provision. The girls had followed the occupation for three years or more. Exposure to large amounts of radio-active material is followed by changes in the blood of the workers, microscopical examination revealing a reduction in the number of polymorphonuclear and lymphatic corpuscles. The leucopenia is pronounced. There is also a degree of anæmia suggesting a diminished output of red blood corpuscles from the bone-marrow. The colour-index, however, remains high. Many of the women in this occupation complained of headache, malaise, tiredness, and a sense of the need of more sleep, nervous irritability, and disordered menstruation, but the morbid condition which specially attracted attention was necrosis of the jaw-bone. For information of these cases we are indebted to a report furnished by Dr. Cecil K. Drinker, Dr. Martland, and others. The necrosis closely resembles the diseased bone found in phosphorus poisoning. An interesting point in regard to exposure to radio-active compounds is that the disease which develops may lie latent for a few years before showing its destructive effects upon the teeth and jaw-bone. From the outset these agents affect the blood and blood-making organs; in small doses they temporarily increase the numbers of red and white corpuscles of the blood, and this increase is followed, if the exposure continues, by a destruction of the white and by a diminished production of the red corpuscles, hence the consequent anæmia. In September, 1927, I examined in New Jersey five of these women dial painters; three of them could hardly walk or sit on a chair, except in a slanting position with limbs fully extended. Osteitis and strong adhesive fibrositis of the hip-joints prevented abduction of the limbs. In some of the women small areas of exposed portions of the lower jaw-bone could be seen and felt in the mouth.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

THE Seventy-third Annual Exhibition of the work of this Society's members now being held at 35, Russell-square, London, W.C., shows vividly the degree of perfection which photography, both utilitarian and artistic, has attained. Colour photography has made great strides and many fine stereoscopic colour transparencies were on view; on the scientific side it is of great value in many fields. Several spectra of salts, glass and other substances photographed by polarised light illustrated the diacritical value of this method, which also serves to check the quality of artificial sunlight. One interesting use of monochrome photography is to test the efficiency and freedom from glare of motor-car headlights, and the general Motors Corporation exhibited an excellent series of photographs to show how this was done. Eastmans displayed their Panchromatic film and Wratten light filters, which immensely facilitate the reproduction of many coloured objects, such as paintings. Of especial medical interest was a fine series of X ray photographs by Kodak Ltd. and Ilford Ltd.; among others taken by Dr. J. H. Mather, one illustrated a gall-bladder after the oral administration of sodium tetraiodo-phenolphthalein. The life-history and minute structure of the green-house fly was depicted in five frames of microphotographs by Dr. G. H. Rodman. In addition to pictures many cameras and pieces of apparatus were on view. The exhibition remains open until Oct. 13th.

NEGLECT OF VACCINATION IN IRELAND.

FROM recent reports in the local press it would seem that, notwithstanding pressure from the authorities, there is still a good deal of opposition to vaccination in some areas in Ireland. At a recent meeting of the Fermoy (co. Cork) Urban District Council a letter was read from the Department of Local Government and Public Health stating that unless the Council took the necessary steps to make sure of compliance with the Vaccination Acts, the Minister would have no option but to institute proceedings to compel the Council to perform its legal duties. When the list of defaulting parents was read out, it was noticed that it contained the names of the chairman of the Council and of at least one other member. At Enniscorthy, co. Wexford, the urban council was directed by the Minister to institute legal proceedings against those who did not comply within a reasonable time after notices to carry out vaccination had been served on them. No action was taken, the chairman declaring that the serving of notices was as far as the Council could go.

PTERYGIUM IN MADEIRA.

THE origin of the peculiar encroachment of the conjunctiva on the cornea known as pterygium is still something of a mystery, some doubt having been thrown on Fuchs's plausible explanation that it is a further stage of pinguicula, but the circumstances under which it arises are fairly well known. Rare in England, it is common in dry climates with sandy soils, and among farmers, threshers, ranchmen, and others exposed to the elements. In the United States it is much more frequent in the south-western than in other areas; heat, dryness, wind, and exposure to sunlight and alkaline dust are there regarded as predisposing causes. Coming nearer home, the island of Madeira has been mentioned as a place where the condition is endemic; this is twice affirmed in the French encyclopædia of ophthalmology published under the auspices of Lagrange and Valude. Dr. Alfredo Rodrigues read a paper before the Third National Congress of Medicine, held at Lisbon recently, to controvert this statement. Pterygium, he admits, does occur in Madeira, where the hygienic conditions are neither better nor worse than in other marine resorts, but in his experience it amounts to less than 15 per cent. of all ocular affections met with on the island. This is much less than the frequency quoted by an English doctor, Heineken, a hundred years ago. The influence of high insolation may be present in Madeira, but the factors of high wind and dust are not. The town of Funchal itself is situated in a sheltered amphitheatre of mountains, and even the sun's rays are tempered by the nebulous atmosphere of the gulf stream.

SWORD-SWALLOWING.

AN advertisement in the personal columns of the *Times* of Sept. 12th for a sword-swallower "required to assist doctor in experiments" is a reminder that sword-swallowing has its dangers, although there may be few cases on record in which it has led to the death of the performer. Gross perforations of the œsophagus are, of course, uncommon, but considerable damage may be done by minor injuries. In 1885 Dr. Charles Gross reported the case of a man, aged 30, who conjured in public-houses as a recreation. Two days before admission the sword hurt him more than usually, and on withdrawing it he spat a little blood. His neck began to swell and swallowing became more difficult and painful, until he died suddenly three days after admission to hospital. Post mortem, there was no sign of any perforating wound, though a little excoriation was to be seen at the upper and posterior part, but the outermost coat of the œsophagus and the surrounding tissues were a diffused abscess extending from the back of the pharynx to the diaphragm. The news of this man's death induced two other sword-swallowers to consult Dr. Gross about the dangers of their curious profession. They were both in the habit of swallowing swords 21½ inches long, the blade tapering from 1¼ to 1 inch, straight, heavy, thick, smooth, with well rounded edges and point. They gave a demonstration which he described thus: "Straightening the passage by well elevating the chin, then putting the point of the sword well to the back of the throat, with one thrust they pushed it down as far as the hilt." Both of these experts acknowledged that they frequently hurt themselves, and one of them had been in St. Thomas's Hospital with an injury to the œsophagus, apparently a lesion of the mucous coat of the lower part.

PLASMOQUINE IN MALARIA: A CORRECTION.

IN Dr. Manson-Bahr's paper on the Therapeutic Action of Plasmoquine, published in our issue of Sept. 8th (p. 496), the statement is made, under the heading "For Benign Tertian and Quartan Malaria" that "treatment should extend over a further 44 days, composed of four separate weeks' treatment (making five weeks in all) of *12* tablets of plasmoquine compound daily with four days' interval between each week." In this sentence the figure 12, which we have italicised, should read 6.

UNEQUAL PUPILS.

M.R.C.S. writes: For years I have been in the habit of shaving in my bath, but have only recently taken to using a mirror. Since doing so I have noticed that my pupils, equal before I begin, become unequal during the act of shaving—the left much larger than the right. Within half an hour they return to equality. I am told I am physically sound and have no aneurysm. I have no explanation to offer, other than a very localised fear reflex due to performing a risky operation whilst on an insecure foundation. I should be interested to hear what other explanations occur to your readers.

MEDAL FOR A MEDICAL MAN.—Dr. J. H. Sheldon, of Wolverhampton, has been awarded a bronze medal by the French Government for courageous rescue work on the Aiguille du Petit Dru in the Alps.

A WOODEN HOSPITAL BURNED.—About one-half of Driffield Isolation Hospital, which consisted chiefly of wooden hutments of the army pattern, has been burned down. The fire was caused by a rubber mat hanging on a bathroom wall falling upon a lighted gas ring, and spread so rapidly that in five minutes all the wards were in flames. Of the 60 beds only 18 were occupied by patients, suffering from scarlet fever, typhoid, and diphtheria, and they were all safely removed to a new brick block which had just been completed. It will be remembered that it was only at the end of April last that two wards at the King Edward VII. Hospital at Windsor were burned.

Lettsomian Lectures
ON
RHEUMATIC HEART DISEASE IN CHILDHOOD.

Delivered before the Medical Society of London

By F. JOHN POYNTON, M.D., F.R.C.P. Lond.,
PHYSICIAN TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET; PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL.

LECTURE III.*

Delivered on March 7th, 1928.

The first general principle in the treatment of heart disease in the child is that rheumatic disease of the heart is only one manifestation of a general disease, and the problem is not a purely cardiac question. Success must turn on a general knowledge of acute rheumatism. The second is that as far as possible convalescent treatment should be linked up with well-known central hospitals whenever the private practitioner is not in a position to take their place. There will be a great loss of purpose if a heavy drift takes place towards isolated convalescent homes. The third is that, without interfering overmuch with the liberty of the subject, increasing organisation should give all cardiac cases after childhood careful supervision in the factory, the large business-house, or elsewhere. I hold that we possess no drug or other treatment which has a specific action upon rheumatic morbus cordis, though I do not expect general agreement with this view. Lastly, we must realise that our problem at the moment is very much more than the prevention of rheumatism and rheumatic heart disease, for it includes the amelioration of the latter. In the present state of our knowledge we have not failed when a child has developed organic disease of the heart, but we fail if we do not exert all our resources to secure for the child a full convalescence and do not make every effort to prevent further attacks and to indicate reasonable occupations for later life. The problem, in general, resembles that of tuberculosis, but there is more encouragement, because at puberty the incidence of heart disease in rheumatism tends to diminish. There must be further laboratory and clinical research, for we cannot cease from efforts to decide the exciting cause, from arriving at decisions upon the nature and frequency of predisposing causes, and from investigations into a more successful medicinal treatment.

Predisposing Causes.

There is much interesting work in progress upon the predisposing causes of acute rheumatism, and many differing views upon their relative importance. One point which I would emphasise is that acute rheumatism is particularly likely to follow when a spell of dry warm weather changes to cold winds and wet. It is not the dry weather, or the wet, upon which I lay the great stress; it is the sudden atmospheric change. Dry weather tends to dust formation and sore-throats in the large towns, and sudden cold and wet, in my experience, develop the rheumatic infection.

A good deal of attention has been directed to the infrequency of acute rheumatism in the well-to-do, but it is only a relative infrequency, for I have seen the disease occur severely in prosperous families. Again, it has been pointed out that it is not the poorest in the social scale who suffer, but those who are not actually necessitous. To explain this I fall back on my view that nervous tension is an important predisposing factor, and I believe that this is a salient feature in that particular class of life. These children often come from small families and have parents who feel the full stress of keeping a position above the fringe of careless poverty. The children are anxious to shine at school and at home, and do not possess the stolidity that many of the very poor show. I believe that damp, low-lying localities are harmful. I have never thought that damp localities or damp houses, or damp feet, are actual exciting causes, but they undermine the general health, and I am confident that the rheumatic child fares badly in such surroundings and that the rheumatism particularly tends to become intractable. I have seen too many examples to be disturbed by any statistics. I also believe that defective sanitation in a house is important as a predisposing cause.

The question of diet seems to me one which should be inquired into further in a large convalescent hospital. It has never attracted me as an important factor, and I have sometimes thought that it must be an echo from former days when gout was so much in the minds, and sometimes bodies, of our profession. Nevertheless a careful investigator, with an opportunity for prolonged inquiry, might well upset such a general impression and throw some light on this problem. For instance, Dr. Arbour Stephens has suggested that acute rheumatism is dependent upon a calcium deficiency. We certainly cannot allow any field to be unexplored in such a subject as acute rheumatism.

One statement that seems to me true, though I know it has been doubted, is that chorea is much more frequent in the elementary than in other schools. Chorea is a nervous manifestation of acute rheumatism frequently associated with heart disease, and we must strive to explain this frequency.

Our climate is in accord with the disease, for it is very variable and shows many manifestations, and its vagaries recur year in, year out. Local epidemics of acute rheumatism are very interesting and require further investigation. I have never been in the position to investigate the accurate details, but we shall now be on the watch for them and may learn some new facts. The disease is undoubtedly more frequent and more severe in some years than in others.

Methods of Invasion of Exciting Cause.

If we do not know the exciting cause, how can we detect its path of entry into the body? We do know that streptococci from inflamed tonsils will produce heart disease on experimental injection into the veins of animals, and that in children, particularly the very young, heart disease may sometimes follow a tonsillitis as dramatically as in an animal. I have also seen it follow immediately upon the old operation for guillotining tonsils and after enucleation.

Recently a girl was under my care in hospital for an attack of rheumatism with mitral endocarditis following tonsillitis, and the tonsils were obviously unhealthy. She made a good recovery. It is my rule to allow such cases to make a prolonged convalescence before operation, so three months later, after a change into the country, the tonsils were enucleated by a master hand. A fortnight later she was readmitted with severe pericarditis and eventually left hospital a cardiac invalid.

Another striking case came under my notice in June, 1926.

A school-girl, aged 13, who had suffered from a sore-throat and had enlarged tonsils and an attack of acute rheumatism with mitral disease, made a good recovery. Three weeks later the tonsils were enucleated, and three days after this the temperature rose and she rapidly developed a dangerous carditis with pericarditis which was almost fatal.

Incidentally, I think this case was a striking support of the streptococcal theory of the disease, for it began on the third day, which in our experimental experience was a frequent event with a virulent culture, and it reproduced precisely the events which happen when a rabbit is infected by injection. It is my belief that in such a case the child is directly inoculated with the micrococci through the raw surfaces caused by operation at a time when the susceptibility to infection is still high, for we must admit that, though a child may appear to have recovered from an attack of rheumatism, we are still ignorant of the completeness of recovery.

---

* Lectures I. and II. appeared in The Lancet of Sept. 15th and 22nd respectively.

A rather remarkable case was that of an only child, with acute pericarditis and aortic and mitral endocarditis, a clear history of sore-throat, and large unhealthy tonsils. This boy had repeated attacks of fever and tonsillitis while in hospital, but he was so ill that I was afraid to advise operation, and repeatedly delayed. Eventually he was taken from the hospital by his parents.

It seems clear, from experiment, that the tonsils must destroy infection when they are healthy, but the difficulty is to ascertain when they cease to act as a protection and become a danger. The only solution that I can see will be from collective experience, based upon the observations of many careful investigators extending over a considerable period of time. So far, I think the balance is in favour of the opinion that the removal of unhealthy tonsils by enucleation tends to diminish the frequency and severity of further attacks, even if it does not prevent them. Dr. R. Miller is of the opinion that chorea, a minor evil, rather than heart disease, is the most frequent manifestation when rheumatism again attacks a child after removal of the tonsils. There must soon be at our disposal a great mass of evidence on the number of cases of acute rheumatism and heart disease that develop in children who have had no obvious signs of the disease before their tonsils were removed. When this is published it will give us a much more definite basis upon which to build our views upon this most important question. Because removal of the tonsils does not prevent further attacks when once a child has become infected, it does not follow that removal would not have prevented the original attack altogether. Once infection has taken place, we are not yet in a position to say when it has been destroyed in the tissues of the body or where it may be hiding. If a child has had an attack of rheumatism with evidence of tonsillitis, has apparently recovered and the tonsils seem healthy, and the tonsillar glands are not enlarged at all, or only to a slight degree, ought we to advise their removal as a precautionary measure or not? If so, should we operate at the end of the acute illness or wait until the child has made a thorough convalescence? There is considerable difference of opinion upon these questions, and it is for this reason that I am anxious for evidence upon the occurrence of first attacks of rheumatism in children who have already had the tonsils enucleated; if this be frequent it must influence our procedure and make us cautious. I endeavour to judge each case individually, but the judgment, however well intentioned, may very easily be faulty because of the intrinsic difficulties. I do not think there is any practical problem in the prophylactic treatment of rheumatic heart disease that requires more immediate attention than the correct line to take with the tonsils; routine operation requires complete justification.

I have not been impressed with the origin of acute rheumatism from dental disease in childhood, and am not convinced of the frequency of an alimentary infection. Many rheumatic children, it is true, suffer from abdominal pains, chiefly epigastric; some suffer from colitis and some from acetonæmia, t these may all be the results of the established ase and not evidence of primary foci. There is rly room for further investigation upon these questions.

Medicinal Treatment.

The medicinal treatment of rheumatic heart disease introduces another question upon which I think we, as a profession, ought to arrive at some definite conclusion. Much has been written upon the specific action of salicylates in acute rheumatism, but if by specificity is meant the action of a drug which, if used skilfully, produces the clear-cut results of a true antidote, like quinine in malaria, then I am convinced that salicylates are not specific. In recent years I have abandoned their use in the most severe forms of carditis in childhood. In some respects I have had an almost unique experience of this drug, because I was working at Great Ormond-street on cardiac dilatation when the late Dr. D. B. Lees was carrying out his well-known investigations on the use of large doses of salicylate of soda for acute rheumatism. It was then that I saw examples of its toxic action, which led to the introduction of the well-known formula combining it with double the dose of bicarbonate of soda. In the Encyclopædia of Medicine, published in Edinburgh in 1902, I pointed out the severe depression, dangerous vomiting, and fatal coma that might result from large doses of this drug in childhood, and my observations were corroborated by Prof. F. Langmead. I am now only concerned with rheumatic heart disease in the young. The value of the researches of Dr. Lees upon the use of this drug in adult rheumatic arthritis has met with ample proof, and its value for the arthritis and pains in childhood is unquestionable. For many years I used the drug for rheumatic heart disease in acute cases, in chronic cases, and as a prophylactic, but to-day I am not prepared to say that it exerts any specific action, but am of opinion that it is a *dangerous drug when given in large doses to fragile rheumatic children*. It introduces into the severe cases of carditis difficulties such as vomiting, depression, pulmonary œdema, and even coma. The temperature certainly may be lowered, but fever is very rarely any real danger, and the most virulent cases of rheumatic carditis may be practically afebrile. The only unexpected death I have had in the last five years from rheumatic heart disease was that of a little girl admitted for slight mitral endocarditis. The temperature was obstinate but not high, and my house physician, with the very best intentions, gave salicylate of soda grs. 20 every four hours—not a large dose to the enthusiast. I saw the child three days later for vomiting which, in spite of all efforts, proved fatal. So great a hold, however, has this treatment on the minds of our profession, that it is most difficult to break through its tradition. There is no alternative treatment with any claim to the term specific, and if salicylates are specific, they should logically be pushed in the severe cases.

The Ethyl-ester of Methyl-phenyl Cinchoninic Acid.

Fortunately, I have found a cinchonic acid preparation, an ethyl-ester of methyl-phenyl cinchoninic acid called "tolysin," which has some definite action in rheumatism and which is admittedly less toxic than the salicylates. I do not for a moment hold that it is specific, but it has enabled me to treat the worst cases of carditis without the anxiety of drug complications, and has satisfied the sceptic that I have at least been attempting to treat the disease. My great object has been to find a treatment which would not complicate the difficult problem of the management of severe carditis. Not only have we often to treat very nervous children, but in addition to the dangers of carditis there may be arthritis, pleurisy with or without effusion, massive collapse of the lungs, broncho-pneumonia, and chorea. In very rare cases acute œdema of the lungs, beginning, like "renal œdema," at the apices, may occur. This I have only seen in four cases, all of which had been treated with salicylates, but the number is too small to incriminate the drug wth certainty. It is a most dangerous complication. though not always fatal.

For success in the treatment of such a perilous condition as severe carditis I consider it imperative to diminish any tax on the resources of the child, and there are two clear lines of guidance. One is never to attempt paracentesis *pericardii* unless absolutely assured that the quantity of exudation is the real danger; the other is to explore the pleura first if doubt exists whether the distress is the result of a left pleural effusion or a pericardial effusion. If we push drugs like digitalis or salicylates, which produce vomiting, we imperil our success, for careful feeding and the taking of nourishment are essential. To explore unnecessarily is to add to the dangers, but to calm and obtain sleep with small doses of nepenthe, and possibly some bromide, is invaluable. Tolysin has seemed to me, in small doses (grs. 5-7 every four hours), to improve the general condition, and certainly has never done harm.

Oeller in 1911 showed that the action of phenylcinchoninic acid was akin to that of the salicylates, but, as it also produced similar toxic effects, the tasteless and less toxic ethyl-ester was introduced. In 1912 Bendix employed the ethyl-ester of methylphenyl cinchonic acid ("tolysin") for rheumatism, and Chace, Myers, and Killian, in 1921, obtained good results with it is America. Boots and Miller, of the Rockefeller Institute, made a further study of its use and dosage in 1924, as had Hanzlik, Scott, Weidenthal, and Fetterman, in 1923. They found it a safe drug, though not so potent as the salicylates. Most of the observations were made on acute rheumatism in adults, and doses from 7–15 g. were used in 24 hours. In 20 cases, in which very large and long-continued dosage was employed, the only toxic effects were buzzing in the ears, headache, vertigo, nausea, and vomiting, this last in three cases. All the evidence I could collect when I began to use the drug for severe carditis in childhood pointed to its slight toxic effects and definite action in rheumatism. For these reasons I selected this compound, but had the greatest difficulty in getting it, and more than once failed to obtain it at all, so I bring before you no exhaustive study.

Illustrative Examples.

The following are examples of patients not treated with salicylates, but with this drug. I have treated 11 cases of great severity.

Case 1.—Female, aged 10. Enucleation of tonsils had been done at 5 years. Fourteen days before her admission to hospital, vomiting and pains in the chest and abdomen developed. There were mitral disease, dilatation of the heart, pericarditis, and massive collapse of the left lower lobe. Streptococci were isolated from the blood by Dr. D. Nabarro and endocarditis produced experimentally with the culture by Prof. Wright at University College Hospital School. Excellent recovery. Salicylates were never used, but "tolysin" was given. Seen two years later, when at school, she was leading a normal life with stable heart and mitral systolic murmur.

Case 2.—Male, aged 8. Had rheumatic fever at 6 and 7 years; the heart was damaged as a result. Fourteen days' history of generalised pains. Admitted with acute dilatation, pericarditis, and left pleural effusion. Treated throughout with "tolysin." Good recovery after extreme illness.

Case 3.—Male, aged 4½. Admitted to hospital May 16th, 1927. Extremely anæmic, with numerous large nodules and profuse sweating. There was severe arthritis, causing some contraction of both knee-joints, great cardiac dilatation, general pericarditis and mitral endocarditis, massive collapse of the left lung, and chorea. The mental state was one of extreme nervousness, and later of actual disturbance of mentality. It is almost impossible to conceive a more severe case of virulent rheumatism in a child so young. Treated throughout with tolysin and most skilfully nursed, this child is now at the country branch at Tadworth. The nodules have mostly disappeared, and though he is still short of breath the pericarditis has cleared up. The heart extends one finger's breadth to the right of the sternum and one finger's breadth to the left of the left nipple line. There is a mitral systolic murmur at the apex. He is gaining weight and strength. It is my belief that this child would have certainly died if any attempt to push salicylate of soda as a specific remedy had been attempted.

Emergencies in Pericarditis.

Occasionally a large pericardial effusion does occur in a child under 12, and the fluid may push forward the intercostal spaces and give all the other classical signs. Ought we to aspirate, or, bearing in mind the fibrino-plastic character of the exudation, should we open and drain the pericardium? I have seen both methods used and each seems to me to have its place. If the exudation is very rapid and copious, the pressure great, and the patient very ill, it has been my experience that the exudation is more fluid than usual and that paracentesis will be sufficient to tide over the crisis. In other and more gradual cases, incision of the pericardium is preferable, as it enables the more fibrino-plastic exudate to escape. The operation which has seemed to me best is the abdominal route with removal of the xiphisternum.

I have seen this operation done in an earlier stage, when there is little exudation, with the idea of getting rid of a toxic fluid. My view of the pathology of the pericarditis as commencing in the subendothelial tissue does not make me optimistic about the results of this measure, and the operation, not in itself serious, is a formidable one for a child with carditis. The results have not impressed me, and in any case we should need to follow up such a step with some specific serum or vaccine.

Grave difficulties arise if, by mistaken diagnosis, a dilated heart with an adherent and thickened pericardium is explored, whether by paracentesis or incision. Only a surgeon who has had the misfortune to undertake such a case can realise how impossible it is to know where to stop. In one case the heart cavities were explored in three places and the child, curiously enough, improved greatly, but this is exceptional, and it is no light thing to puncture a cardiac wall much damaged by myocarditis.

I have never advised Braner's operation for stripping the pericardium in a rheumatic case, though good results have been reported. The first published operation of this kind in this country was done for me by Mr. Wilfrid Trotter, but the condition proved to be tuberculous. There was wonderful improvement, but death occurred four years later from tuberculous pleurisy. Another equally remarkable operation was done by Mr. George Waugh on a young man who was seen by Sir William Willcox and myself; this was a case of recently adherent pericardium due to a chronic septic infection. The result again was remarkably good, although the patient was apparently in extremis. The rheumatic children I have had under my care have been either too feeble or had too severe valvular disease to permit me to feel justified in risking operation.

Convalescent Stage.

It must be apparent that for the treatment of heart disease sufficient time must be given for the heart muscle to recover tone and for the nervous system to be strengthened by country air and quiet. Gentle education of the mind proves also a great assistance. We have a most treacherous disease to handle and delicate children to treat, and for these reasons no ordinary convalescent home can answer the purpose.

It is some 15 years since I brought forward reasons for special convalescence before the Association of School Medical Officers, and in "School Hygiene" for August, 1912, I ventured to write: "In years to come I believe medical supervision of school children, combined with the efforts of medical officers of health, both supported by the skill and care of general hospitals and assisted by special convalescent homes, will be the means of prevention of much chronic heart disease," and the pioneer efforts of the Invalid Children's Aid Association deserve a special mention.

To-day there is a general recognition of the need for special convalescent methods. Such a step means a considerable outlay of money, and those who provide this have the right to know whether there is a good return, in the relief of suffering and greater possibilities for a useful life in the future, where previously the State lost good citizens and the skill, care, and money spent on the illness in the city hospital were often frittered away. The real object of the special convalescent hospital is to give a child the necessary time to recover as thoroughly as possible from a carditis. I have never thought or suggested that it is a new method for the cure of rheumatism, but it is a means of correcting a serious fault in our therapeutics, a result of the necessity for keeping the beds in the parent hospitals free for acute cases. In addition, it is possible in such hospitals to add much to our knowledge of the life-history of rheumatism and rheumatic heart disease. It would, however, be dangerous to send severe acute carditis to such an institution. Children who are already hopelessly damaged by the scars of former rheumatic attacks, who have an adherent pericardium and grave valvular lesions and can only exist as complete invalids, are not going to be so much benefited by this treatment as to make their occupation of the beds economically sound.

I would, however, lay down no hard-and-fast lines upon these questions, for circumstances differ in various localities. Again, I would have no hard-and-fast time-limit for the stay of a child in hospital, but, choosing an enthusiastic and sagacious medical officer as the head of the institution and supporting him with a capable nursing staff, I would then leave it to him to decide the question.

Acute and passing dilatations of the heart will have time to recover from the immediate damage and also to regain tone. The slight mitral lesion and the early aortic and mitral lesions will have time to compensate thoroughly. A severe acute carditis will be given the prolonged rest and graded exercise which are indispensable. On the scientific side there is much to be learnt about the recovery of a damaged heart, not only from the study of the heart, but from a study of the child. We all recognise persistent fever in the rheumatic child, and at the back of our minds we suspect some activity in the cardiac lesions or some absorption of infection from a local focus. In these hospitals we shall eventually learn more about this question; we may find, for instance, a vaccine that will be helpful or that in some patients the fever is not an indication for continual rest. Light will be thrown upon the degree of recovery possible in heart disease. I do not mean the mere estimation of exercise tolerance, but the ability to lead a normal life. In these hospitals, if anywhere, we shall learn more of the history of mitral stenosis and of atmospheric influences. There is some difference of opinion on the question of the admission of chorea in the recovering phase. I think that these cases are most suitable when they can be accommodated, but we must be patient until doctors and nurses are convinced that chorea is a rheumatic and not solely a nervous complaint. In some of the hospitals, also, it is to be hoped that there will be opportunities for skilled cardiologists to carry out strictly scientific researches.

It is my hope, too, that one day in this great city there will be a centre for research and the coördination of research on the whole problem of rheumatism, a centre from which indications for lines of advance will be forthcoming and from which trained workers will be sent to the various clinical institutions where cardiac cases are congregated. The great prevalence of rheumatism would make such a step justifiable as soon as this country is able to recover from its financial stress. In no other way can we avoid a great waste of time and energy from scattered and incoördinate attempts at solving the many problems involved.

It will be advantageous if girls can be admitted for convalescence up to the age of 14, for then we may be able to learn more about the nervous disturbances that occur at that age, and their influence upon those difficult cases of myocardial weakness that sometimes result from acute rheumatism without valvular lesions. If disturbances of the thyroid and other endocrine organs take a part in the rheumatic infection or produce unusual disturbances in the rheumatic patient, it is in these institutions that their effects can best be studied. In particular, we need to know more certainly the real necessity, in disturbances of the cardiac action, for a progressive or more cautious line of treatment. These are some of the special advantages that I believe will accrue from this method of supervising the child who is convalescing from rheumatic heart disease.

There will naturally be difficulties. The choice of suitable cases must of course depend at first upon the accommodation available. While beds are scarce, we must use them for cases of early heart disease in which we have every hope of obtaining good and lasting results. This is not a simple problem, for a physician at a parent hospital may have under his care a child with active rheumatism and acute dilatation of the heart, which disappear as the case runs a favourable course. When the child is transferred it is not easy for the physician in the country annexe to realise that there has been any trouble at all. Yet this is the very case in which cautious progressive training of the heart is most important. It will therefore be very needful for the report from the private doctor or the parent hospital to set out clearly the facts of the active phase of the cardiac weakness. In all cases, indeed, the activity of the rheumatic attack before admission to the country annexe must be the chief point.

The certificates that have to be filled up for admission to such an institution need some thought. The questionaire can easily be made too long and tiresome, the certificate fail to get filled up, and the child lose its chance. The problem of the rheumatic child affords a splendid opportunity for the great sections of the medical profession, the general practitioner, the hospital physician, and the officials of the Ministry of Health, to draw closer to one another. The official can give way a little to the other branches of the profession and make his certificate as short and yet to the point as is consistent with safety, and in return the others can make it a duty to see to the signing of the certificate. The result will be that the sick child will have its chance.

I think we must be very careful in collecting evidence upon what are to be called hopeless and therefore unsuitable cases. Let me give two examples.

A little girl of 5 had a severe attack of general pericarditis with mitral disease, and was desperately ill, suffering from repeated attacks of anginal pains which threatened immediate death. Her condition seemed hopeless and her home surroundings were most unsuitable. As a last hope, and I admit with a very uneasy conscience, I obtained her admission to the Heart Home at Kurandai. My colleagues were extremely forbearing to me and kept the child—entirely against their own judgment, I felt—until she was foolishly removed by the parents when much improved. A year after the illness she came back to me with an obviously adherent pericardium and a heart which one could not expect to make a good recovery. The child was, however, marvellously better, had no anginal attacks, and was living a happy life under invalid conditions. If such a hopeless case can do as well as this—and it was for me a test case—I am sure we must be most careful, as accommodation increases, before we condemn any child's heart as incapable of useful recovery, still more of recovery sufficient to make a short existence bearable.

The other case, treated at home by good parents, had been under my care first with severe aortic and mitral disease, then later with what seemed must be a fatal pericarditis. This boy lived to be 21 years of age and did four years' steady work as a clerk without any breakdown until the dreadful and mysterious malignant type of endocarditis developed and proved rapidly fatal.

I cannot, however, pretend to believe that treatment in the best convalescent hospital will prevent children from having further attacks if they return to surroundings likely to produce them. As our knowledge increases, we shall learn to restore these children to the best health possible, and many will probably resist further infection. We shall not, however, succeed with them all until we know the whole history of causation; should this prove to depend upon some atmospheric conditions we cannot alter, control, or surroundings which we cannot alter, there must remain a certain percentage of relapses. Here comes in the great need for improvement in our medical treatment by medicine, vaccine, serum, or other methods yet to be discovered.

SOME RECORDS FROM KURANDAI.

I am very much indebted to my friend and colleague, Dr. B. E. Schlesinger, who is acting physician to the Heart Home of the I.C.A.A., at West Wickham, for an analysis of the results from the previous

Heart Home at Kurandai. This home was a pioneer effort in this country at open-air treatment, and was carried out under considerable difficulties.

Three hundred and ten children, varying in age from 3 to 14 years, were treated from 1924 to 1926. The duration of stay was from three to 12 months. All were rheumatic children; many had suffered from previous attacks. Three had severe relapses. One, with arthritis, tonsillitis, and pericarditis, was discharged improved; two, with tonsillitis, pneumonia, and pericarditis, died immediately after removal from Kurandai. There were two cases, both severe on admission, who had slight relapses with passing pericarditis. Eleven cases had some recurrence of arthritis, and all recovered. Five cases developed chorea, four of them having suffered from previous attacks. These relapses occurred most frequently in the winter months. Later histories were obtained in 153 cases, but the period of time between 1924, when the Home was opened, and December, 1927, when this analysis was made, is too short for the observations to be of outstanding value. Ninety-three were reported to be "well," 31 to be in "fair health," 3 to be "ill," and 10 to have died (including the two cases which have been already mentioned). Sixty-four were at an elementary school, 35 at physically defective schools, and 22 were at work.

The history of relapses after leaving the Home is not so satisfactory, but I would once more emphasise that the question of relapse in the home surroundings is another problem which requires special investigation.

Ninety-seven of the 153 had not relapsed, and 56 reported as follows: 10 relapsed with chorea, 13 with arthritis, 2 with "heart attacks," and in 31 the nature of the relapse was not definitely stated. It is interesting that 46 out of these 56 cases relapsed in the first year after leaving the Home. The cases admitted during these years varied widely: 122 had mitral regurgitation, 76 had mitral stenosis, 30 had disease of the aortic and mitral valves, 8 had aortic regurgitation, 37 were examples of simple dilatation, and 4 of recent pericarditis; 23 were cases of uncomplicated chorea, and 10 of uncomplicated arthritis.

I believe that children with rheumatic heart disease gain by convalescence in an open-air country institution where they can also receive education; if this is correct we are making a step forward in the treatment of heart disease in the early phase of its evolution.

Dr. A. P. Thomson has most kindly given me his latest analysis from the Baskerville Residential School at Birmingham of the first 100 children that passed through the institution. He traced 83, and some of these have been repeatedly examined over a period of four years from the time of leaving; 27, who had signs of permanent cardiac damage on admission to Baskerville, had either improved or held their own; 24, admitted with the diagnosis of carditis, were found later to have normal hearts; 12, who had no signs of carditis at Baskerville, had never developed them; 9 had deteriorated; and 11 had died.

Since these lectures were completed, Dr. Coombs has kindly sent me his latest impression of these results; he also supports my views on the promises of special convalescent treatment. Lastly, I should do a grave injustice if I did not refer with great admiration to the pioneer work of the American Heart Association.

LIMITATIONS OF COMPLETE REST.

It is difficult to decide the time for which a child should be kept at complete rest after an attack of rheumatic morbus cordis. Opinions differ because children differ, but my general impression is that the value of complete rest, so valuable in active heart disease, can be overestimated in convalescence. A child's heart gains very little—in fact, I think it loses—by prolonged, aimless rest in bed, and certainly the general tone of the child suffers. Graded exercise acts as a tonic to a child's heart. We have to judge when the stage for its employment is reached by observation of each individual case. We have to look to the general condition of the child. Is he gaining weight, cheerful, and fretting for movement? Has the pulse steadied, the impulse of the heart become firm, the area of cardiac dullness become constant? Has the temperature settled and the active signs of rheumatism disappeared? The heart of a child is not so frail that it will suddenly collapse, even if we do advance one stage a little prematurely, provided we keep a close watch. What happens is that the child becomes tired and pale, and the heart may be quickened when at rest and may possibly even dilate a little, or the temperature rise slightly in the evening. This set-back happens more rarely if we can start with skilful massage of the limbs. If a murmur becomes louder, the heart is probably reacting well. The young heart has remarkable vitality. In my cricketing days one of my friends, a double Blue, a County cricketer, and a brilliant fielder and hard-hitter, had, I discovered later, won all his successes in spite of a combined aortic and mitral lesion dating from acute rheumatism in childhood. I do not advocate this method of treatment, but if such a heart can stand the strain of first-class athletics and in the end only succumb to a malignant endocarditis at middle age, we cannot go far wrong in cautiously replacing complete rest with graded exercise for the many children who are kept moping and unnerved for months because they *have had a definite but mild carditis.*

For over 20 years I have made attempts to treat rheumatic heart disease by sera and vaccines. Messrs. Burroughs and Wellcome made the first serum for me when Dr. Vernon Shaw was working at the subject, and later I tried various antistreptococcal sera, but I never succeeded in obtaining results which justified any clear statement. My experience of vaccines in malignant endocarditis has been one uniform record of complete failure in both child and adult, used early or late, in combination with sera or separately, autogenous or stock, simple or complex, given by the expert or by myself. Not one case has recovered. If acute rheumatism be streptococcal, I consider that the vaccine I now use, prepared by Dr. D. Nabarro from eight strains of streptococci obtained from ante-mortem and post-mortem cases of rheumatic carditis, is rational. I am using it for subacute cases with persistent mild fever, and believe it to be worth a trial. The dosage is a safe one, and is as follows:—50 millions, 100, 250, 500, 750, 1000, 1500, 2000 millions, twice weekly at first, and once a week when the largest doses are reached. The vaccine is sensitised by Besredka's method.

THE BORDERLANDS OF FEEBLEMINDEDNESS.*

BY G. A. AUDEN, M.D. CAMB., F.R.C.P. LOND.,
SCHOOL MEDICAL OFFICER FOR THE CITY OF BIRMINGHAM.

IT is a characteristic of all social problems that they have no sharply defined frontiers. They are all so intimately related that we cannot view any one problem as an isolated entity, any more than we can picture any nation in a position of "splendid isolation." For instance, the problems of housing and rents cannot be considered without reference to the earning capacity and industrial efficiency of the workers who dwell in them. These questions in turn depend upon the character of the employment, the current rate of wage associated therewith and, above all, upon the mental equipment and physical fitness of the individual worker. But in no social problem is this interdependence more striking than in the great question of mental welfare. In England there has been too great a tendency to study it apart from its cognate problems. This tendency is the natural result of the historical development of our interests and of our attitude to the problem under changing social conditions, which until recently have centred attention too closely upon the educational aspects of feeblemindedness, forgetful of the fact that feeblemindedness is but one facet of the many-sided problem of youth and adolescence. On the Continent there has been less confusion of thought and, I think, a wider grasp of the issues involved, with the result that the subject of mental deficiency has been there regarded more from what one may term the eschatological point of view, by which I mean that which estimates the future character-development of each child and the possibilities of his *becoming* a satisfactory citizen, adjusted to the demands made upon him by the *community* in which he lives and capable of that ordered and regulated conduct and self-control which is the essence of citizenship. The child with a psychopathic inheritance, the neuropathic child, the neglected or ill-treated child, and the child who is the victim of mental conflicts which result from maladjustments at home, all form an integral part of this problem. It must ever be kept in mind that the outlook on life engendered by adverse circumstances such as these, and the defects in character which so frequently result therefrom, are at least as important as that reduction in general intellectual capacity which is labelled "feeble-mindedness." In attempting to widen our horizon, however, we meet the initial question: Are we to regard mental deficiency (from idiocy to intellectual retardation) as a unitary condition in which the effect follows a given cause, just as the congeries of symptoms which we call "enteric fever," follows infection by the specific Eberth's bacillus? Is it not more probable that under this general term we are grouping a number of conditions, ætiologically distinct, but manifested by the same general type of mental phenomena and conduct which are the direct outcome of mental processes? An analogy will perhaps explain my meaning. Until comparatively recent years all kinds of infections which were characterised by a continuous rise of temperature were grouped together under the term "continued fever," but with the increased knowledge of causation afforded by bacteriology these are now differentiated into distinct morbid conditions.

---

* A paper read at the Conference of the Scottish Association for Mental Welfare at Edinburgh.

Two Categories of Mental Deficiency.

We can, I believe, distinguish two main divisions of mental defect; these may be termed "evolutive" and "devolutive." In the former the evolutionary processes have been retarded, and the individual, and usually also the stock from which he springs, has not reached that level of mental development which is demanded by our educational and social systems. In the latter group some intercurrent factors have come into play tending to the destruction of the stock in which they appear. To these factors, such as failure of, or lack of, balance between the activities of the ductless glands, I have applied the term "phthersigenic."[1] The types belonging to this devolutive category frequently show "stigmata of degeneration," whereas the evolutive types in no way differ in appearance from their normal fellows. In the evolutive group there is a reduction in the specific educational capacities, such as those for the acquisition of arithmetic, or of reading, rather than a reduction in the general intelligence. There is abundant proof that general intelligence is distributed in any community along a "normal curve of frequency" similar to the distribution of height, whereas these specific capacities show a markedly irregular distribution. This difference in the distribution of the two factors which go to form general intellectual capacity is a clear indication of the truth of the "Two Factor" theory of intellectual capacity formulated by De Sanctis and Spearman. In the evolutive group the specific capacities remain "larval," and though in this age of commerce and literary education the individuals who belong to it find themselves handicapped in the struggle to maintain themselves, yet they perform a necessary, though it may be humble, service to the community as "hewers of wood and drawers of water." In fact, the presence of such persons to do the drudgery and menial work in a complex civilisation is one of the safeguards of society as at present constituted.

If we take as our criterion capacity to conform to the standards and inhibitions of the community, the menace to society of individuals who show temperamental or character defects is far greater than that of the so-called feeble-minded. The original meaning of the word "character" was the impress of the die upon the plastic material of a seal or coin. It is of the greatest importance that we should keep in mind this twofold implication of the term—i.e., the innate plasticity or receptivity of the mental make-up and the forces and influences which are brought to bear upon it, by which it is shaped and moulded. Remembering this we realise how misleading is the antithesis "Nature *versus* Nurture," for the implied antagonism cannot exist, nor is it possible to calculate the relative values of each component. Heredity and environment form the warp and woof of the texture of personality.

Exogenous and Endogenous Factors.

The same facts can be expressed in another way. The material or bodily components of the mind of every individual share with the rest of the body the debts which each of us owes to the generations which have preceded us, the physical capabilities and weaknesses which are handed on from parents to offspring according to the so-called "laws of heredity." These are thus fundamentally biological factors and as they are inherent in us they may be termed endogenous. On the other hand, as Aristotle[2] points out again and again, man is by nature a social animal, and from the earliest days of his life suggestions of social import pour in upon him and with a pressure which increases year by year mould him to the pattern demanded by the community of which he is a member. Thus his conduct, which is the expression of his degree of adjustment to his social environment, is the impression of the design which has been cut upon the die. These factors are exogenous. "Character," therefore, implies a degree of permanence and stability of conduct, and the lack of these qualities constitutes in the main what is popularly termed a "weak character." But in the light of recent developments in psychology we are led to regard as the mainspring of conduct not the intellectual qualities of reason and judgment, but the emotions, and have come to associate the manifestations of the emotions with the activities of the endocrine glands. But since the regulation of bodily growth is also a function of these organs, a definite relationship has been established between the bodily and mental functioning. This is the explanation of the frequent presence of "stigmata of degeneration" in individuals belonging to the "devolutive" category.

Continental observers, for example, describe two distinct physical types as associated with markedly anti-social proclivities—i.e., the "Kobold type" amongst boys and the "Steatic type" amongst girls. The latter type is said to be found chiefly amongst prostitutes and women of the most degraded class. With a marked tendency to fatness, a coarse, greasy skin and thick tousled hair, is associated an incurable indolence and inability for any form of sustained work. The "Kobold," so called from his fancied resemblance to the gnomes or goblins of our fairy stories and myths, is a short, thick-set muscular individual with a large thick-boned skull balanced by a powerful jaw. (See figure.) Prof. Lazar, of the Psychological Clinic attached to the Children's Court in Vienna, told me in conversation that all of the five boy-murderers whom he had examined belonged to this type. The following is a good example of this Kobold type:—

CASE 1.—Boy, born April 4th, 1917, and first examined Oct. 18th, 1926.

Family History.—A bigamous marriage; father imprisoned and on release absconded to Australia. Mother a careful intelligent woman, anxious to do her maternal duties.

ὦ μεγάλαυχοι καὶ φθερσιγενεῖς
Κῆρες Ερινύες.

[2] Aristotle: Nicomach, Ethics 1, VII. 6, also Politics 1253 a2. See also Seneca, De Beneficiis, vii., i., 8.

School Report.—Was in Board of Guardians' Cottage Homes for several years. For past year has been stealing regularly and frequently, chiefly apples, bottles of sauce, sausages, jam, &c. Headmaster reports, "intelligent boy, above the average of his class." Untruthful and cruel but willing to help in the house-work.

On March 16th, 1928, he was charged with persistent wandering into railway trains. On March 1st he took a small sister at 10 P.M. to the station, where they secreted themselves in a train which he said was labelled "Crewe." On reaching Crewe they got out, seeing another labelled "Glasgow," got into it. Ultimately they found their way to Stockport. Three days later he took his sister by a local train for a 25-mile journey. On March 10th he again found his way to the station at 10 P.M. and, seeing a train to York, got into it, but was found at Burton-on-Trent. He gave the following account of his escapade :—

Child of the Kobold type.

"I played in the street after I had scrubbed the floors, until it got dark, and then went to the station. I got in a train; it was going to York. I wanted to go in a ship on the River Humber. I've seen (pictures of) people going on to the ship. I thought the ship would go down the Humber, round Scotland, and then past Ireland and over the 'Lantic Ocean' to Canada. New York is by North America. I thought I'd see some Red Indians and go with them in a tent; I'd work for them and scrub the floors. There's a lot of fruit. I'd live with the Indians because they're kind. The porter took me to a little office and they gave me some bread and cheese and put me in another train in the guard's van. I looked through the window and saw the fields and a fair and an aerodrome." (This is quite correct.)

He reads with ready facility and with the same tendency to fantasy building. Calculates quickly, and at once gave the correct change from half-a-crown after buying four loaves at 4½*d.* each. Physically he is short, thick-set, with large head and jaws, and no evidence of disease.

Physical and Mental Correlation.

Kretschmer [3] and others have noted that when a mental break-down occurs, the form of insanity which results is largely conditioned by the bodily configuration of the individual; that there is, in fact, a biological affinity between the bodily and the mental make-up. Bearing in mind this biological affinity and also the hereditary transmission of physical or endogenous characters, we are prepared for the discovery of a strong familial association of certain types of mental abnormality, including the various forms of insanity, mental deficiency and those neurasthenic manifestations which are grouped together under the inclusive term "neurotic temperament." This intimate relationship between types of bodily conformation and mental traits and dispositions is of course recognised in our experience of every-day life. Don Quixote, the lean and lanky idealist, is the opposite of Sancho Panza, the jovial exponent of animal spirits. In fact, amongst German writers the "Sancho typus" and the "Quixote typus" are used to designate opposite poles of combination of bodily and mental characteristics. From the social point of view these cases are much more important than pronounced cases of mental defect. From an administrative point of view they form a far more difficult and intricate problem, for they cannot be brought within the ambit either of the Lunacy or of the Mental Deficiency Acts. They belong to the borderlands of feeblemindedness. Yet even the most ardent of eugenists would scarcely at present propose that a mental break-down should entail segregation or sterilisation, and that marriage and parentage should be for ever prohibited. Yet such stocks may supply examples of every kind of anti-social behaviour. In the Minutes of Evidence presented to the Royal Commission on the Care and Control of the Feebleminded [4] is a genealogical tree which gives a vivid illustration of the burden which the community has to bear from stocks which carry this neurotic temperament. Here is another example :—

Some years ago, in the course of examining a boy of 11 who had been absent from school for two years with severe chorea, I was struck by the mental inertness of his mother. She was a highly neurotic, garrulous woman, who complained that "her nerves had affected her memory." She had received a better education than might have been expected from her social status. Two of her sisters had been insane. Two of her children had died in infancy; her other older son was normal but suffered from chronic ear-disease. Her two remaining daughters, aged 18 and 16, already showed marked mental instability. Her late husband, who was said to go "violent mad when drunk," had attacked her with a razor, and the question of his certification as a lunatic had been raised before his death from typhoid at the age of 48. He was the father of an illegitimate child. Of her husband's family one sister was insane before marriage, had had an illegitimate child, and was very violent-tempered. The first husband of this sister had been hanged for murder, and her second husband, whom she had attacked with an axe, had left her owing to her violence. Her daughter from her first husband had been certified insane. Another sister was a chronic alcoholic with one illegitimate child. A brother was described as "most violent," who "threw the crockery about." Another brother was described as "highly strung, most irritable."

This family history affords a good example of the various manifestations of mental instability and of the social havoc which degenerate stock may wreak in a community. It is indeed probable that the severe chorea in my patient was but part and parcel of the same genetic instability.

CASE 2.—A girl, aged 9, was examined on March 3rd, 1928.

Family History.—The father, who was discharged from the army as mentally unfit, states that while serving in North Russia "they reckoned I went mad in the firing line. I went properly mad. I jumped over the barbed wire and started firing, I don't remember much about it." He was placed in an asylum, and later had a second attack and was again in the asylum for four months. Is a quiet-mannered, debilitated man who earns his living by cutting firewood.

Present Condition.—A bright and engaging little girl who for the past two months has been a persistent thief from home and school, but her parents had noticed a tendency to pilfer for some time. She spends part of the money on herself and gives part of it away to other children. She shows a marked deftness and method in her pilfering, and no idea of remorse in robbing her father of the money he had saved to buy his wood. "I took 10*s.* from upstairs—mother was keeping it for my coat." "The teacher's bag was hanging on the pipes, I took 18*s.* I went with another girl to Woolworth's. We bought some sweets, a powder-puff and face cream, and some fancy garters. I've some long stockings at home. We went on the bus. We went to the coffee house and bought a boiled egg and bread-and-butter. We often go to the pictures. Dad gives us the money."

The girl showed no evidence of physical or mental defect except much fidgetiness, and was quite up to the average intelligence and education for her age.

CASE 3.—Boy, born on Sept. 27, 1910. Left school from Standard VII.

Headmaster's Report.—"Mental capacity fairly good, takes an interest in games; of fairly even temperament. Possesses considerable capability."

At the age of 10 he was sent to an Industrial School, having been charged with stealing £15 and a bicycle pump. While in the school his general conduct was good and no signs of mental abnormality were noticed. On being licensed out to a farm, in 1926, he set fire to the stacks of his employer. He states that he had been happy and well-treated at the farm. "I went to the pictures. I saw a ship on fire, and when I was coming across the field I was thinking of lighting a fire. When I came back I went to the farm and lit six or seven hayricks. I went to bed and got a drink of water. I was frightened because I knew I should get into trouble. I've never done it before. The idea came to me when I was coming across the fields and I felt I'd like to do it. I thought they'd blame someone else. I didn't want to damage the master. I weren't thinking when I was lighting it. I was sorry afterwards."

---

[3] Kretschmer: Korperbau und Charakter, Berlin, 1921.

[4] Royal Commission, vol. i., pp. 611, 612.

Mental Examination.—Memory span of six figures. Understood the use and object of postage stamps. Calculated the change from 2*s.* 6*d.*, on buying four loaves at 4½d. each, quickly, and gave the number of halfpence in 7*s.* 6*d.* For three-word combination sentence gave "London's like a money (many) flowing river." Failed in detection of a fallacy, gave fair list of differences between wood and glass. Did Healy's Form Board B correctly. No physical disease.

Family History.—Mother has been in a lunatic asylum on three different occasions, is now at home, but is reported to be again in need of certification. Though the examination showed that he could not be certified under the Mental Deficiency Act, it is of course quite possible to argue that his actions are the preliminary signs of mental degeneration, though his subsequent history gives no indication at present of any such degeneration. He is now in regular employment.

It is clear from the family antecedents of these illustrative cases that when they reach adult life they are likely to constitute a menace to the well-being of the community unless the force of social suggestion acts with sufficient power to mould the character with the impress of social obligation. But the problem which presents the most acute difficulty is that of dealing with the numerous children who, as the result of an attack of encephalitis lethargica, show the strange perversions of character which manifest themselves in anti-social conduct. These children become addicted to persistent thieving, lying, and sex-delinquencies and are the bane of the home in which they live. Not a few of them find themselves in the Children's Courts, and some are convicted to industrial schools, reformatories, and prisons. Yet few show a deterioration of intellectual capacity sufficient to bring them within the Elementary Education (Defective and Epileptic Children) Acts or the Mental Deficiency Acts, and the majority remain free to pursue their own course of wayward and unruly conduct. The few who are to be seen in mental hospitals differ in no way from the rest of their fellow sufferers.

Austrian Methods.

But how is this impress of social obligation to be made if we narrow the scope of our efforts by the limitations imposed by the Mental Deficiency and Lunacy Acts? Herein I think we may learn much from the methods in Austria, where the problem is viewed from a wider standpoint without the departmentalisation which has grown up in England. There the basis of classification is in the main a psychological examination. There may be a tendency to rely too completely upon conformity to certain preconceived psychological types, but I think there is no doubt that such an examination and classification yields more valuable results, from the point of view of the capacity for future citizenship, than those which accrue from a determination of the mental age and intelligence quotient, useful as these may be. For example, at the Great Colony of Egginburg, some 50 miles from Vienna, there are about 900 male and female inmates of ages ranging from 6 to 25 who, on the results of a careful psychological examination, are housed in pavilions containing 25 beds under a supervisor. The inmates of the male section meet in common in the workshops, extensive gardens, farms and orchards and, where possible, boys from the country districts are employed in occupations which are likely to interest them and to be of value to them in after-life—e.g., gardening, farming, fruit-growing, carpentering—while the town-dwellers are taught the more mechanical trades which will serve them in good stead when they return to their homes in the towns—e.g., tailoring, weaving, shoemaking, baking, building, &c. This division, according to their individual interests, in itself tends to reduce mental conflict and to arouse an increased interest and contentment.

The groups into which the inmates are divided are: (1) Those suffering from simple neglect without character defects. (2) Those who have suffered from neglect or ill-treatment and exhibit true character defects and conflicts at home, showing a tendency to gang-formation. (3) Those who show slight neuropathic tendencies. (4) Those who show severe neuropathic conditions, but with good intelligence—the "difficult child" type. (5) Those who suffer from psychopathic defects, but without instability of character; mental conflicts. (6) The aggressive or Apache type, often with reduced general intelligence. (7) Those with severe psychopathic defects, epilepsy, early dementia præcox cases. (8) The feeble-minded.

It is only when one sees a mass parade of all the inmates divided into groups that one realises the practical validity of this method of classification.

A very similar classification system is carried out at other institutions which I have visited in Vienna, as for example at the Schutzheim for difficult boys managed by Dr. Kehrein under the auspices of the *Sodalitas Salesiana.*

It must not, however, be inferred that no psychological classification is used in England, but the point upon which I wish to lay emphasis is that here each group would be treated, if at all, in a separate institution and generally under separate authorities, both central and local—e.g., the local Education Authority under the Board of Education; the Poor Law Guardians under the Ministry of Health; Industrial and Reformitory Schools under the Home Office; the Mental Deficiency Committee under the Board of Control; and voluntary organisations. Yet each group represents one aspect of the great protean problem of childhood and adolescence and most of them belong to the borderlands of feeblemindedness, each being symptomatic of a difficulty in adjustment to the environment and the realities of life. We cannot too often remind ourselves of the saying of the Roman philosopher, Seneca,[5] *non scholæ sed vitæ discimus,* for the purpose of our educational efforts is not the mere inculcation of knowledge, but to aid each individual to play his part, however humble that part may be, in the community of which he is a member; to give, in fact, in the words of Plato,[6] "that education in virtue from youth upwards, which makes a man eagerly pursue the ideal perfection of citizenship and teaches him how rightly to rule and how to obey."

Upon the standpoint from which we survey the problem will depend not only the scope of our endeavours but the means which we shall employ. The wider our view the better able shall we be to envisage the problem of mental maladjustments as a whole, unfettered by any artificial sub-division of the individuals whom we hope to benefit by our efforts, and the greater will be the advantage to the community which we serve.

---

[5] Seneca: Epist. 106, §12. [6] Plato: Laws, i., 643.

LOTTERIES FOR BOMBAY HOSPITALS.—It was recently proposed to the Corporation of Bombay that money for the maintenance of the local hospitals should be raised by means of lotteries. The plea was supported by the argument that the public of Bombay are already supporting hospitals and charitable institutions in Goa through the Goa lotteries, of which there is one every fortnight, and it was calculated that from 20 to 25 lakhs of rupees could be raised in this way. The Medical Relief Committee of the Corporation referred the matter to the Municipal Commissioner, who pointed out that such lotteries would require the sanction of the Presidency Government, which was very unlikely to be given to an organised series. The proposal has therefore not been entertained.

BLOOD TRANSFUSION IN BLACKWATER FEVER.

By G. CARMICHAEL LOW, M.D. Edin.,
F.R.C.P. Lond.,
SENIOR PHYSICIAN, HOSPITAL FOR TROPICAL DISEASES, LONDON, AND SEAMEN'S HOSPITAL, ROYAL ALBERT DOCKS; CONSULTING PHYSICIAN FOR TROPICAL DISEASES, TILBURY HOSPITAL;

W. E. COOKE, F.R.C.S. Irel., D.P.H.,
MEDICAL SUPERINTENDENT, HOSPITAL FOR TROPICAL DISEASES;

AND

P. H. MARTIN, B.M., B.Ch. Oxf., M.R.C.P. Lond.,
D.T.M. & H.,
LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

(From the Hospital for Tropical Diseases, Endsleigh-gardens, W.C. 1.)

THERE is no disease in which the prognosis is so uncertain as blackwater fever, whether treated in the tropics or in England. From time to time practitioners get a series of favourable cases and are then apt to conclude that the success is due, say, to the administration of some special drug. A subsequent unfavourable series, however, causes them to doubt, and warns them not to boast about their previous results. An experience of 28 years, both abroad and at home, leads me to the conclusion that, apart from careful nursing and attention, there is no specific treatment for this disease. Many drugs have been lauded from time to time, only to fall into disfavour and disuse.

The main causes of death in blackwater fever are (1) syncope, (2) acute hæmolysis, (3) suppression of urine, (4) hyperpyrexia, and (5) asthenia, which produces, perhaps, the most disappointing results. In this type of case the urine clears, yet the patient does not improve, the blood does not regenerate, and gradually a semi-comatose condition supervenes and death takes place. Looking back, one is impressed by our powerlessness to prevent death in such cases. The marrow seems to become exhausted, and no longer capable of producing new blood.

In a recent case of this kind we tried to save life by blood transfusion, and so had the opportunity of seeing its effect in stimulating the marrow to renewed life and the formation of fresh blood corpuscles. We had no hesitation about trying this, even considering the possibility of causing more hæmolysis, because the patient could not have lived through the night.

In a paper on blackwater fever in London,[1] Manson-Bahr and Sayers record a somewhat similar case. They say:—

> "In a recent moribund case in whom the urine had cleared, but who was suffering from extreme anæmia (the blood count showing only 850,000 red cells per c.mm.), blood transfusion of 700 c.cm. of blood was performed, with the result that the patient revived in a miraculous manner and regained consciousness. There was no evidence of any further hæmolysis, and the urine remained clear. Unfortunately the improvement was not maintained and, in spite of a further transfusion, the patient died three days later."

In this case the authors considered the results encouraging and thought it was worthy of another trial if a suitable case occurred.

The Present Case Described.

The history of our case is as follows:—

European, male, aged 50, a planter in British Guiana. Born in England; went to British Guiana about 1896 and has lived there ever since with the exception of holidays in England, the last of which was four years ago.

Previous Illnesses.—Measles; no scarlatina, enteric, or rheumatic fever. Many attacks of malaria during the last 25 years; one attack of dysentery. Had an attack of (?) hæmaturia five years ago (1923), and was in hospital six weeks. No definite diagnosis was made. Came to England after this attack and saw a specialist, who could find no cause for the hæmaturia. X ray examinations were negative.

Present Illness.—In January, 1928, the patient suffered from a series of short attacks (about four in number) of what was called hæmaturia. He did not go to bed, but went on with his work the whole time. The attacks lasted three or four days to a week, with three to ten days' intervals. Patient then sailed for England and at first felt fit and well, but a little later he felt feverish once or twice. On Friday morning, March 23rd, he got a chill while on deck and developed a sharp fever. He passed dark-coloured urine that afternoon, and his temperature was 103° F. that night. The ship arrived at Tilbury on March 26th, 1928, and the patient was immediately brought up to the Hospital for Tropical Diseases and admitted at 1 P.M. A cursory examination at once showed that he was suffering from hæmoglobinuria (blackwater) and not hæmaturia. He was desperately ill, deeply jaundiced, anæmic, with a large spleen and a subnormal temperature, 96·6° F. The pulse was fair. The lungs showed considerable bronchitis, with râles and rhonchi over both bases. A blood count showed the number of red blood corpuscles to be as low as 980,000 per c.mm.; white blood cells, 7000; hæmoglobin, 30 per cent.; differential count: polymorphonuclear leucocytes, 67 per cent.; large mononuclear leucocytes, 7 per cent.; lymphocytes, 26 per cent.; eosinophils, 0. No parasites. Anisocytosis and poikilocytosis marked. Urine: dark reddish black colour; albumin, + +; many granular casts and debris; no red blood corpuscles; hæmoglobin present.

Treatment was at once commenced with rest, warmth, fluids, nourishment, and alkalies. The foot of the bed was raised; milk diluted with soda water, orange water with glucose, barley-water, and sodium bicarbonate in water were given repeatedly in small amounts by the mouth.

At 11 P.M. on the night of admission, considering the journey from the dock to the hospital, the patient's condition was fair. Since admission at 1 P.M. over 20 oz. of black urine had been passed, which showed evidence of clearing in the later samples. Fluids were being taken well; the pulse was 112, and its volume fair.

At 6.30 A.M. next morning the patient showed signs of collapse. The pulse became almost imperceptible at the wrist, and the breathing irregular and of the Cheyne-Stokes type. The mouth and tongue were very dry and sore. Strychnine gr. 1/30 subcutaneously was followed by intravenous glucose ℥ viii. at 8 A.M. By 10 A.M. a rapid change for the worse set in, with sweating, pain in the chest, rapid and feeble pulse, and respiration-rate 42. The features became pinched, the eyes dull, and a mucus rattle appeared with respiration, the patient being too weak to cough. Strychnine gr. 1/30 was again given, followed by camphor in oil 1 c.cm. an hour later. Some delay (through no fault of the London Blood Transfusion Service, who in this case, as in all previous cases, have never failed to provide volunteer donors to this hospital at short notice) arose in arranging for a blood donor, and during the interval before his arrival the temporary improvement, which had again followed the stimulants given at 3 P.M., passed off. By 6 P.M. signs of rapid dissolution were present: a semi-conscious state, glazing of the eyes, rattle in the throat, and very feeble pulse. We were unanimous that without blood transfusion death was imminent.

The patient's blood had previously been examined and found as follows: red cells, 980,000 per c.mm.; hæmoglobin, 30 per cent.; white cells, 7000; blood-group III.; van den Bergh: direct test negative; indirect test strongly positive—about 22 units. Test for hæmolytic system, as found in cases of paroxysmal hæmoglobinuria, negative. At 7 P.M., after checking the absence of agglutination of the donor's cells by the patient's serum, blood transfusion was started and 400 c.cm. of citrated whole blood was given. During the transfusion a visible improvement took place; the pulse became stronger, the colour less ashy, the tongue less dry, and at the close of the transfusion the patient succeeded in coughing up mucus from his throat. The urine subsequently passed showed no evidence of any further hæmolysis; 44 oz. of black water had been passed in the first 16 hours in hospital, and contained much albumin and some granular casts. Red blood cells were not seen, but hæmoglobin was present. At 10.45 P.M. strychnine was again used to treat a sudden collapse; the very brief improvement was followed at 11.20 P.M. by another period of collapse. Shortly afterwards the bowels moved in response to an oil enema; there was a very distinct improvement, the pulse being better and stronger. As the bowels had been confined for some time and, as was discovered later, hæmorrhoids caused much pain on defæcation, it is probable that the collapse was associated with the bowel movement.

March 28th: The patient had slept for short periods during the night. He maintained the improvement during the day, but had slight incontinence of fæces and urine with pain on micturition. His general condition remained much the same until the afternoon of the 29th, when he became distressed and appeared to have considerable pain over the [illegible] f the right chest, where pleuritic friction was audible.

---

[1] P. Manson-Bahr and E. G. Sayers: THE LANCET, 1927, i., 273.

The application of antiphlogistine gave relief and the condition appeared to resolve. The urine collected for the two periods of 24 hours was 61 oz. and 47 oz. The blood count showed 1,000,000 red cells and hæmoglobin 30 per cent.

30th: In the morning the breathing became laboured, the pulse quickened, and the patient appeared more drowsy and weaker. He was coughing up large quantities of sputum. As he was obviously sinking, it was decided to transfuse blood again, and at noon 300 c.cm. of citrated whole blood were given. There was an immediate general improvement, which was maintained throughout the afternoon and evening.

31st: Patient had slept a little during the night, in spite of a distressing cough, and was stronger and mentally brighter by the morning. A blood film showed normoblasts for the first time. A blood count on April 1st showed 1,630,000 red cells and still no parasites, and another, next day, showed 2,200,000 red cells.

From April 1st onwards the history was one of slow but steady progress. The amount of urine passed daily varied from 60 to 80 oz., the temperature, which had been swinging between 99·5° F. to 101° F., began to subside, and the cough became less troublesome. Liquor arsenicalis ♏i. t.d.s. was started on April 2nd, and was gradually increased. On the 9th "ring" forms of the parasite of subtertian malaria (*Plasmodium falciparum*) were found for the first time. Quinine hydrochloride gr. i. with iron and arsenic was therefore given three times. On April 10th, tablet plasmochin co., one twice a day, was started, and the iron and arsenic were discontinued. The plasmochin tablets were gradually increased.

4–7	—	—	Plasmochin co. 12 tab.
4	4250	80	—
9	—	—	Out for first drive.
10	—	—	Plasmochin co. 3 tab. daily. Tab. iron and arsenic started.
14	4490	80	—
15	—	—	Patient discharged from hospital, with instructions to continue taking quinine hydrochlor. grs. v. twice daily for the next three months.

* From this date onwards.

The maximum dose of plasmochin co. given was 12 tablets per diem; this dosage was reached gradually from an initial dosage of two tablets per diem. The plasmochin was given in short courses of decreasing length—viz., six, four, and four days—and the intervals of rest from plasmochin co. between each course increased—viz., five–eight days in this case.

Blood transfusion is not an entirely new line of treatment in blackwater fever, for Manson-Bahr and Sayers[1] record a case. Nevertheless, the results in our case, considered with the scanty records of other people's work on this line, appear to justify this somewhat lengthy account of our single case.

The clinical condition, combined with the laboratory tests of our patient on his admission on the fourth day of his illness, suggest that as a case he would come into Group II. as described by G. R. Ross.[2] Group II. cases are described as those showing "definite hæmoglobinuria of moderate severity; no suppression; recovery." These cases show Fouchet's test for bile pigments in blood + +. van den Bergh: direct—negative; indirect—5 and 16 units. If placed in this group our patient must have been in the severest attack compatible with inclusion in the group, and were it not for the fact that he was alive, almost untreated, 70 hours from the onset of blackwater, it might be justifiable to place his case in Group III.: "Cases with severe hæmoglobinuria: no suppression; death in 24 to 48 hours." These cases showed Fouchet's test + +: van den Bergh: direct—negative; indirect—6 (first day) to 20 units.

W. Kikuth[3] gives a comprehensive summary of the therapy recorded by various authors in blackwater fever, but no reference to blood transfusion appears.

Actual and Theoretical Effects of Blood Transfusion in Blackwater Fever.

1. It undoubtedly treats anoxæmia symptomatically by helping to replenish the patient's supply of red blood cells.

2. It acts as a stimulus to blood cell formation. There may or may not be an adequate stimulus already provided, but in our case the rise in the number of red cells per cubic millimetre coincided with the time at which blood rejuvenation occurs in other diseases after blood transfusion.

3. The urine in blackwater fever is loaded with albumin. The introduction of healthy blood plasma is probably advantageous.

4. It dilutes the hæmoglobin and the bile pigment already free in the plasma, and so may aid the kidney in its work of excretion.

5. It replenishes blood-volume without unduly increasing the amount of sodium chloride. Baker and Dodds[4] have shown in their work on obstruction of renal tubules during the excretion of hæmoglobin that a percentage of more than about 1 of sodium chloride is a very important factor in causing coagulation of hæmoglobin, and therefore tends to cause suppression of urine. Further, Dr. J. G. Thomson, in conversation with one of us (P. H. M.), has recounted how disappointing and sometimes even disastrous were his results in treating blackwater fever in S. Rhodesia with intravenous salines. This was, of course, before the publication of the work of Baker and Dodds in 1925.[4]

6. It provides the most natural antidote possible to the acidosis and the acid urine which Baker and Dodds have shown in the same paper to be so very important in causing coagulation of the liberated hæmoglobin.

It is noteworthy that in our case, in spite of the alkali treatment which was carried out from the start of hospital treatment, the urine was still acid to litmus on the second day—after nearly 24 hours' treatment.

7. It provides such antibodies as the donor may have in his blood against organisms which are likely to cause intercurrent infection—e.g., lung complications.

8. It does not appear to lead to further hæmolysis, provided the bloods are carefully matched. Auto-agglutination has been observed by us in severe malarial infections, and demands the utmost care to keep the temperature of the ingoing blood and of the receiving limb as near normal as possible.

9. Whether there is any specific therapeutic action against *P. falciparum* is very doubtful.

It should be noted that neither our patient nor the donor had any quinine in his system at the time of the transfusion. M. Ghiron, in his studies on the pathogenesis of blackwater fever[5] has demonstrated in vitro the marked hæmolytic action of blackwater fever serum on quininised red cells, particularly on those from a malarial patient. Transfusion of blood would therefore appear to be inadvisable at a time when the blood of either donor or recipient contains quinine. Prof. Ghiron's charts suggest that the hæmolytic system disappears from the serum of a blackwater fever patient within a month of the attack.

Conclusions.

In view of the facts brought out by this case, it would seem that transfusion of whole blood at the time of, or immediately after, an attack of blackwater fever, provides us with a new and useful therapeutic measure in the treatment of certain types of this disease, the usual methods of rest, warmth, fluids, and alkalis of course being combined.

Further, our case suggests that the fear of causing more hæmolysis should never be allowed to prevent blood transfusion in desperate cases of blackwater fever, and that even in less severe cases transfusion may be a useful addition to treatment. We feel sure that transfusion should not be delayed until a patient is moribund, but that even at the last minute it is worthy of trial. The exhibition of tablet plasmochin co. several days after the initial hæmoglobinuria caused no further hæmolysis and it was successfully exhibited against the parasites of *P. falciparum* when they reappeared in the peripheral blood.

SOME ASPECTS OF VESICAL TUMOURS
AND THE RESULTS OF TREATMENT.

BY G. A. Q. LENNANE, M.B. CAMB.,
M.R.C.S. ENG.,

LATE HOUSE SURGEON TO THE SURGICAL UNIT, ST. THOMAS'S HOSPITAL; ASSISTANT MEDICAL OFFICER, QUEEN MARY'S HOSPITAL FOR CHILDREN, CARSHALTON.

THIS investigation began in an endeavour to ascertain the best form of treatment for papilloma of the bladder, more especially to prevent recurrences, but it soon became evident that other vesical neoplasms would have to be included. The neoplasms to which the bladder is susceptible are classified into simple and malignant, the latter being either locally or generally malignant, according to whether they invade the bladder alone or form metastases in other parts of the body. The most important simple tumour is the papilloma, which may be sessile or pedunculated, varies in size from a small pea to an orange, and possesses long villous processes. Other simple tumours, such as the connective tissue tumours which arise in childhood, adenomata arising in glands at the base, and cholesteatomata, are exceedingly uncommon and none occurred in this series.

The malignant growths which attack the bladder are the malignant papilloma, the carcinoma, and the sarcoma. In the malignant papilloma the villi are more stunted and irregular than in the benign form, the bladder wall becomes infiltrated, and the mucous membrane at the base of the tumour adheres to the submucous tissue. Carcinoma of the bladder may be a sessile nodular growth, irregular in appearance, projecting into the lumen of the bladder, and varying in size from a marble to an orange, or it may be mainly intramural with a few nodules of the surface. Sarcoma is extremely rare and is found only in infancy and late adult life. Only epithelial neoplasms occurred in this series.

The difficulty in diagnosing, in certain cases, between carcinoma and the more malignant forms of papilloma has made it necessary to include all cases of vesical new growth in this investigation. For instance, in some of the cases examined the clinical findings at operation have been those of carcinoma, but on section no pathological evidence of invasion has been found. One of the chief reasons for this is that, in the specimen removed for pathological examination, the base of the tumour has not been cut. On the other hand, tumours which to the naked eye appear to be innocent papillomata have, on pathological investigation, shown evidence of invasion. One of the chief methods of treatment of vesical new growth is diathermic cauterisation, the destruction of the growth being performed through an operating cystoscope. Specimens from these cases are not suitable for pathological investigation, so that the diagnosis rests mainly on the cystoscopic appearances. It would therefore not be justifiable to distinguish definitely between simple and malignant tumours on clinical appearances alone.

Incidence and Course.

Vesical neoplasm is a fairly common and fatal disease. Of 168 cases taken from the records of St. Thomas's Hospital between the years 1914 and 1926 only 59 were known to be alive in the latter year; 57 had died and the remainder were untraced.

The disease is most common between the ages of 50 and 65, but two patients in this series were aged 18, one being male and one female. It is more common in males than females, in the proportion of 3 to 1. The tables show the sex- and age-incidence (Table I.).

TABLE I.

Age.	Males.	Females.	Total.	Percentage.
Below 20	1	1	2	1·19
20–29	6	1	7	4·17
30–39	9	3	12	7·14
40–49	21	8	29	17·26
50–59	40	12	52	30·95
60–69	37	12	49	29·17
70–80	12	5	17	10·12
Totals	126	42	168	100·00

Of these 168 cases, only 116 could be traced up to 1926 or till death; 11 additional cases were traced for a time and then lost sight of. Up to the end of 1922, 68 cases were treated for vesical new growth. Of these, 59 were traced from the date of their first treatment until 1926 or until death. These cases, therefore, have a minimum possible post-operative lifetime of at least four years, and (as one first received treatment in 1911) a maximum up to 15 years, according to the date on which they first received treatment. The period since 1922 is too short to give a fair idea of the comparative fatality of the disease in cases treated after that year. The following table shows the number of cases treated up to the end of 1922 and the duration of life after the first treatment.

TABLE II.

Duration of life after operation.	1926.		Total.	Duration of life after operation.	1926.		Total.
	D.	L.			D.	L.	
3–6 m. ..	10	—	10	7–8 yrs. ..	3	3	6
6–12 „ ..	1	—	1	8–9 „ ..	1	6	7
1–2 yrs. ..	3	—	3	9–10 „ ..	1	2	3
2–3 „ ..	2	—	2	10–11 „ ..	—	1	1
3–4 „ ..	2	—	2	11–12 „ ..	1	—	1
4–5 „ ..	2	10	12	Over 12 yrs.	—	1	1
5–6 „ ..	2	5	7				
6–7 „ ..	2	1	3	Total ..	30	29	59

D = dead. L = Living. m = months; yrs. = years.

Only about half of these patients, therefore, are still alive, and of the 30 who are dead 20, or 66 per cent., lived less than five years after operation. A large proportion of deaths occur within six months of treatment. The fatality of this disease is just as strikingly shown in 43 traced patients who received treatment between 1922 and 1926. Only 27 of these 43, or 63 per cent., have managed to live four years and many have lived very much less, as some only received treatment in 1925. It must be borne in mind that many of these patients have had several treatments, and of those who were still alive in 1926 many still had symptoms. The two main causes of death from vesical tumours are hæmorrhage and pyelonephritis. Post-mortem reports were only found of 12 of the cases which died in hospital. The causes of death in these were :—

Hæmorrhage and cystitis	3
Pyelonephritis and cystitis	4
Uræmia	1
Bronchitis and œdema of lungs..	1
Extra-peritoneal abscess..	1
Secondary growths in viscera	2

A noteworthy feature of vesical new growths, more especially papillomata, is their tendency to local recurrence after complete removal. They may recur in the actual spot from which the original tumour was removed, or elsewhere in the bladder.

There is some evidence, though it is not conclusive, that innocent tumours do at times become malignant, as the following cases show :—

(1) Male, aged 36, a porter, was operated on on Oct. 21st, 1918, a suprapubic excision of a tumour being performed. The growth had all the naked-eye appearances of a villous papilloma, but unfortunately it was not examined microscopically. Four years later, on Dec. 14th, 1922, suprapubic excision was performed again, and the tumour, on pathological examination, was found to be a carcinoma.

(2) Male, aged 44, on whom a suprapubic excision of a bladder neoplasm was performed on Oct. 15th, 1919. The tumour was reported to be a papilloma by the pathological department. He died six years later in Southwark Infirmary on Dec. 27th, 1925, "after many operations," his death being certified as due to "epithelioma of bladder."

(3) A charwoman underwent on Nov. 8th, 1911, a suprapubic excision of a papilloma of the bladder. The diagnosis was confirmed microscopically. She was readmitted ten years later and at cystoscopy another tumour was seen. This was removed by the suprapubic route on Feb. 9th, 1921. The pathological report was "papilloma; there are also foci present at the base which must be regarded as an early carcinomatous change." She died a year later.

That even pathological examination as a means of diagnosis was not always to be depended on, the following cases show :—

(4) A governess, aged 64, was admitted to hospital in May, 1917. At cystoscopy a tumour was seen. A suprapubic cystotomy was performed on May 30th, 1917, and a growth the size of an orange was removed, together with a portion of the bladder wall which was adherent to the bowel. The left ureter was involved. One and a quarter inches of the latter were excised and the remaining portion was transplanted into another part of the bladder wall. The pathological report on the tumour was "carcinoma." Four years later the patient was again admitted to hospital with symptoms, and suprapubic excision of a tumour was performed. The pathological report on this tumour was "papilloma." The patient was still alive in 1926, nine years after the alleged carcinoma had been removed, and was free from all symptoms.

(5) A labourer, aged 60, was admitted to hospital in May, 1918. At cystoscopy a growth was seen. This was excised suprapubically on May 16th, 1918, the pathological report being "carcinoma." Three years later the patient was again admitted with a recurrence, which was excised, and also reported on as a carcinoma. He attended in January, 1926, and was then in excellent health and free from all bladder symptoms, eight years after his first operation.

In the last two cases the length of time which had elapsed since the first diagnosis and treatment of the tumour, and in which the patients had been free from symptoms, might almost be regarded as evidence against the previous diagnosis of carcinoma. In fact, as pointed out by Raymond Johnson and T. W. P. Lawrence,[1] "it is extremely difficult, if not impossible, to determine whether a papillary tumour of the urinary tract is entirely benign."

Methods of Treatment.

The age and constitution of the patient, the type of tumour, its position and size, and the amount of involvement of the surrounding structures, all have their influence on the line of treatment. Successful treatment depends primarily on early diagnosis, and the use of the cystoscope for this purpose is of enormous advantage. With the modern instrument very little experience is required. Before its introduction the diagnosis was made from the patient's symptoms, by rectal examination, and by the use of a sound.

The methods of treatment employed on the above-mentioned 168 cases were either radical or palliative. The radical treatments were as follows :—

(*a*) *Defulgurisation*, or cauterisation of the tumour by means of a bi-polar high-frequency current, applied by a pointed flexible electrode through a cystoscope, such as is used for catheterising the ureters. The other electrode consists of a flat piece of metal which is held in close contact with the patient's thigh by a bandage. The bladder is previously distended with warm normal saline solution. The part of the tumour in contact with the pointed electrode shrivels up when the current is passed, and the whole tumour is destroyed by moving the electrode. Several applications at intervals of a week or ten days may be necessary.

This method is suitable for small tumours or small recurrences. It does away with the necessity for opening the bladder and is very useful in destroying small seedlings. It cannot, however, be used when there is much hæmorrhage. This method was used alone, or previous or subsequent to other methods of treatment, in 50 cases.

(*b*) *Excision of the tumour* through a suprapubic opening into the bladder may be performed with an electric or thermal cautery, curette, or knife, according to the consistency of the tumour and its liability to hæmorrhage. The diathermic cautery prevents hæmorrhage and is said to prevent the dissemination of seedlings. (Only one case showed dissemination of growth in the scar of the abdominal wall.) Suprapubic excision was used in 85 cases, either alone or previous or subsequent to other operations.

Twenty cases were treated by both the above methods, at different times.

(*c*) *Partial cystectomy* entails removing the tumour together with the surrounding bladder wall and involved structures. The ureters may have to be transplanted into another portion of the bladder or into the colon or skin, or a urinary fistula may be established. This operation was performed five times in the series. Complete cystectomy was never done.

No other forms of radical treatment were employed.

Palliative treatment resolved itself into operative and non-operative. The operative treatment consisted in suprapubic cystotomy, with drainage or the insertion of radium into the growth. This was done in 32 cases. Non-operative treatment, consisting of bladder lavage and deep X ray therapy, was the only thing possible in 20 cases.

Recurrence and After-history.

No matter what form of treatment was adopted, recurrences were frequent. Of the 59 patients known to be alive in 1926, 34 only have had no recurrences. Six of these were treated less than two years before the end of 1926, leaving 28 who have been two years or more without recurrence. Table III. shows the number of years they have been free from symptoms, and the particulars of their treatment.

TABLE III.

Years free from symptoms.	Suprapubic excision.	Defulgurisation.	Partial cystectomy.	Total.
2	4	3	—	7
3	2	1	—	3
4	4	—	2	6
5	3	1	—	4
6	2	—	—	2
7	—	—	—	—
8	1	1	—	2
9	1	1	—	2
10	—	—	—	—
11	—	—	—	—
12	1	—	1	2
Totals ..	18	7	3	28

The number of cases among the whole 116 of the series who were traced, in which one or more recurrences took place, was 48. Table IV. shows the number of recurrences and details of their treatments. In addition to the cases tabulated one patient had an uncertain number of recurrences.

---

[1] A System of Surgery. Edited by C. C. Choyce, i., 483.

To summarise: Of the 116 patients who were traced to 1926 or to a fatal termination, 59, or 50·9 per cent., were still alive in 1926; 34, or 29·3 per cent., of them had had only one treatment and had no recurrences. As shown in Table IV., 48 of the 116, or 41·4 per cent., have had one or more recurrences. The remaining patients died after a single treatment, either radical or palliative. Treatment can, therefore, only be said to have been absolutely successful in 29·3 per cent. From Table II. it will be seen that the average duration of life after operation is 5·5 years. The total number of patients who had suprapubic excision only was 31 and those who had defulgurisation only 16. The percentage of absolutely successful treatments by suprapubic excision alone was 58·4 per cent., and by defulgurisation alone 43·75 per cent.

* Combination of defulgurisation and suprapubic excision at different times.

These figures are so small that very little value can be attached to them, and they give no indication of the type of tumour treated. Nevertheless, they seem to point to the fact that, in the large majority of cases, suprapubic excision gives the better results. Of the two patients in whom the disease occurred at the early age of 18, the male underwent a suprapubic excision in 1921 and has been free from symptoms since then. Defulgurisation on the female in 1922 was followed by two recurrences, both of which were also defulgurised, the last occasion being in 1926.

Rafin's statistics of the operation of suprapubic excision, quoted by Sir J. Thomson Walker,[2] show a mortality-rate of 3·8 per cent. in 156 cases, and recurrence in 28 per cent. The corresponding figures in this series (taken only from traced cases) were 6·2 per cent. and 43 per cent. respectively. It must, however, be borne in mind that many of the cases in this series were definitely carcinomata, whereas Rafin's statistics relate only to papillomata, and are, therefore, likely to be much more favourable.

Conclusions.

1. Epithelial vesical tumours have a high rate of mortality, in spite of treatment.
2. Males are more susceptible to the disease than females, in the proportion of 3 to 1.
3. Papillary tumours tend to recur in a large number of cases; in this series in 41·4 per cent.
4. The diagnosis of malignancy is extraordinarily difficult in many cases, and pathological examination cannot be relied upon.
5. Treatment of the tumours by means of suprapubic excision seems to yield slightly more favourable results than defulgurisation.

I should like to acknowledge my indebtedness to Sir Cuthbert Wallace, director, and Mr. B. C. Maybury, assistant director, of the Clinical Surgical Unit, St. Thomas's Hospital, for their useful suggestions and advice in the compilation of this thesis; to Mr. C. A. R. Nitch, for the use of his own records; to Mr. C. V. Patrick, late surgical registrar, for facilities in looking up the records, and to Miss J. E. Creese, secretary to the clinical units, for her valuable assistance in helping to trace a large number of patients.

---

INFECTION WITH *B. DYSENTERIÆ* SONNE.

A FATAL CASE INVOLVING THE SMALL INTESTINE AND SIMULATING FOOD POISONING.

BY F. H. A. CLAYTON, M.D., M.R.C.P. EDIN.,
LECTURER IN BACTERIOLOGY, UNIVERSITY OF DURHAM COLLEGE OF MEDICINE;
AND
J. W. HUNTER, M.B., CH.B. EDIN., B.HY., D.P.H. DURH.,
R.M.O., CITY HOSPITALS, NEWCASTLE-ON-TYNE.

THE recovery in the College of Medicine laboratory, Newcastle-on-Tyne, of dysentery bacilli from a considerable number of undiagnosed cases has led during recent years to an increase in the number of specimens submitted and a steady rise in the number of positives. The majority of the cases have been comparatively mild, with definite symptoms, but there has been a proportion, mainly in young children, with ill-marked signs, in which the disease has been fulminant and the organism isolated post mortem. An interesting point is that on more than one occasion the organism has been isolated very many hours after death; this raises the question whether its unusual persistence may not be related to an absence of bacteriophage similar to that lately described by d'Herelle and Malone[1] in acute cholera.

Until recently, all these fatalities had resulted from one or other variety of *B. dysenteriæ* Flexner, but in the following case the organism proved to be the bacillus first described by Sonne,[2] of Copenhagen, and now usually known by his name. The common experience is that this organism gives rise to mild attacks, but Mita,[3] in describing two organisms which he named pseudo-dysentery A and B, recorded six fulminating and fatal cases in a total of 73, although most of them were mild.

Smith[4] seems to claim that Mita's organisms are one and the same with *B. dysenteriæ* Sonne; their reactions, as described, are identical. Cultures, obtained from the National Collection, were found not only to give precisely similar reactions to those of the Sonne organism, but also to agglutinate well with the Oxford Sonne serum.

CASE 1.—The patient was a boy, aged 11, whose family consisted of father, mother, three sons, and a daughter. On May 16th, 1928, he had a severe headache, complained of tiredness and went to bed, but by next day had recovered. On the 20th, at about 10.30 A.M., he complained of pains in the stomach, which were succeeded by diarrhœa with brown slimy motions, and in the evening by several attacks of vomiting. At 5 A.M. on the 21st he was found in bed unconscious and incontinent. He was admitted to the Infectious Diseases Hospital at 1 P.M. the same day. He remained unconscious, vomited once—greenish fluid with mucus—and, still incontinent, with blood and mucus in the motions, he died at 8 P.M.

The post-mortem examination, held 13 hours after death, revealed marked congestion, chiefly of the ileum and cæcum and to a lesser extent of the descending colon. The adjacent lymphatic glands were slightly enlarged and there was definite splenic enlargement. The heart, liver and kidneys showed definite toxic changes. No gross pathological change was detected in the central nervous system. The stomach and a portion of small intestine and of colon were ligatured and sent direct to the laboratory, together with the spleen, but no blood could be obtained. The colon and stomach were found to contain adhesive mucus and films from the former showed inspissated epithelium. The portion of small intestine, which was inflamed, contained blood-stained liquid fæces, and films showed this to consist mainly of red-blood and pus cells.

Cultures, both direct and after brilliant green reinforcement, were sown on MacConkey plates from the contents of the hollow viscera and the spleen. No pathogenic organisms were obtained from the stomach, colon, or spleen, but the plates from the intestine showed large numbers of white colonies with crenated edge and heaped-up centre, which in 24 hours gave the reactions of *B. dysenteriæ* Flexner. They differed, however, in the following particulars, which have been found to be very suggestive of *B. dysenteriæ* Sonne. Growth was unusually profuse and there was a tendency to sedimentation, while production of acid from glucose and mannite was more marked after 24 hours than is usual with *B. dysenteriæ* Flexner. Brilliant green seemed to have comparatively little inhibitory effect, a point also noted but not recorded with a previous case.[5]

Subsequently the reactions changed in the manner characteristic of *B. dysenteriæ* Sonne, including the late clotting of milk. Nine colonies give similar reactions and with five of these agglutination was tried against polyvalent Flexner, typhoid, and a rather old "Sonne" serum. There was a total absence with the first two, but all showed more or less agglutination with the last. The most agglutinable strain was then tried against the Oxford serum, and agglutinated to practically the same titre as the homologous emulsion, although it failed to show a trace with the five Flexner-type Oxford sera.

Inquiry into Food Ingested by the Patient and the Rest of Family.

The patient appears to have partaken of the ordinary meals of the family up to May 20th, including sausage for dinner on the 19th, but none of the others showed any signs of illness at the time. In addition, he had ice-cream on the 19th and some whelks about noon of the day (20th) on which he first developed severe symptoms.

One of his brothers (A), about a month previously, together with two other boys, one (Case 2) living in the upper flat of the same house and one (B) further along the street, ate some bruised fruit and all became ill. A and B had evanescent symptoms, but Case 2 died after a few hours' illness. The father of my patient, aged 53, was ill from May 31st to June 3rd, with pains in the stomach and slight diarrhœa, which he ascribed to drinking some water from a "runner" in the country while on holiday on the 28th. None of the other members of the family seemed to have been ill.

The family, of which the second fatal case was a member, lived, as already mentioned, in the upper flat, and consisted of father, mother, and three children under 12.

CASE 2.—This boy, aged 7, after eating the bruised fruit on April 11th, became ill at 8 P.M. of that day, with pains in the head, vomiting, but no diarrhœa, and died three hours later. The death was inquired into by the coroner and a post-mortem was held, but unfortunately, owing to a misunderstanding the gut was slit from end to end during the autopsy and washed, so that when it arrived at the laboratory it was not possible to carry out a proper bacteriological examination, and no pathogenic organisms were isolated.

Dr. G. E. Stephenson, who performed the post-mortem, has kindly given an account of the findings:—

> "Stomach, duodenum, ileum and large intestine all showed hyperæmia. There was in the ileum, especially in the upper part, well-marked swelling and hyperæmia of Peyer's patches, with general hyperplasia of lymphoid tissue, there as well as in large intestine. The spleen was slightly enlarged and the liver showed an acute toxic change. No gross naked-eye change was apparent in the other organs."

This boy is said, with several others, to have had some ice-cream on the previous day, but there is no evidence to incriminate this. In addition to the three boys, the father of Case 2 is said to have suffered from diarrhœa on the night of April 11th, but otherwise there is no history of illness in the family.

The Question of a Carrier.

As soon as it was determined that the organism isolated from Case 1 was *B. dysenteriæ* Sonne inquiry was made whether any members of the two families had been in districts where the disease has been prevalent. None of the family gave such a history, but the father of Case 2 had been in Glasgow for eight months, and only returned at Easter, just before his son became ill and died. This is rather a coincidence, although there was in this case no direct evidence of the nature of the infection, and the father's blood and fæces, when examined on one occasion, proved negative. The blood and fæces of the entire family of Case 1 were examined on two occasions, and on the first an organism giving the typical Sonne reactions was isolated from the fæces of the father and the daughter. Tested against Oxford Sonne serum these proved inagglutinable, but eventually, after considerable subculture, they displayed some degree of agglutinability. Curiously enough, however, an organism was isolated in large numbers almost at the same time from an entirely unconnected case, a girl of 1½ years suffering from dysenteric symptoms, and this gave similar reactions and proved persistently inagglutinable even after subculture. The blood serum of the family of Case 1 showed no evidence of agglutinins against the organism isolated.

Discussion.

Judging from this case and from Mita's experience, it would appear that the Sonne bacillus may give rise at times to severe enteritis and fatal toxæmia. Wiseman,[6] in describing a Glasgow outbreak of enteritis due to the Sonne bacillus, has recently called attention to the occurrence of inagglutinable types of the organism. This is borne out by my case and is interesting in view of the three outbreaks of food poisoning, with three fatalities among children (recorded by Savage and Bruce White[7]), in which the organism isolated gave the reactions of Sonne and proved inagglutinable with a specific serum, although it was partially agglutinated by a serum prepared from Getting's bacillus.

No definite evidence of the source of infection could be obtained, and it is quite possible that the dietary indiscretions which preceded the illness of the two boys and the father may merely have served to fan the flame of an already existent but dormant infection. The father, at all events, was found later to be harbouring the organism.

Addendum.—Since this paper was written a very similar case has been recorded by Howel Evans.[8] Dr. W. M. Scott, of the Ministry of Health, to whom the cultures were sent, has since found that all four strains agglutinate well with a Sonne serum.

A SIMPLE METHOD OF PERFORMING ARTHROPLASTY IN TRUE ANKYLOSIS OF THE JAW.

BY ARNOLD K. HENRY, M.B. DUB., F.R.C.S. IREL.,

PROFESSOR OF CLINICAL SURGERY, FACULTY OF MEDICINE,
CAIRO; AND DIRECTOR OF THE SURGICAL UNIT,
KASR-EL-AINI HOSPITAL.

IN the excision of the mandibular condyle surgical freedom is limited in three directions: below, retraction may stretch the facial nerve; above, the brain has more than once been injured; and, on the medial side, the internal maxillary artery lies close to the neck of the mandible. Tubby[1] figures 12 different incisions for excising the joint—a sign that none is satisfactory—and whichever the surgeon employs he is cramped if he uses ordinary tools. This constraint and risk of injury disappear with the use of the special drill devised by Hudson for opening the skull. Two advantages make this well-known drill the instrument of choice for removing bone in ankylosis of the jaw: (1) it can be used in a cramped field, thus leaving no excuse for stretching the facial nerve; (2) it jams directly it perforates, and does no injury to brain or vessel. The Hudson drill does not fail to stop provided the bone can resist sufficiently to prevent the drill being pushed through it. I have once seen the drill plunge into a dog's cerebellum but, warned by this accident, we have been able to avoid it in a series of more than 40 intracranial experiments, made in collaboration with Prof. Heathcote. We have learnt that the drill can safely be used on very thin bone if the pressure is gentle and discriminate. There is, of course, no risk of unintentional penetration when drilling the bony mass in true ankylosis of the jaw.

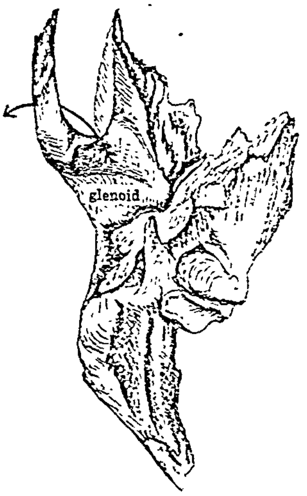
---

[1] Tubby, A. H.: Deformities, including Diseases of the Bones and Joints.

The Operation.

The tragus is a useful landmark, since the normal line of the joint, continued back, bisects its base. The joint lies one finger-breadth in front of it. The incision begins in front of the tragus, immediately anterior to the pulsation of the temporal artery; it extends for one and a half inches along the lower border of the zygomatic arch. From the hinder end of this cut a second is made, at right angles to the first, extending vertically for four inches above the zygoma and for half an inch only below it. This incision is, of course, a common one for arthroplasty of the jaw, and—provided the Hudson drill is used—gives good access. It is my practice here, as in every "clean" operation. to apply side-curtains. They are fixed to the skin by means of Michel clips, as I have recommended elsewhere for small or multiple incisions.[2] In this way the surgeon is not embarrassed by the handles of towel-forceps. A clip bisecting the base of the tragus marks the level of the normal joint. The site of ankylosis is exposed by displacing downwards and forwards the hindmost fibres of the masseter muscle. The three bits of the Hudson drill, usually numbered 1, 2, and 3, are used in this order to remove the ankylosing bone, just as they are used in drilling the skull. the bits numbered 2 and 3 enlarging the hole made by the first. All these jam directly they have pierced the bone.

FIG. 1.

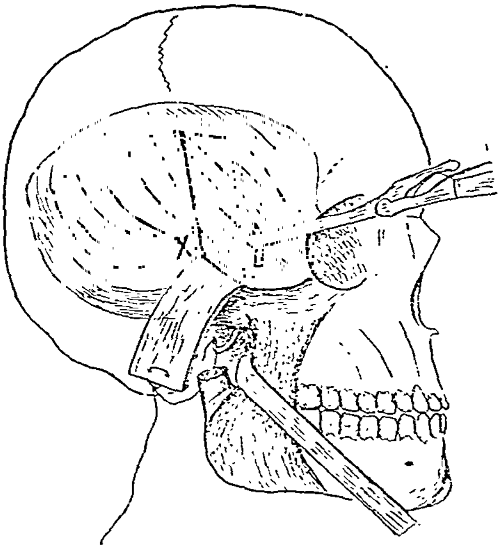


The glenoid fossa of the temporal bone seen from below, showing how the free arch of the zygoma here becomes a shelf. The suture guiding the fascial flap must—like the arrow—avoid the shelf and go *forward* under the arch.

The Fascial Flap.—A flap of fascia is next cut—either from the temporal fascia itself or from the fatty connective tissue covering it—for interposition between the neck of the mandible and the site of the glenoid cavity. Writers vaguely advise that this flap be sutured into place, which is not easy to do as the bottom of the deep, narrow wound is unsuited for placing a stitch. A neat adjustment can be made by a simple manœuvre suggested to me during an operation by my former clinical assistant, Dr. Edward Sadek. The middle part of a catgut suture is fastened to the free extremity of the flap and, by means of a curved needle, each end of the catgut is brought in turn from below upward, deep to the arch of the zygoma. The needle goes through the temporal muscle and the flap is drawn down into place by pulling on the suture; it is then made fast by knotting the ends of the catgut on the temporal belly.

The Hinge.—A detail of anatomy in the skull makes it imperative to hinge the flap in such a way that when the suture guiding it is drawn under the zygoma the flap will fully separate the raw faces of the new joint. Fig. 1 shows that it is not possible to pass a needle directly round the zygoma at the glenoid site, for at that place the free bony arch becomes a shelf attached to the skull. The needle which carries the guiding suture must, therefore, travel upward beneath the arch in a forward direction. If, then, the base of the flap is parallel to the zygoma, the fascia—strained forward by the suture and folding on a transverse hinge—will come to lie in a futile, ectopic, position in front of the glenoid site. The flap, however, can be made to lie properly by providing its pedicle with a hinge which is oblique; it then folds vertically down under the forward strain (Fig. 2). The correct slope of the hinge is obtained by cutting the flap in the form of an inch-wide strip, with its free end three inches above the zygoma, taking care that in front the incision goes right down to the zygoma, and behind stops a thumb's-breadth short. The flap, hinged obliquely in this way at the pedicle, would of itself droop backwards, but under the forward pull of the guiding suture it takes a middle course and folds straight down into place. A final stitch serves to fix the centre of motion.

FIG. 2.



The flap is outlined by a long cut in front and a short cut behind; its pedicle has therefore an *oblique* hinge. The flap folds vertically when pulled forward by the guiding suture and so covers the glenoid area. (A stitch at X fixes the centre of motion.)

After-treatment.—The patient is encouraged to chew and should begin to try when he recovers from the effects of anæsthesia. A boy, aged 15, who had had a bilateral ankylosis of the jaw for three years, was able to chew meat on the fourth day after his second arthroplasty. The first arthroplasty was done ten days before the second.

My thanks are due to Dr. Boris Boulgakow, Curator of the Museums of the Faculty of Medicine, Cairo, for the two figures which illustrate my paper. The finishing touch of the oblique hinge I owe to my wife.

LIVERPOOL OPEN-AIR HOSPITAL FOR CHILDREN.—On Saturday last the Earl of Derby opened a new artificial light and treatment block which has been added to this hospital at a cost of £17,000. In addition to the artificial light treatment rooms the block contains an operating suite, a dental department, plaster and X ray rooms, gymnasium, laboratory, and dispensary.

FEE FOR REPORT TO CORONER.—The Finance Committee of the Worcestershire County Council, having received a suggestion from the local branch of the British Medical Association that medical practitioners who supply to coroners at his request a written report in connexion with a death should be paid a fee of 10*s.* 6*d.* for the report, and having been informed that it is legal for local authorities to authorise such payment, has recommended the Council to pay the fee.

Clinical and Laboratory Notes.

TWO CASES OF FAMILIAL ENLARGEMENT OF THE THYMUS

ASSOCIATED WITH COLLAPSE OF LUNG.

BY GERALD M. SLOT, M.D., M.R.C.P. LOND., D.P.H.,
PHYSICIAN TO THE ROYAL WATERLOO HOSPITAL AND ROYAL HOSPITAL, RICHMOND; HARMSWORTH RESEARCH FELLOW.

THE interest of these cases lies chiefly in the fact that two members of the family seem to have died of the same condition—a syndrome in which gross enlargement of the thymus is associated with the collapse of the right lung.

CASE 1.—G. W., aged 5 months, was admitted to Guy's Hospital on Nov. 10th, 1926, complaining of dyspnœa and cyanosis, which had existed since birth. The respiration was entirely thoracic and inverted—*i.e.*, the abdominal wall was retracted during inspiration. Breathing was laboured, with occasional sighing respiration. Previous to an X ray, three diagnoses were suggested: (*a*) Anterior poliomyelitis affecting the phrenic nerve. (*b*) Birth injury affecting the phrenic nerve. (*c*) Diaphragmatic hernia. An X ray examination taken without a bismuth meal showed a large opacity at the left apex which was thought to be the thymus gland.

While the patient was being given a bismuth meal for an X ray examination in view of the possibility of diaphragmatic hernia, the meal was suddenly regurgitated through the mouth and nose. He became very cyanosed and died suddenly on Nov. 11th, 1926. At the post-mortem the thymus was found to be about three times its normal size, weighing 26 g., and was partially adherent to the pericardium. There was a collapse of the upper and middle lobes of the right lung and partial collapse of the lower lobe of the right lung.

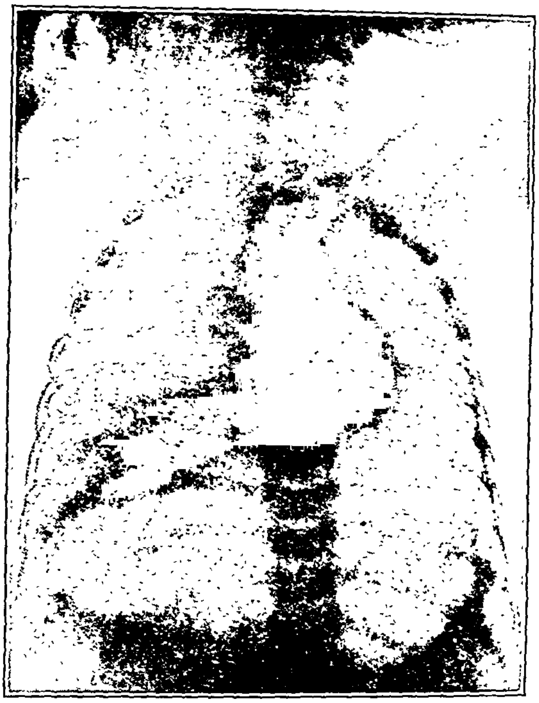
CASE 2.—E. W., sister of G. W., was admitted to the Royal Waterloo Hospital with respiratory embarrassment for observation and diagnosis on July 25th, 1928. She was 5 months old. Two months before admission she had shown signs of difficulty in respiration. This became more marked, so that the child could only feed at the breast for five minutes at a time. The confinement had been normal and the weight at birth 6 lb. 11 oz.

On admission the child was ill-nourished, pale, but not cyanosed. The finger-nails and ends of the fingers were normal. The cry was weak and infrequent. She lay in the bed with the head fully retracted, but the retraction was not fixed. The striking feature was the marked inspiratory effort, which ended in a short grunt and involved the whole accessory muscles of respiration, abdominal, thoracic, and alæ nasæ. The respiratory rate was, on an average, 45 per minute. Temperature averaged 99° F. and the pulse 140. The mouth and upper air passages were clear, the heart not displaced; rhythm and heart sounds were normal. The chest was not retracted, but there was practically no movement of the right side. The percussion note was dull from the base to the apex, both anteriorly and posteriorly on the right side. Breath sounds were very weak and distant, the air entry being very feeble. The breathing was vesicular and no adventitious sounds were heard. The left side of the chest appeared normal. Nothing abnormal could be felt in the suprasternal notch, and there was no enlargement or displacement of the liver or spleen. No enlarged glands were palpable.

A skiagram (here reproduced) showed a heavy shadow extending from the right of the mediastinum upwards into the neck; the right side of the diaphragm was elevated. The stomach was large and distended with gas. The right lung has evidently re-expanded to some extent. The shadow was compatible with thymic enlargement.

The child took her feeds well and was at the start fed partly by breast, but gradually lost weight in spite of all feeding efforts and died on August 2nd, 1928.

The *autopsy*, performed by Dr. H. W. C. Vines, showed the body of a well-nourished infant with no external injuries. When the thorax was opened, the thymus appeared to be enlarged, the lungs collapsed and small. The thymus weighed approximately 56 g. The lungs were slightly congested. The left lung floated in water, but the right (smaller) lung did not. Their appearance suggested collapse or failure to expand rather than pathological consolidation. The trachea showed no gross evidence of compression. The heart showed minute petechial hæmorrhages under the visceral pericardium. The veins were dilated. The liver, spleen, and kidneys were congested. The intestines did not show any very marked enlargement of the lymphoid follicles. There were numerous rather enlarged lymph glands in the mesentery. The cortex of the suprarenals appeared to be rather thin, and the medulla not very evident. There was no evidence of hæmorrhage. Microscopically, the thymus appeared active and vascular. Hassall's corpuscles were numerous and large. The lung showed collapse and congestion; the mesenteric lymph glands simple enlargement. In the suprarenals the medullary cells were present in patches, but appear to have been replaced by vascular connective tissue.



CASE 2.—Skiagram showing heavy shadow extending from the right of the mediastinum upwards into the neck.

Remarks.

In a large number of post-mortem examinations where death has occurred either under anæsthetic or suddenly in young children, I have found a large thymus, but have never previously observed any collapse of the lung. These, however, have been acute cases where there has been no previous history of respiratory distress. In Case 2 there was no evidence of tracheostenosis or compression. It is difficult to say definitely whether the right lung had ever expanded or whether the collapse was of post-natal origin. The absence of recession and the non-displacement of the heart, together with the X ray appearances, would seem perhaps to indicate a gradual collapse.

Dysthymic constitutions are well recognised as having constitutional disturbances, delayed growth, and sometimes rickety changes. The noisy respiration, with a slight souffle, best heard in the horizontal position, are well known. Acute phenomena pass away but leave the child in a state of torpor which may give rise to anxiety. Percussion and skiagrams, especially when there is a large mediothoracic shadow, greatly increased in its upper part, may give a clue.

Various reasons have been suggested for death due to thymic conditions—*e.g.*, vagal stimulation, compression of inferior cardiac nerve, stimulation of cardiac centres producing inhibition, compression of phrenic nerve producing diaphragmatic paralysis, lymphotoxæmia. Much discussion has centred round the question as to whether direct pressure of the thymus on the trachea is responsible for the dyspnœa.

In Case 2 the retraction of the head would tend to project the vertebræ forward and diminish the superior opening of the thorax. Since the enlargement was chiefly on the right side, obstruction, if obstruction there was, would probably be on the right main bronchus, causing the abnormal condition of the right lung. There was no evidence of tracheostenosis in this case and none to support J.-A. Hammar's contention that most cases of thymic death are due to compression of the trachea. Through the courtesy of Dr. F. Parkes Weber, I have traced an account[1] of familial sudden thymic death, but in the cases recorded above death was not sudden or unexpected.

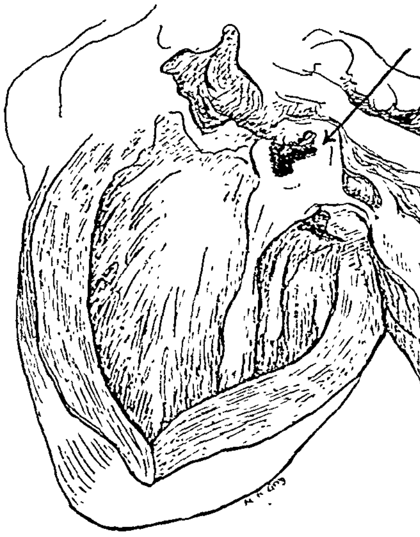
I have been unable to trace in the literature a description of familial cases with enlargement of the thymus associated with a collapsed condition of the right lung.

I am indebted to Mr. H. L. Eason and Dr. H. C. Cameron, of Guy's Hospital, for the account of Case 1, and to Dr. A. S. Woodwark for permission to publish Case 2. I should also like to thank my house physician, Dr. C. G. Walker, for help with the clinical investigation.

A CASE OF ANEURYSM OF THE MITRAL CUSP.

BY W. S. WHIMSTER, M.B. LOND.,
RESIDENT MEDICAL OFFICER, ANCOATS HOSPITAL, MANCHESTER.

DURING the course of malignant endocarditis bacterial emboli break off from the affected valves and are distributed all over the body. These emboli cause septic infarction of the organs in which they are arrested. When, as not uncommonly occurs, the site of arrest is a vas vasorum, a mycotic aneurysm may follow; this event may take place in any artery. Osler reports a case in which five such aneurysms were present in the thoracic aorta. Many other cases have been put on record, and every artery of any size has been affected. More rarely the site of aneurysm formation is the heart itself, and in such cases the lesion may involve the valves. According to Osler (System, 1908), the commonest site for such an aneurysm is the aortic valve, in which case the cusps are dilated towards the ventricle. Less commonly, a similar condition occurs in the mitral valve, the aortic cusp being more frequently affected than the posterior. In any of these sites the aneurysm may rupture or may be filled with fibrin. The following case illustrates the commoner type of mitral aneurysm.



Drawing of heart showing aneurysm of the mitral cusp.

A girl of 15 was admitted into Ancoats Hospital under the care of Dr. Kletz on Feb. 2nd, 1928, suffering from pyrexia. The previous history showed measles and chickenpox. For many years she had been troubled with rheumatic pains and stiffness of the knees, but recently she had been free from them. Her present illness began insidiously at Christmas, 1927, with headache and severe lassitude. During the first week in January she had a sensation as of a purple veil drawn over the outer half of the visual field of the right eye. After a few days this disappeared. She then tried to resume work but had to return to bed. The headache increased in severity during the last week before admission; she became very short of breath and purple painful spots appeared on the fingers and toes, remained for a day or so and disappeared. The sensation of the purple veil over the right eye returned. For a day or so she complained of pain in the right loin, but had no hæmaturia. There had been no indigestion and the bowels were regular.

Examination.—Patient was extremely pale, with a floury skin and slight malar flush. Intelligence and cheerfulness above normal, as is frequently noted in this disease. Nothing abnormal was found in the alimentary and respiratory systems. The apex-beat was found in the sixth space in the anterior axillary line. A very harsh systolic murmur was heard in the mitral area. This was propagated to the axilla and was heard behind. There were systolic and presystolic murmurs in the aortic area. The heart rhythm was regular. Blood pressure was 110/80. There were some petechiæ, red and painful to touch, the feet and conjunctiva being most affected. There was a small hæmorrhage in the macular region of the right fundus oculi, which probably accounted for the purple veil sensation.

During the course of the disease, which lasted for three weeks in hospital, no change was found in the heart. The temperature was swinging up to 102° F., but blood culture was negative. At no time was the spleen felt.

Post-mortem Examination.—The heart was much enlarged. The right side was normal, the left side greatly hypertrophied and dilated. The mitral valve was encrusted with recent vegetations. In the aortic cusp of the valve was an aneurysm extending three-quarters of an inch into the auricle. This was ruptured at its apex, and the margins were covered with vegetations. The aortic valve was also scarred and encrusted with recent vegetations. The only other abnormality found was an old infarct of the left kidney.

In all probability the rupture of the aneurysm had taken place some weeks previously and the resulting incompetence was responsible for the harsh systolic murmur.

I am indebted to Dr. Norman Kletz, under whose care the patient was admitted, and to Dr. Arnold Renshaw, pathologist to the hospital, for permission to publish this case.

THE BROMSULPHALEIN TEST IN EARLY DISEASE OF THE LIVER.

BY A. D. FRASER, B.SC., M.B. GLASG.,
PATHOLOGIST TO THE BRISTOL ROYAL INFIRMARY.

THE bromsulphalein test for liver function, introduced by Rosenthal and White,[1] depends upon the capacity of the liver cells to remove the dye phenoltetrabromphthalein sodium sulphonate from the blood stream and excrete it in the bile.

These authors found that when a certain amount of the dye—2 mg. per kg. of body-weight—was injected intravenously, none of it could be demonstrated in the blood 30 minutes later if the liver were normal. In marked liver disease, however, there was retention of dye, the amount retained being apparently proportionate to the degree of damage to the liver. No cases of early liver disease were examined by Rosenthal and White, but they suggested that the amount of dye retained five minutes after the injection would indicate the extent of the liver insufficiency. In their series of normals the dye retention at the five minute interval varied from 20 to 50 per cent., with an average of 35 per cent. There were no local or general ill-effects from the use of the dye.

Others have made use of this test, and report favourably on it as a hepatic function test in advanced disease of the liver. Friedenwald and Armstrong[2] found retention of the dye in catarrhal jaundice,

cirrhosis of the liver, and carcinoma of the liver. A negative result in two cases of cirrhosis of the liver with free abdominal fluid was regarded by them as due to compensatory hyperplasia of liver cells. Vaughan's[3] opinion was that in obstructive jaundice, and in jaundice due to liver damage, the bromsulphalein retention agreed roughly with the bilirubin retention. King[4] and Siegel[5] considered that the test might prove useful for the differentiation of nephritic and pre-eclamptic types of toxæmia and of neurotic and toxic vomiting.

To determine the usefulness of this test in early liver disease a series of patients with suspected minor degrees of liver insufficiency were chosen, and the lævulose-tolerance and bromsulphalein tests were compared. In each case also some indication of the degree of disturbance in pigment metabolism was obtained by estimating the blood bilirubin by van den Bergh's method. The technique used in the dye test was as recommended by Rosenthal and White, and the bromsulphalein was obtained in 5 per cent. solution from Messrs. Hynson, Westcott, and Dunning, of Baltimore, U.S.A. The exact quantity, in cubic centimetres, of this 5 per cent. solution to be injected was obtained by dividing the patient's weight in pounds by 55. The amount of dye retained in the blood was determined at intervals of 5 and of 30 minutes.

For the lævulose-tolerance test half-hourly estimations of the blood-sugar were made for two hours after the ingestion of 50 g. of lævulose on a fasting stomach. A rise in the blood-sugar of 20 mg. with a non-return to normal was considered positive.

The results of these tests are given in Table I., and the figures obtained with the dye test in six normal individuals are shown in Table II.

TABLE II.—*Normals.*

Sex.	Age.	Bromsulphalein test. Percentage of dye retained. 5 minutes.	30 minutes.

M.	52	15	0

Summary and Conclusions.

Of 20 cases with early liver disease the lævulose-tolerance test was positive in 16, while the bromsulphalein content of the blood serum 5 and 30 minutes after injection of the dye showed no variation from the normal. Ten of the 16 had bilirubin retention. The five-minute interval retention of bromsulphalein does not appear to afford much information in early liver disease, nor does the retention of bromsulphalein run parallel with the bilirubin retention.

I am indebted to my colleagues on the staff of the Bristol Royal Infirmary for their kindness in allowing me to examine their patients.

INTERNATIONAL HOSPITAL CONGRESS, 1929.—On August 29th, at the headquarters of the League of Red Cross Societies in Paris, a meeting was convened of the International Executive Committee of the International Hospital Congress, of which Dr. René Sand, Technical Counsellor of the League of Red Cross Societies, is chairman, and Dr. Lewinski-Corwin, Director of the Hospital Information and Service Bureau, United Hospital Fund, U.S.A., is secretary-general. Great Britain was represented by Mr. J. Courtney Buchanan, honorary secretary of the British Hospitals Association; Mr. W. H. Harper, house governor of the Wolverhampton and Staffordshire Hospital; and Mr. G. Watts, representing the Incorporated Association of Hospital Officers. The committee agreed with the American Hospital Association in its proposal to hold the International Congress at Atlantic City on June 13th–15th, 1929. In accordance with the practice of the American Hospital Association, the Congress is to be open to hospital administrators, physicians, surgeons, nurses, architects, engineers, and others interested in hospital problems. Official invitations are to be sent to the various Governments through the Secretary of State in Washington, and at the same time a questionaire will be sent to each country on its hospital situation and statistics. The American Hospital Association proposes to organise a tour of inspection of the hospitals of New York, Philadelphia, Baltimore, and other centres for the benefit of the official delegates from June 5th to 12th. The object of the Congress, the first of its kind, is to facilitate personal contacts, to provide for exchange of information, and to promote discussion among persons interested in hospitals throughout the world, whether public or voluntary. The preliminary programme provides for an address on essential hospital functions, and this will be followed by discussions on hospital planning in relation to economy and efficiency, the problem of hospital economies, the respective fields of public and private hospital work, the questions related to psychopathic hospitals and hospitals for chronic disease, and various other matters such as the creation of an International Hospital Association. For further particulars of the International Hospital Congress, the membership fee of which is five dollars, inquiries should be addressed to Dr. René Sand, 2, Avenue Velasquez, Paris VIII.; or to Dr. E. H. Lewinski-Corwin, the American Hospital Association, 2 East 103rd Street, New York.

Reviews and Notices of Books.

THE GENESIS OF EPIDEMICS.

By CLIFFORD ALLCHIN GILL, M.R.C.S., L.R.C.P., D.P.H., D.T.M. & H. Eng., Director of Public Health, Punjab. London: Baillière, Tindall and Cox. 1928. Pp. 550. 21s.

THE havoc wrought throughout the world by epidemic diseases makes the solution of the problem of their causation one of peculiar interest and importance. Theories and speculations to account for their occurrence have not been lacking; and, although many of these have been proved to be inconsistent with the facts revealed by advancing medical knowledge, there is still no unanimity of opinion among epidemiologists. It is only from prolonged and systematic effort to collect, arrange, and correlate all the facts that a consistent and intelligible theory is likely to emerge. We are, therefore, indebted to Dr. C. A. Gill, director of public health in the Punjab, who has published the outcome of a painstaking study of epidemics, in particular of malaria. The subject matter is presented in five parts, of which the first is introductory, consisting of a brief account of the views held by various authorities as to the cause of epidemics, a critical analysis of the methods employed in epidemiological research, and a summary of the author's own theory of the genesis of epidemics. The material from which the theory has been evolved is presented in detail in the second part of the work, where an interesting account of the investigation of epidemic malaria is followed by a note on the epidemiological features of influenza and plague. Since epidemicity is confined neither to diseases of which the causative organisms belong to closely allied groups nor to those exhibiting similar modes of transmission, these three widely diverse diseases are well chosen as examples. In Part III. the general applicability of Dr. Gill's theory to all epidemiological phenomena is examined and discussed, while Part IV. is devoted to a consideration of the response of disease to the influence of evolution and the effect of climate on health and disease in the light of the views propounded in the preceding chapters. Finally, in Part V., the failure of certain diseases to assume epidemic and pandemic characteristics is shown to be in no way inconsistent with the general argument: certain practical deductions from the study are summarised, and their bearing on the practice of preventive medicine reviewed.

As a result of his study, the author has come to the conclusion that the generic features of all epidemics, irrespective of the nature of the *materies morbi*, are the outcome of the same mechanism. "Nature exhibits a remarkable unity of design, and it would, therefore, be as unnatural to anticipate a separate mechanism of epidemicity in each specific disease as to assume a separate act of creation in the case of each zoological species." Dr. Gill's theory as to the nature of this mechanism—the quantum theory—postulates that the essential factor in the causation of epidemics is a loss of equilibrium between the dose of toxin and the degree of resistance, or, in short, between infection and immunity. If we regard an epidemic as the analogue in the community of an attack of disease in the individual, the theory is simply an extension of existing knowledge concerning individual infection, involving, therefore, neither the adoption of any new principle nor the formulation of any fresh hypothesis. If this theory be ultimately found to fit all the facts, the complexity of the problem will be materially reduced and future investigation simplified. The arguments presented in its favour are skilful, but not always convincing. For example, the author says, "a sudden depression of communal immunity is less likely to occur than a sudden increase in the amount of infection, and it is consequently held that circumstances conducive to a sudden increase of the infection quantum play a predominant part in epidemic explosions." An epidemic visitation is undoubtedly a sudden upheaval; but there is no apparent reason why the forces requisite to lead to a "loss of equilibrium" should be assembled in an equally dramatic manner. A gradual increase of susceptible persons—i.e., a gradual decrease in communal immunity—has, on this theory, as much chance of ultimately upsetting the balance as a gradual or sudden increase of the infection quantum. Again, "since, during their passage from one human host to another parasites are exposed, directly or indirectly, to the influence of meteorological conditions and atmospheric states, it is held that the latter are intimately concerned in determining the frequency and intensity of epidemics." This point of view has led Dr. Gill to attribute great prominence in the genesis of epidemics to meteorological conditions. It need only be noted that the length of exposure of organisms during their passage from one human host to another, at least in diseases spread by direct transmission, must be small; that under laboratory conditions, where meteorological variations are almost negligible, epidemics tend to occur and recur, and that the host as well as the parasite is susceptible to changes in weather conditions.

However, the author admits freely that the thesis put forward in this volume embodies few certainties and will occasion many doubts, and while his explanations are not entirely convincing, the detailed presentation of the facts leaves nothing to be desired, and on this account alone the work deserves warm commendation.

SURGERY OF CHILDHOOD.

By RICHARD WALTER BOLLING, M.D., F.A.C.S. Attending Surgeon, St. Luke's and Babies' Hospitals, New York City. London and New York: D. Appleton and Co. 1928. Pp. 390. 16s.

THIS book forms Vol. XV. of a series on clinical pædiatrics. The title of the volume is more comprehensive than its contents, since these do not include orthopædic subjects. There is thus no reference to talipes, congenital dislocation of the hip, or birth palsies, though 50 pages are devoted to fracture and epiphyseal separation. Joint tubercle has apparently been considered in Vols. VI. and VII., and hydrocephalus in Vol. V. We are not told where to look for a consideration of the tonsils and of mastoid infections: they receive scant notice in the volume under review. There are over 200 illustrations, and the X ray reproductions gain considerably by presenting the normal as well as the abnormal. This is a feature which might be widely imitated with advantage.

The book contains little that is new or provocative. Tannic acid in the treatment of burns and scalds is very properly advocated, but blood transfusion is advised for more conditions than most surgeons would consider necessary. A few of the author's opinions —e.g., those on appendicitis (p. 309)—are not generally held, but on the whole the book contains sound teaching. If it lacks balance and cohesion the fault lies partly in the scheme of producing units in a series of monographs.

PYODERMITES ET ECZÉMAS.

By Dr. R. SABOURAUD. With 149 original illustrations in the text. Paris: Masson et Cie. 1928. Pp. 284. Fr.60.

IN this work, the fourth of a series which includes previous volumes on seborrhœic dermatitis, squamous groups, and mycelial infections of the skin, the author presents a most comprehensive and careful study of the cutaneous coccal infections and their eczematous complications. Clinical photographs of typical cases, and many admirable microphotographs and diagrams depicting the actual causal organisms in situ, amplify the text and illustrate the immense scope of a subject which is here considered in three main sections, a fourth being devoted to treatment.

In the first section are described the various ways in which staphylococci can gain access to the skin; the frequency with which *S. aureus* is recovered on culture; the peculiar type of perifollicular abscess, the furuncle, and its necrotic sequela; Bockhardt's impetigo (which is not a streptococcal infection), and the consecutive alopecia sometimes noted in hairy regions. In the second chapter of this section the various forms of sycosis, nail infections and granuloma pyogenicum, due to *S. aureus*, are considered with a scrupulous regard for accuracy.

Section 2 is devoted to the streptococci. Impetigo is discussed in detail; intertrigo and its eczematous complications are then described, and eczema is considered from the bacterial aspect. It is admitted that the universality of the cocci and their low-grade specificity render all conclusions based on bacteriological findings vague and uncertain. The ætiology and nosological relationships of "eczema" are further elaborated in section 3. Some of the terms used, for example "eczematides," "coccides," introduce a finesse of diagnosis which makes a special appeal to the dermatologist, but which nevertheless has a practical bearing referred to later in the section on treatment. The study of this complex elaboration is much assisted by the photographs of actual cases, many of which recall the multiplicity of clinical types in which the author is striving to create some semblance of order, a task for which his famous treatise on the ringworm fungi has especially fitted him. The final section is a therapeutic synopsis of methods and formulæ of the old and well-tried French school. The lucid table of contents and a complete international bibliography are additional features in a most admirable production.

THE ULTRA-VIOLET RAYS.

Their Action on Internal Diseases and Use in *Preventing Loss of Colour and Falling of the Hair*. By ARNOLD LORAND, M.D. Vienna, Physician at the Carlsbad Springs, Czecho-Slovakia. Philadelphia: F. A. Davis Company. 1928. Pp. 258. $2.50.

THE title of the volume leads one to expect a study of the action of ultra-violet light on digestive, nervous, and ductless gland diseases. This has not been supplied; no effort has been made to study the action of light, apart from the many other methods of treatment employed, and no series of comparative cases is given. The statement is made here and there that better results were obtained when light treatment was superimposed on other methods, including gland extracts, iodine, mud-packs, and mineral spring water cures. The dosage employed is seldom stated in precise terms and the degree of erythema aimed at is not always given. The author attributes the reddening of the skin in strong sunlight to an irritation of the blood-vessels of the skin, and says that for this to occur the sympathetic (splanchnic) must positively be involved (p. 27). The book contains innumerable dogmatic statements for which no scientific proof is adduced. Dr. Lorand advocates light treatment as a means of lessening pain—e.g., by irradiation of the gall-bladder area in cases of gall-stones—and claims that the symptoms of old age are alleviated by the use of the mercury-vapour lamp; here, again, he does not limit treatment to ultra-violet light, but gives extracts of ductless glands and iodine as well (p. 95). The use of ultra-violet light for cosmetic purposes will hardly recommend itself to actinotherapists. The author states that after desquamation has occurred the complexion improves and that wrinkles disappear. It must be remembered, however, that mercury-vapour reactions are, as a rule, very painful, that turgescence of the skin is mostly transitory, and that this treatment may stimulate hair-growth in any irradiated part, not on the scalp only. The author's claim that light treatment is efficient in reducing obesity and in lowering blood pressure (apart from a small temporary fall) is not upheld by other investigators in this field; but since he uses light mainly as an auxiliary treatment, he is not really in a position to make specific claims for its efficacy. Several chapters are devoted to the subject of the action of light in stimulating hair-growth and to the treatment of greying hair, the work of Nagelschmidt in this field being duly acknowledged.

We have nothing but praise for the way in which the book is published; the clear type, the good binding, and light weight, are an achievement at the moderate cost of $2.50.

SPINAL NEURO-SYPHILIS.

La Syphilis Médullaire. By Dr. LORTAT-JACOB, Physician to the Saint-Louis Hospital, Paris; and Dr. POUMEAU-DELILLE, Interne of the Paris Hospitals. Paris: *Masson et Cie.* 1928. Pp. 151. Fr.70.

THIS volume belongs to the series entitled *Collection Médecine et Chirurgie Pratiques*, and contains in a concise form, for student and practitioner, present-day information on the varieties of spinal neuro-syphilis, their pathology, semiology, differential diagnosis, and treatment. Tabes dorsalis is excluded, for no very obvious reason; combinations of tabes with amyotrophy, with lateral column involvement, with incomplete transverse "myelitis" are not so infrequent as to suggest a fundamentally differing ætiology for parenchymatous as compared with interstitial manifestations, but the authors describe only the meningovascular types under the chosen title. A good account is given of acute and chronic meningomyelitis, gummatous forms, syphilitic muscular atrophy, and of rarer groups such as syphilitic combined sclerosis, and spinal compression of syphilitic origin. A place is found for "pseudo-tabes syphilitique" and "pseudo-sclérose en plaques syphilitique," although in our view these terms are misleading and should be abandoned. Neither of them should be characterised with the epithet "pseudo," for the former is merely a tabetic variety with overflow from the posterior funiculi, while the latter is a multiple, disseminated, syphilitic "myelitis." On the other hand, attention might have been drawn—since rarities are included—to the interesting combination of systematised posterolateral sclerosis with amyotrophy.

The purpose of the authors, however, is well served by this little vade-mecum.

GONOCOCCAL URETHRITIS IN THE MALE.

By P. S. PELOUZE, M.D., Associate in Urology and Assistant Genito-Urinary Surgeon, University of Pennsylvania. London and Philadelphia: W. B. Saunders Company. 1928. Pp. 357. 24s.

IN this small monograph Dr. Pelouze has produced an excellent summary of modern methods in the diagnosis and treatment of gonorrhœa in the male. Methods of culture and identification of the gonococcus are described; a feature of particular interest is the application of the action of the bacteriophage in the differentiation of the pathological urethral flora. Special attention is drawn to the need of employing a culture medium of correct hydrogen-ion concentration. In view of recent enthusiasm about the use of diathermy in the treatment of gonorrhœa, the survival of gonococci in the author's cultures after exposure to a temperature of 113° F. for 30 minutes, is noteworthy. In an admirable account of the pathological aspects of this condition, based chiefly on the classical work of E. Finger, Dr. Pelouze suggests that the spread of infection from urethra to epididymis is due to the passage of infected urine along the vas deferens. He comments on the low incidence of infection of the seminal vesicle in comparison with that of the epididymis and assumes that the former has natural immunity to infection. Surgical treatment for chronic infection of the seminal vesicles is advised only as a last resort. In the section on treatment, no new departures are recommended; neither

vaccines nor diathermy have yielded very favourable results in the author's experience, and the action of acriflavine and mercurochrome has proved disappointing. The main maxims set out are thoroughness in diagnosis and gentleness and patience in treatment.

The volume terminates with an excellent selection of typical case histories followed by the author's comments. Readers will find this small book both refreshing and stimulating, but some will be disappointed by the brevity of the practical details of technique in treatment.

MODEL ANSWERS TO QUESTIONS FOR MENTAL NURSES set by the General Nursing Council. By HECTOR MACPHAIL. London: The Scientific Press; Faber and Gwyer, Ltd. 1928. Pp. 273. 5*s*.

THIS companion volume to the author's well-known book, based on the questions set for the Medico-Psychological certificate, will be found equally useful by students. His skill in putting clearly and concisely the essential points required for the perfect answer is beyond praise. In the anatomical section there are, perhaps, rather more technical terms than are really necessary, and the phraseology of the answers is rather that of the medical student than that of the nurse. In the section on mental diseases and psychology this fault has been ably avoided. A few minor points call for criticism: the definition of seclusion on p. 227 has not been brought up to date; on p. 147 para. 11 has been reversed, making incontinence characterise fainting and not epileptic fits; and an answer on glycogen omits mention of its storage in the muscles; but, generally speaking, the book is remarkably free from errors, and so pleasantly written that it will be found an attractive aid to study.

THE RELATION BETWEEN LABYRINTH AND OCULAR MUSCULATURE.

Die Labyrinthreflexe auf die Augenmuskeln nach einseitiger Labyrinthextirpation. By Dr. R. LORENTE DE NÓ, Assistant in the Cajal Institute, Madrid. With 186 figures in the text and 22 plates. Berlin and Vienna: Urban and Schwarzenberg. 1928. Pp. 205. M.15.

THE work performed for Dr. Lorente de Nó's monograph has been conceived and carried out on a high level of scientific knowledge and skill. The book gives the reader an insight into the technical and other difficulties and complexities surrounding the investigation of the relation between labyrinth and ocular musculature, and is far from easy reading. Probably it is well that this should be so; Dr. de Nó is at pains to point out that in regard to the actual anatomical connexions of central labyrinthine structures ignorance is not by any means dispelled, and if this is true of morphology it is truer still of physiology. His book deals only with one aspect of labyrinthine function, yet it is based on uninterrupted researches during a number of years. The major portion is taken up with protocols of a large number of personal experiments, mainly on guinea-pigs, in which the labyrinth has been extirpated and ocular movements studied by a special technique. The author gives us a highly technical discussion of his own conclusions and of those of others, which is of interest mainly to the specialist, and which, moreover, embodies abstruse mathematical data with which few can be familiar. Incidentally, he is critical of certain findings as to the causation of decerebrate rigidity, and claims that his experiments are not in harmony with the teaching of Rademaker and others of the Magnus school. The monograph does not lend itself readily to summarisation, in view of its peculiarly technical character. Possibly its chief problem is that concerned with the quick phase of nystagmus; the author's experiments lead to the view that for the occurrence of this phenomenon the substantia reticularis of the pons must be intact and that its neurones must be in relation with the central nuclei of the labyrinthine system. He considers that both quick and slow components result from peripheral labyrinthine excitations, not, however, corresponding to separate end-organs; on the contrary, his opinion is that a peripheral stimulus starts a diphasic reflex from a given semicircular canal, comparable to the awakening of the scratch-reflex in the spinal animal by a single cutaneous impression.

CLINICAL GYNÆCOLOGY AND OBSTETRICS.

A Handbook of Clinical Gynecology and Obstetrics. By R. T. LA VAKE, A.B., M.D., F.A.C.S., Assistant Professor, Obstetrics and Gynecology, University of Minnesota. London: Henry Kimpton. 1928. Pp. 281. 18*s*.

IT is difficult to place this book into any definite category. It is not a systematic text-book, nor does it treat any definite part or aspect of gynæcology. The writer's object seems to be the correction of the perspective of the practitioner or student who has made a thorough study of encyclopædic text-books and is left "in a daze of countless facts and details arranged according to the demands of logical and complete exposition rather than according to practical importance." Granting that there is a class suffering from the consequences of encyclopædic study, the need for a corrective becomes obvious, and probably this book will serve as well as any other.

The book, then, is a medley of the author's teaching on those points of gynæcology and obstetrics—chiefly the latter—which he considers of clinical moment and on which he feels he has something to impart. Orderly arrangement is entirely absent. Part I. begins with gynæcological examination and diagnosis, and a chat on displacements follows; a diversion then occurs to pelvimetry and obstetrical diagnosis, and post-partum examination, after which we are switched back to gynæcological conditions considered on a pathological basis. Part II. is almost wholly obstetrical, the subjects apparently being taken in the order of their prominence in the maternal mortality list. It begins with sepsis, toxæmia of pregnancy, and hæmorrhage, after which follow obstetric operations, malpresentations, repair of birth injuries, post-partum care, and alleviation of pain in labour.

Much of the matter is excellent and the work throughout is eminently clinical and practical; the modification of treatment to meet the particular patient is emphasised. The book will interest and instruct those who are in the mood to browse here and there as their inclination may direct.

JOURNALS.

BRITISH JOURNAL OF CHILDREN'S DISEASES. Vol. XXV. July–September.—Dr. A. P. Cawadias contributes a paper on treatment of chronic polymicrobian colitis in children, in which he maintains that better therapeutic results would be obtained if the pathology of the disease were taken into account and a more thorough clinical diagnosis was made, especially as regards what Tendeloo calls the "constellation" of ætiological factors of the disease.—Dr. F. Parkes Weber records a case of temporary pulmonary œdema in a leukæmic child during a stage somewhat resembling aplastic anæmia. The patient was a boy, aged 14, suffering from lymphatic leukæmia of the undifferentiated cell type, in whom acute pulmonary œdema followed blood transfusion.—Dr. Hazel H. Chodak Gregory reports a case of splenectomy for purpura hæmorrhagica in a boy aged 7 years. When seen ten months after the operation he was in good condition. The spleen, which was enlarged and weighed 2¼ oz., was connected by dense adhesions with the anterior abdominal wall, which suggested some primary inflammatory lesion of the spleen and its covering peritoneum as a possible cause of the disease.—Dr. J. D. Rolleston describes a case of non-surgical subcutaneous emphysema in laryngeal diphtheria. The patient was a girl, aged

In the first section are described the various ways in which staphylococci can gain access to the skin; the frequency with which *S. aureus* is recovered on culture; the peculiar type of perifollicular abscess, the furuncle, and its necrotic sequela; Bockhardt's impetigo (which is not a streptococcal infection), and the consecutive alopecia sometimes noted in hairy regions. In the second chapter of this section the various forms of sycosis, nail infections and granuloma pyogenicum, due to *S. aureus*, are considered with a scrupulous regard for accuracy.

Section 2 is devoted to the streptococci. Impetigo is discussed in detail; intertrigo and its eczematous complications are then described, and eczema is considered from the bacterial aspect. It is admitted that the universality of the cocci and their low-grade specificity render all conclusions based on bacteriological findings vague and uncertain. The ætiology and nosological relationships of "eczema" are further elaborated in section 3. Some of the terms used, for example "eczematides," "coccides," introduce a finesse of diagnosis which makes a special appeal to the dermatologist, but which nevertheless has a practical bearing referred to later in the section on treatment. The study of this complex elaboration is much assisted by the photographs of actual cases, many of which recall the multiplicity of clinical types in which the author is striving to create some semblance of order, a task for which his famous treatise on the ringworm fungi has especially fitted him. The final section is a therapeutic synopsis of methods and formulæ of the old and well-tried French school. The lucid table of contents and a complete international bibliography are additional features in a most admirable production.

THE ULTRA-VIOLET RAYS.

Their Action on Internal Diseases and Use in Preventing Loss of Colour and Falling of the Hair. By ARNOLD LORAND, M.D. Vienna, Physician at the Carlsbad Springs, Czecho-Slovakia. Philadelphia: F. A. Davis Company. 1928. Pp. 258. $2.50.

THE title of the volume leads one to expect a study of the action of ultra-violet light on digestive, nervous, and ductless gland diseases. This has not been supplied; no effort has been made to study the action of light, apart from the many other methods of treatment employed, and no series of comparative cases is given. The statement is made here and there that better results were obtained when light treatment was superimposed on other methods, including gland extracts, iodine, mud-packs, and mineral spring water cures. The dosage employed is seldom stated in precise terms and the degree of erythema aimed at is not always given. The author attributes the reddening of the skin in strong sunlight to an irritation of the blood-vessels of the skin, and says that for this to occur the sympathetic (splanchnic) must positively be involved (p. 27). The book contains innumerable dogmatic statements for which no scientific proof is adduced. Dr. Lorand advocates light treatment as a means of lessening pain—e.g., by irradiation of the gall-bladder area in cases of gall-stones—and claims that the symptoms of old age are alleviated by the use of the mercury-vapour lamp; here, again, he does not limit treatment to ultra-violet light, but gives extracts of ductless glands and iodine as well (p. 95). The use of ultra-violet light for cosmetic purposes will hardly recommend itself to actinotherapists. The author states that after desquamation has occurred the complexion improves and that wrinkles disappear. It must be remembered, however, that mercury-vapour reactions are, as a rule, very painful, that turgescence of the skin is mostly transitory, and that this treatment may stimulate hair-growth in any irradiated part, not on the scalp only. The author's claim that light treatment is efficient in reducing obesity and in lowering blood pressure (apart from a small temporary fall) is not upheld by other investigators in this field; but since he uses light mainly as an auxiliary treatment, he is not really in a position to make specific claims for its efficacy. Several chapters are devoted to the subject of the action of light in stimulating hair-growth and to the treatment of greying hair, the work of Nagelschmidt in this field being duly acknowledged.

We have nothing but praise for the way in which the book is published; the clear type, the good binding, and light weight, are an achievement at the moderate cost of $2.50.

SPINAL NEURO-SYPHILIS.

La Syphilis Médullaire. By Dr. LORTAT-JACOB, Physician to the Saint-Louis Hospital, Paris; and Dr. POUMEAU-DELILLE, Interne of the Paris Hospitals. Paris: *Masson et Cie.* 1928. Pp. 151. Fr.70.

THIS volume belongs to the series entitled *Collection Médecine et Chirurgie Pratiques*, and contains in a concise form, for student and practitioner, present-day information on the varieties of spinal neurosyphilis, their pathology, semiology, differential diagnosis, and treatment. Tabes dorsalis is excluded, for no very obvious reason; combinations of tabes with amyotrophy, with lateral column involvement, with incomplete transverse "myelitis" are not so infrequent as to suggest a fundamentally differing ætiology for parenchymatous as compared with interstitial manifestations, but the authors describe only the meningovascular types under the chosen title. A good account is given of acute and chronic meningomyelitis, gummatous forms, syphilitic muscular atrophy, and of rarer groups such as syphilitic combined sclerosis, and spinal compression of syphilitic origin. A place is found for "pseudo-tabes syphilitique" and "pseudo-sclérose en plaques syphilitique," although in our view these terms are misleading and should be abandoned. Neither of them should be characterised with the epithet "pseudo," for the former is merely a tabetic variety with overflow from the posterior funiculi, while the latter is a multiple, disseminated, syphilitic "myelitis." On the other hand, attention might have been drawn—since rarities are included—to the interesting combination of systematised posterolateral sclerosis with amyotrophy.

The purpose of the authors, however, is well served by this little vade-mecum.

GONOCOCCAL URETHRITIS IN THE MALE.

By P. S. PELOUZE, M.D., Associate in Urology and Assistant Genito-Urinary Surgeon, University of Pennsylvania. London and Philadelphia: W. B. Saunders Company. 1928. Pp. 357. 24s.

IN this small monograph Dr. Pelouze has produced an excellent summary of modern methods in the diagnosis and treatment of gonorrhœa in the male. Methods of culture and identification of the gonococcus are described; a feature of particular interest is the application of the action of the bacteriophage in the differentiation of the pathological urethral flora. Special attention is drawn to the need of employing a culture medium of correct hydrogen-ion concentration. In view of recent enthusiasm about the use of diathermy in the treatment of gonorrhœa, the survival of gonococci in the author's cultures after exposure to a temperature of 113° F. for 30 minutes, is noteworthy. In an admirable account of the pathological aspects of this condition, based chiefly on the classical work of E. Finger, Dr. Pelouze suggests that the spread of infection from urethra to epididymis is due to the passage of infected urine along the vas deferens. He comments on the low incidence of infection of the seminal vesicle in comparison with that of the epididymis and assumes that the former has natural immunity to infection. Surgical treatment for chronic infection of the seminal vesicles is advised only as a last resort. In the section on treatment, no new departures are recommended; neither

vaccines nor diathermy have yielded very favourable results in the author's experience, and the action of acriflavine and mercurochrome has proved disappointing. The main maxims set out are thoroughness in diagnosis and gentleness and patience in treatment.

The volume terminates with an excellent selection of typical case histories followed by the author's comments. Readers will find this small book both refreshing and stimulating, but some will be disappointed by the brevity of the practical details of technique in treatment.

Model Answers to Questions for Mental Nurses

set by the General Nursing Council. By Hector MacPhail. London: The Scientific Press; Faber and Gwyer, Ltd. 1928. Pp. 273. 5s.

This companion volume to the author's well-known book, based on the questions set for the Medico-Psychological certificate, will be found equally useful by students. His skill in putting clearly and concisely the essential points required for the perfect answer is beyond praise. In the anatomical section there are, perhaps, rather more technical terms than are really necessary, and the phraseology of the answers is rather that of the medical student than that of the nurse. In the section on mental diseases and psychology this fault has been ably avoided. A few minor points call for criticism: the definition of seclusion on p. 227 has not been brought up to date; on p. 147 para. 11 has been reversed, making incontinence characterise fainting and not epileptic fits; and an answer on glycogen omits mention of its storage in the muscles; but, generally speaking, the book is remarkably free from errors, and so pleasantly written that it will be found an attractive aid to study.

The Relation Between Labyrinth and Ocular Musculature.

Die Labyrinthreflexe auf die Augenmuskeln nach einseitiger Labyrinthextirpation. By Dr. R. Lorente de Nó, Assistant in the Cajal Institute, Madrid. With 186 figures in the text and 22 plates. Berlin and Vienna: Urban and Schwarzenberg. 1928. Pp. 205. M.15.

The work performed for Dr. Lorente de Nó's monograph has been conceived and carried out on a high level of scientific knowledge and skill. The book gives the reader an insight into the technical and other difficulties and complexities surrounding the investigation of the relation between labyrinth and ocular musculature, and is far from easy reading. Probably it is well that this should be so; Dr. de Nó is at pains to point out that in regard to the actual anatomical connexions of central labyrinthine structures ignorance is not by any means dispelled, and if this is true of morphology it is truer still of physiology. His book deals only with one aspect of labyrinthine function, yet it is based on uninterrupted researches during a number of years. The major portion is taken up with protocols of a large number of personal experiments, mainly on guinea-pigs, in which the labyrinth has been extirpated and ocular movements studied by a special technique. The author gives us a highly technical discussion of his own conclusions and of those of others, which is of interest mainly to the specialist, and which, moreover, embodies abstruse mathematical data with which few can be familiar. Incidentally, he is critical of certain findings as to the causation of decerebrate rigidity, and claims that his experiments are not in harmony with the teaching of Rademaker and others of the Magnus school. The monograph does not lend itself readily to summarisation, in view of its peculiarly technical character. Possibly its chief problem is that concerned with the quick phase of nystagmus; the author's experiments lead to the view that for the occurrence of this phenomenon the substantia reticularis of the pons must be intact and that its neurones must be in relation with the central nuclei of the labyrinthine system. He considers that both quick and slow components result from peripheral labyrinthine excitations, not, however, corresponding to separate end-organs; on the contrary, his opinion is that a peripheral stimulus starts a diphasic reflex from a given semicircular canal, comparable to the awakening of the scratch-reflex in the spinal animal by a single cutaneous impression.

Clinical Gynæcology and Obstetrics.

A Handbook of Clinical Gynecology and Obstetrics. By R. T. La Vake, A.B., M.D., F.A.C.S., Assistant Professor, Obstetrics and Gynecology, University of Minnesota. London: Henry Kimpton. 1928. Pp. 281. 18s.

It is difficult to place this book into any definite category. It is not a systematic text-book, nor does it treat any definite part or aspect of gynæcology. The writer's object seems to be the correction of the perspective of the practitioner or student who has made a thorough study of encyclopædic text-books and is left "in a daze of countless facts and details arranged according to the demands of logical and complete exposition rather than according to practical importance." Granting that there is a class suffering from the consequences of encyclopædic study, the need for a corrective becomes obvious, and probably this book will serve as well as any other.

The book, then, is a medley of the author's teaching on those points of gynæcology and obstetrics—chiefly the latter—which he considers of clinical moment and on which he feels he has something to impart. Orderly arrangement is entirely absent. Part I. begins with gynæcological examination and diagnosis, and a chat on displacements follows; a diversion then occurs to pelvimetry and obstetrical diagnosis, and post-partum examination, after which we are switched back to gynæcological conditions considered on a pathological basis. Part II. is almost wholly obstetrical, the subjects apparently being taken in the order of their prominence in the maternal mortality list. It begins with sepsis, toxæmia of pregnancy, and hæmorrhage, after which follow obstetric operations, malpresentations, repair of birth injuries, post-partum care, and alleviation of pain in labour.

Much of the matter is excellent and the work throughout is eminently clinical and practical; the modification of treatment to meet the particular patient is emphasised. The book will interest and instruct those who are in the mood to browse here and there as their inclination may direct.

JOURNALS.

British Journal of Children's Diseases. Vol. XXV. July–September.—Dr. A. P. Cawadias contributes a paper on treatment of chronic polymicrobian colitis in children, in which he maintains that better therapeutic results would be obtained if the pathology of the disease were taken into account and a more thorough clinical diagnosis was made, especially as regards what Tendeloo calls the "constellation" of ætiological factors of the disease.—Dr. F. Parkes Weber records a case of temporary pulmonary œdema in a leukæmic child during a stage somewhat resembling aplastic anæmia. The patient was a boy, aged 14, suffering from lymphatic leukæmia of the undifferentiated cell type, in whom acute pulmonary œdema followed blood transfusion.—Dr. Hazel H. Chodak Gregory reports a case of splenectomy for purpura hæmorrhagica in a boy aged 7 years. When seen ten months after the operation he was in good condition. The spleen, which was enlarged and weighed 2¼ oz., was connected by dense adhesions with the anterior abdominal wall, which suggested some primary inflammatory lesion of the spleen and its covering peritoneum as a possible cause of the disease.—Dr. J. D. Rolleston describes a case of non-surgical subcutaneous emphysema in laryngeal diphtheria. The patient was a girl, aged

In the first section are described the various ways in which staphylococci can gain access to the skin; the frequency with which *S. aureus* is recovered on culture; the peculiar type of perifollicular abscess, the furuncle, and its necrotic sequela; Bockhardt's impetigo (which is not a streptococcal infection), and the consecutive alopecia sometimes noted in hairy regions. In the second chapter of this section the various forms of sycosis, nail infections and granuloma pyogenicum, due to *S. aureus*, are considered with a scrupulous regard for accuracy.

Section 2 is devoted to the streptococci. Impetigo is discussed in detail; intertrigo and its eczematous complications are then described, and eczema is considered from the bacterial aspect. It is admitted that the universality of the cocci and their low-grade specificity render all conclusions based on bacteriological findings vague and uncertain. The ætiology and nosological relationships of "eczema" are further elaborated in section 3. Some of the terms used, for example "eczematides," "coccides," introduce a finesse of diagnosis which makes a special appeal to the dermatologist, but which nevertheless has a practical bearing referred to later in the section on treatment. The study of this complex elaboration is much assisted by the photographs of actual cases, many of which recall the multiplicity of clinical types in which the author is striving to create some semblance of order, a task for which his famous treatise on the ringworm fungi has especially fitted him. The final section is a therapeutic synopsis of methods and formulæ of the old and well-tried French school. The lucid table of contents and a complete international bibliography are additional features in a most admirable production.

THE ULTRA-VIOLET RAYS.

Their Action on Internal Diseases and Use in Preventing Loss of Colour and Falling of the Hair. By ARNOLD LORAND, M.D. Vienna, Physician at the Carlsbad Springs, Czecho-Slovakia. Philadelphia: F. A. Davis Company. 1928. Pp. 258. $2.50.

THE title of the volume leads one to expect a study of the action of ultra-violet light on digestive, nervous, and ductless gland diseases. This has not been supplied; no effort has been made to study the action of light, apart from the many other methods of treatment employed, and no series of comparative cases is given. The statement is made here and there that better results were obtained when light treatment was superimposed on other methods, including gland extracts, iodine, mud-packs, and mineral spring water cures. The dosage employed is seldom stated in precise terms and the degree of erythema aimed at is not always given. The author attributes the reddening of the skin in strong sunlight to an irritation of the blood-vessels of the skin, and says that for this to occur the sympathetic (splanchnic) must positively be involved (p. 27). The book contains innumerable dogmatic statements for which no scientific proof is adduced. Dr. Lorand advocates light treatment as a means of lessening pain—e.g., by irradiation of the gall-bladder area in cases of gall-stones—and claims that the symptoms of old age are alleviated by the use of the mercury-vapour lamp; here, again, he does not limit treatment to ultra-violet light, but gives extracts of ductless glands and iodine as well (p. 95). The use of ultra-violet light for cosmetic purposes will hardly recommend itself to actinotherapists. The author states that after desquamation has occurred the complexion improves and that wrinkles disappear. It must be remembered, however, that mercury-vapour reactions are, as a rule, very painful, that turgescence of the skin is mostly transitory, and that this treatment may stimulate hair-growth in any irradiated part, not on the scalp only. The author's claim that light treatment is efficient in reducing obesity and in lowering blood pressure (apart from a small temporary fall) is not upheld by other investigators in this field; but since he uses light mainly as an auxiliary treatment, he is not really in a position to make specific claims for its efficacy. Several chapters are devoted to the subject of the action of light in stimulating hair-growth and to the treatment of greying hair, the work of Nagelschmidt in this field being duly acknowledged.

We have nothing but praise for the way in which the book is published; the clear type, the good binding, and light weight, are an achievement at the moderate cost of $2.50.

SPINAL NEURO-SYPHILIS.

La Syphilis Médullaire. By Dr. LORTAT-JACOB, Physician to the Saint-Louis Hospital, Paris; and Dr. POUMEAU-DELILLE, Interne of the Paris Hospitals. Paris: Masson et Cie. 1928. Pp. 151. Fr.70.

THIS volume belongs to the series entitled *Collection Médecine et Chirurgie Pratiques*, and contains in a concise form, for student and practitioner, present-day information on the varieties of spinal neuro-syphilis, their pathology, semiology, differential diagnosis, and treatment. Tabes dorsalis is excluded, for no very obvious reason; combinations of tabes with amyotrophy, with lateral column involvement, with incomplete transverse "myelitis" are not so infrequent as to suggest a fundamentally differing ætiology for parenchymatous as compared with interstitial manifestations, but the authors describe only the meningovascular types under the chosen title. A good account is given of acute and chronic meningomyelitis, gummatous forms, syphilitic muscular atrophy, and of rarer groups such as syphilitic combined sclerosis, and spinal compression of syphilitic origin. A place is found for "pseudo-tabes syphilitique" and "pseudo-sclérose en plaques syphilitique," although in our view these terms are misleading and should be abandoned. Neither of them should be characterised with the epithet "pseudo," for the former is merely a tabetic variety with overflow from the posterior funiculi, while the latter is a multiple, disseminated, syphilitic "myelitis." On the other hand, attention might have been drawn—since rarities are included—to the interesting combination of systematised posterolateral sclerosis with amyotrophy.

The purpose of the authors, however, is well served by this little vade-mecum.

GONOCOCCAL URETHRITIS IN THE MALE.

By P. S. PELOUZE, M.D., Associate in Urology and Assistant Genito-Urinary Surgeon, University of Pennsylvania. London and Philadelphia: W. B. Saunders Company. 1928. Pp. 357. 24s.

IN this small monograph Dr. Pelouze has produced an excellent summary of modern methods in the diagnosis and treatment of gonorrhœa in the male. Methods of culture and identification of the gonococcus are described; a feature of particular interest is the application of the action of the bacteriophage in the differentiation of the pathological urethral flora. Special attention is drawn to the need of employing a culture medium of correct hydrogen-ion concentration. In view of recent enthusiasm about the use of diathermy in the treatment of gonorrhœa, the survival of gonococci in the author's cultures after exposure to a temperature of 113° F. for 30 minutes, is noteworthy. In an admirable account of the pathological aspects of this condition, based chiefly on the classical work of E. Finger, Dr. Pelouze suggests that the spread of infection from urethra to epididymis is due to the passage of infected urine along the vas deferens. He comments on the low incidence of infection of the seminal vesicle in comparison with that of the epididymis and assumes that the former has natural immunity to infection. Surgical treatment for chronic infection of the seminal vesicles is advised only as a last resort. In the section on treatment, no new departures are recommended; neither

vaccines nor diathermy have yielded very favourable results in the author's experience, and the action of acriflavine and mercurochrome has proved disappointing. The main maxims set out are thoroughness in diagnosis and gentleness and patience in treatment.

The volume terminates with an excellent selection of typical case histories followed by the author's comments. Readers will find this small book both refreshing and stimulating, but some will be disappointed by the brevity of the practical details of technique in treatment.

MODEL ANSWERS TO QUESTIONS FOR MENTAL NURSES

set by the General Nursing Council. By HECTOR MACPHAIL. London: The Scientific Press; Faber and Gwyer, Ltd. 1928. Pp. 273. 5s.

THIS companion volume to the author's well-known book, based on the questions set for the Medico-Psychological certificate, will be found equally useful by students. His skill in putting clearly and concisely the essential points required for the perfect answer is beyond praise. In the anatomical section there are, perhaps, rather more technical terms than are really necessary, and the phraseology of the answers is rather that of the medical student than that of the nurse. In the section on mental diseases and psychology this fault has been ably avoided. A few minor points call for criticism: the definition of seclusion on p. 227 has not been brought up to date; on p. 147 para. 11 has been reversed, making incontinence characterise fainting and not epileptic fits; and an answer on glycogen omits mention of its storage in the muscles; but, generally speaking, the book is remarkably free from errors, and so pleasantly written that it will be found an attractive aid to study.

THE RELATION BETWEEN LABYRINTH AND OCULAR MUSCULATURE.

Die Labyrinthreflexe auf die Augenmuskeln nach einseitiger Labyrinthexstirpation. By Dr. R. LORENTE DE NÓ, Assistant in the Cajal Institute, Madrid. With 186 figures in the text and 22 plates. Berlin and Vienna: Urban and Schwarzenberg. 1928. Pp. 205. M.15.

THE work performed for Dr. Lorente de Nó's monograph has been conceived and carried out on a high level of scientific knowledge and skill. The book gives the reader an insight into the technical and other difficulties and complexities surrounding the investigation of the relation between labyrinth and ocular musculature, and is far from easy reading. Probably it is well that this should be so; Dr. de Nó is at pains to point out that in regard to the actual anatomical connexions of central labyrinthine structures ignorance is not by any means dispelled, and if this is true of morphology it is truer still of physiology. His book deals only with one aspect of labyrinthine function, yet it is based on uninterrupted researches during a number of years. The major portion is taken up with protocols of a large number of personal experiments, mainly on guinea-pigs, in which the labyrinth has been extirpated and ocular movements studied by a special technique. The author gives us a highly technical discussion of his own conclusions and of those of others, which is of interest mainly to the specialist, and which, moreover, embodies abstruse mathematical data with which few can be familiar. Incidentally, he is critical of certain findings as to the causation of decerebrate rigidity, and claims that his experiments are not in harmony with the teaching of Rademaker and others of the Magnus school. The monograph does not lend itself readily to summarisation, in view of its peculiarly technical character. Possibly its chief problem is that concerned with the quick phase of nystagmus: the author's experiments lead to the view that for the occurrence of this phenomenon the substantia reticularis of the pons must be intact and that its neurones must be in relation with the central nuclei of the labyrinthine system. He considers that both quick and slow components result from peripheral labyrinthine excitations, not, however, corresponding to separate end-organs; on the contrary, his opinion is that a peripheral stimulus starts a diphasic reflex from a given semicircular canal, comparable to the awakening of the scratch-reflex in the spinal animal by a single cutaneous impression.

CLINICAL GYNÆCOLOGY AND OBSTETRICS.

A Handbook of Clinical Gynecology and Obstetrics. By R. T. LA VAKE, A.B., M.D., F.A.C.S., Assistant Professor, Obstetrics and Gynecology, University of Minnesota. London: Henry Kimpton. 1928. Pp. 281. 18s.

IT is difficult to place this book into any definite category. It is not a systematic text-book, nor does it treat any definite part or aspect of gynæcology. The writer's object seems to be the correction of the perspective of the practitioner or student who has made a thorough study of encyclopædic text-books and is left "in a daze of countless facts and details arranged according to the demands of logical and complete exposition rather than according to practical importance." Granting that there is a class suffering from the consequences of encyclopædic study, the need for a corrective becomes obvious, and probably this book will serve as well as any other.

The book, then, is a medley of the author's teaching on those points of gynæcology and obstetrics —chiefly the latter—which he considers of clinical moment and on which he feels he has something to impart. Orderly arrangement is entirely absent. Part I. begins with gynæcological examination and diagnosis, and a chat on displacements follows; a diversion then occurs to pelvimetry and obstetrical diagnosis, and post-partum examination, after which we are switched back to gynæcological conditions considered on a pathological basis. Part II. is almost wholly obstetrical, the subjects apparently being taken in the order of their prominence in the maternal mortality list. It begins with sepsis, toxæmia of pregnancy, and hæmorrhage, after which follow obstetric operations, malpresentations, repair of birth injuries, post-partum care, and alleviation of pain in labour.

Much of the matter is excellent and the work throughout is eminently clinical and practical; the modification of treatment to meet the particular patient is emphasised. The book will interest and instruct those who are in the mood to browse here and there as their inclination may direct.

JOURNALS.

BRITISH JOURNAL OF CHILDREN'S DISEASES. Vol. XXV. July–September.—Dr. A. P. Cawadias contributes a paper on treatment of chronic polymicrobian colitis in children, in which he maintains that better therapeutic results would be obtained if the pathology of the disease were taken into account and a more thorough clinical diagnosis was made, especially as regards what Tendeloo calls the "constellation" of ætiological factors of the disease.—Dr. F. Parkes Weber records a case of temporary pulmonary œdema in a leukæmic child during a stage somewhat resembling aplastic anæmia. The patient was a boy, aged 14, suffering from lymphatic leukæmia of the undifferentiated cell type, in whom acute pulmonary œdema followed blood transfusion. —Dr. Hazel H. Chodak Gregory reports a case of splenectomy for purpura hæmorrhagica in a boy aged 7 years. When seen ten months after the operation he was in good condition. The spleen, which was enlarged and weighed 2¼ oz., was connected by dense adhesions with the anterior abdominal wall, which suggested some primary inflammatory lesion of the spleen and its covering peritoneum as a possible cause of the disease.—Dr. J. D. Rolleston describes a case of non-surgical subcutaneous emphysema in laryngeal diphtheria. The patient was a girl, aged

6 years, suffering from severe faucial and laryngeal diphtheria, who developed subcutaneous emphysema of the neck, face, and chest. Considerable relief followed tracheotomy, and recovery ultimately took place, though the emphysema lasted for 11 days. Rolleston could find only six other examples, a record of emphysema in laryngeal diphtheria apart from tracheotomy or intubation. The condition is probably due to the fact that, as the result of dyspnœa, pulmonary emphysema occurs, vesicles on the surface of the lung rupture, and air passes to the root of the lung and so to the mediastinum and neck.—Dr. Helen Mackay records a case of diabetic coma with subcutaneous emphysema in a boy aged 4 years. The emphysema appeared after about 30 hours' air-hunger and spread over the neck and upper part of the thorax. Recovery took place under insulin treatment.—In a paper on uræmic paralysis following scarlet fever, Dr. M. Shaw, who reports a case of his own, illustrates the rarity of cerebral palsy following scarlet fever by the fact that Rolleston could find only 75 cases on record up to 1927, including four which had come under his own observation. Shaw's case occurred in a boy aged 4 years who, in the fourth week of a mild attack of scarlet fever, developed nephritis followed by symptoms of uræmia and left hemiplegia. The child survived, but the paralysis persisted.—Dr. T. R. Aynsley records two cases of hemiplegia associated with extensive nævus and mental defect, similar to those recently published by Brushfield and Wyatt.—The abstracts from current literature are devoted to acute infectious diseases.

MEDICINE AND THE LAW.

AN UNREGISTERED DENTIST.

THE point in a case which came before the Chichester magistrates on Sept. 11th was whether the extraction of a tooth for a friend by an unregistered man constituted the practice of dentistry. Suffering great pain from toothache all night, a man named Pace went to his friend, Lewis Llewellyn, in the early hours of the morning on July 29th. Knowing that all the dentists were closed at that time of the day, Llewellyn extracted a tooth, and in endeavouring to extract another the tooth broke. Llewellyn was not in possession of the correct instruments, and he advised Pace to go to the hospital. From there he was sent to a qualified and registered dentist, and the remains of the broken tooth were extracted. The Dental Board of the United Kingdom took the case up, and Llewellyn was summoned for practising dentistry without being registered under the Dentists Act. Up to 1921 Llewellyn had been engaged in dental practice on his own account in Swindon. He did not register as a dentist when the Act of 1921 became operative, as he was then under 23 years of age; and he told the court that since the Act he had extracted only one tooth—that of Mr. Pace. The magistrates found that a technical offence had been committed, but they recognised that Pace went to his friend in great pain, and Llewellyn made no attempt to evade the law, but simply tried to help his friend. Furthermore, Llewellyn, when he found he could not do all he wanted to do, sent his friend to a dentist. The magistrates dismissed the case, ordering each side to pay its own costs. The mayor cautioned Llewellyn, telling him to be wiser in the future in regard to such matters. At the outset of the case a request was made that the mayor, Dr. A. H. Bostock, the presiding magistrate, should not sit on the bench, as the Act of 1921 was passed largely through the instrumentality of the medical profession, but after consultation Dr. Bostock intimated that it was the opinion of his colleagues on the bench that it would be quite fair for him to remain there.

CORONER AND JURY'S COURAGE.

The newly appointed coroner for East Sussex, Dr. E. F. Hoare, had something to say at an inquest at Chailey on Sept. 18th on the habit of juries coupling with their verdict of suicide the words, "while of unsound mind." In this case the inquest was on a man aged 43. The widow stated that her husband had often threatened suicide and worried a good deal when he was out of work. About a month ago she found a tin of rat poison in his bag, and fearing that he might use this poison on himself she asked a nephew to bury it in the garden and this was done. The man bought an ounce of prussic acid and signed the poison book, saying that he required the acid for killing wasps. Later he was found under a hedge on his allotment, the cause of death being cyanide poisoning. At autopsy the condition of his viscera appeared to be perfectly healthy, and there was nothing in the state of the body to suggest a motive for the act. Summing up, Dr. Hoare made the following comment: "The point is, is there anyone who saw the man take the prussic acid? I was present at the post-mortem examination and the body was full of cyanide poisoning. The fact that it was found on his body and in his stomach points to the fact that he took it himself. The other question to consider is in regard to the state of his mind at the time. This is not very clear. His wife states that he had talked about committing suicide and thought he was likely to do it. Before you return your verdict I would like you to realise that the mere fact that a person commits suicide does not mean you have got to say he was of unsound mind. Juries are rather apt to do that. You must be convinced there is some evidence of unsound mental balance before the act was actually committed." After a short consideration the jury announced a unanimous verdict of "Suicide" only, to which the coroner replied: "I think you are perfectly right. One must have evidence of definite mental trouble before insanity is mentioned. I am very glad you had the courage to stick to your verdict. Unless you have evidence you must not assume. I congratulate you on the courage you have shown."

DANGEROUS DRUGS ACTS: A DOCTOR PROSECUTED.

It is a legal maxim that nobody is allowed to excuse himself by pleading ignorance of the law. In certain cases, indeed, the courts may expect special knowledge of the law. For instance, a medical practitioner would presumably be expected to know more about the Dangerous Drugs Acts and Regulations than a shoemaker or a plumber. At a recent prosecution at the Tower Bridge Police-court (on a charge of having failed to enter in a register the particulars of the purchase of certain quantities of morphine sulphate on certain dates) it was somewhat unfortunately urged on behalf of the defendant doctor that the practice of the medical profession was extremely lax in these matters, and that the defendant did not realise what the regulations implied. This kind of plea, which the magistrate entirely declined to accept, does no service to the medical profession as a whole, since existing arrangements for the enforcement of the law are based upon the loyal coöperation of the members of that profession. Nor did it assist the particular defendant since, at a later stage of the proceedings, statements were made by the prosecution which appear to have established something more than mere laxness. A representative of the Director of Public Prosecutions informed the court that the defendant had been convicted earlier this year as a drug addict. A detective-inspector mentioned a previous charge in April last of stealing 100 tablets of morphine sulphate. It was stated that last June the defendant was sent to a home until he could be certified as cured, and that he had been released under the Probation of Offenders Act. Fortunately the magistrate found a lenient course possible. On the defendant's partner undertaking to look after him, the defendant was remanded for three months on his own and one other surety in £50 each. This should mean that, if there is no further infringement of the law, there will be no further punishment.

THE LANCET.

LONDON: SATURDAY, SEPTEMBER 29, 1928.

RHEUMATIC HEART DISEASE IN CHILDHOOD.

RHEUMATIC carditis is now recognised as a crippling and fatal disease, of which the complete cure is so rarely achieved that efforts are being centred chiefly on its prevention. In his Lettsomian lectures, the last of which we publish to-day, Dr. F. J. POYNTON makes a weighty contribution to this campaign. He has much to say that will encourage all who are working at the rheumatic problems of childhood, but at the same time he leaves a sobering impression that though the subject has been intensively studied for many years, the gaps in our knowledge are still so wide and formidable as to hinder forward progress. As regards the predisposing causes of the disease, he believes strongly in a hereditary factor and in a nervous element, but also that there may be other causes, endocrinological and dietetic, which have not yet been sufficiently explored. His attitude towards tonsillectomy is hesitant rather than sceptical. "It seems clear," he says, "that the tonsils must destroy infection, but the difficulty is to ascertain when they cease to act as a protection and become a danger." Evidence upon the occurrence of first attacks of rheumatism in children who have already had the tonsils enucleated is being accumulated on a large scale, and its publication is anxiously awaited by Dr. POYNTON, since the standardisation of current practice must depend on the frequency with which such attacks occur. The influence of damp is less to be feared, in Dr. POYNTON'S experience, than that of sudden atmospheric change; in large towns dry weather is held to predispose to dust-formation and sore-throats, and so to rheumatic infection. Dr. POYNTON deprecates the exhibition of salicylate of soda in large doses to frail rheumatic children; in his hands, tolysin, a cinchonic acid preparation, has proved an important addition to the scanty number of drugs which influence the rheumatic infection and is not toxic. The results of "sanatorium" treatment given in the home for heart cases in Sussex, recently transferred to West Wickham, are encouraging. The late effects of prolonged convalescence in this home correspond with those published recently by the Ministry of Health [1]—about two-thirds of the cases investigated after return to their homes were found to have maintained the improvement in their condition.

One of the most difficult problems for the clinician is to know when an attack of rheumatic carditis is over, that is, when the healing of the necrotic areas in the connective tissue of the myocardium is complete. Since it is extremely rare for death to take place during the earliest phases of the illness, pathological material for the study of this problem in prognosis is scanty. One has only to imagine the picture of early tissue-necrosis and attempted healing going on side by side, as caseation and fibrosis go on side by side in the tuberculous lung, to realise the difficulty of estimating the stage of the disease in the living subject. Add to this the uncertainty as to the method of primary invasion of the body by the infective agent, and the outcome is that we know depressingly little about the pathology of the condition. Dr. POYNTON tells us that 25 years ago Dr. ALEXANDER PAINE, his co-worker, and himself prophesied that the great battle of causation would be fought not over acute rheumatism but over malignant endocarditis, and he still holds that malignant endocarditis will prove the key to the situation. In this affection there can only be the two alternatives, either the rheumatic infective agent develops a great virulence and overwhelms the defences, or it has prepared the way for other infections. Dr. POYNTON, holding as he does that a streptococcus is the cause of acute rheumatism, naturally sponsors the former view, and, arguing from actual cases where micrococci have been obtained from patients with rheumatic carditis, states that the important question for the future treatment of heart disease is whether or not there is a malignant type of rheumatic endocarditis. If there is, the cause of acute rheumatism is known at once, but if not, how, he asks, are we to explain the frequent association of streptococci with rheumatic lesions? Against the theory of a secondary infection he claims that though the septic infections of childhood, such as tonsillitis and otitis, should give ample opportunity for attack on damaged valves, yet malignant endocarditis is exceptional in the child. Incidentally he notes that after attempts over a period of 20 years to treat rheumatic heart disease by vaccines or sera he has never succeeded in obtaining results good enough to justify any clear statement, and in malignant endocarditis his experience of vaccines has been "one uniform record of complete failure in both child and adult, used early or late, in combination with sera or separately, autogenous or stock, simple or complex."

Dr. POYNTON considers the pathological lesion in mitral stenosis to be of a different type from the ordinary rheumatic tissue-necrosis and tissue-repair, in that the process of fibrosis is slower and more subacute. Since this lesion is by far the most serious valvular lesion resulting from cardiac rheumatism, by reason of the actual obstruction it presents to the circulation and also of its close association with auricular fibrillation in later life, it is satisfactory to find the process of its evolution considered as a separate subject. If the development of mitral stenosis in the young could be by any means prevented, the late results of rheumatic disease would be less terrifying. Dr. POYNTON emphasises the significance of dilatation as the earliest sign of cardiac disease, and like the late Dr. D. B. LEES, the importance of the light form of percussion. He values electro-cardiographic methods and considers that disturbances in rhythm are probably the result of focal lesions in the connective tissue framework of the heart in the region of the bundle of His. This attitude is in direct opposition to the views of the late Sir J. MACKENZIE on the youthful types of irregularity, extrasystole, and sinus arrhythmia. The presence of sinus arrhythmia, according to Dr. POYNTON'S school, does not signify that the heart has escaped infection. This is fortunate if there is any truth in the view held by some that a return of the respiratory variation in the heart-rate signifies a quiescence of cardiac infection in the rheumatic heart.

MODERN PROBLEMS IN NEUROLOGY.

English neurologists are little given to the writing of systematic books, but on rare occasions we are able to welcome collections of papers by them issued in book form. To Dr. S. A. Kinnier Wilson we are now indebted for a group of selected contributions on the neurological problems which have particularly engaged his attention in the last few years. The first third of the book[1] is devoted to the problem of epilepsy—or "The Epilepsies," as Dr. Wilson prefers to say; the second to the problem with which the writer's name is particularly associated, that of the diseases of the corpus striatum; and among the remaining chapters we find one devoted to a third great problem, the nature of certain disorders of sensation. The problems of epilepsy, using the word in its widest sense, have of late years been engaging the concentrated attention of English specialists, and their activity has frequently been reflected in our own columns; among their more noteworthy contributions Dr. James Collier's recent Lumleian lectures[2] and Dr. Gordon Holmes's Savill Memorial oration[3] rise to our minds. The English school of neurology has behind it the greatest contribution ever made to the knowledge of this subject, Hughlings Jackson's discoveries and teaching in regard to the forms of attack which have since borne his name, and Dr. Wilson reverts frequently to Hughlings Jackson as to the fons et origo of all modern knowledge in this department. In the articles now reprinted his own analytical mind has concerned itself chiefly with the most basal problems of the subject—what constitutes a fit? the type of movement in a general fit, the numerous variants of epileptic attacks, the inhibitory elements which form part of every attack and seem to form the whole of certain attacks, and the essential unity with epilepsy of the peculiar symptom called narcolepsy.

Of the chapters referring to diseases of the corpus striatum the keynote is restraint. Since Dr. Wilson gave the original description of the syndrome of the corpus striatum in 1912 there has been a widespread tendency to add to the syndrome and very varied disturbances of movement and of speech and writing have been attributed to disorders of one or other part of the basal ganglia. But these ganglia are of simple structure and therefore most unlikely to have multiplex functions. Critical judgment and experimental methods applied to some of these symptoms show that it is unjustifiable to ascribe them to striatal dysfunction, and the narrow limits which Dr. Wilson still sets to the functions of the corpus striatum will, we imagine, surprise many of his colleagues abroad. "The main features of disease of the corpus striatum consist of disorder of muscle-tone regulation, and appearance of involuntary movements." "Disease of the strio-spinal system . . . allows rigidity and hyperkinesis." The author, who speaks with authority in this department, sees no reason to add to these.

The third great problem in neurology which this stimulating book raises is that of the nature of certain subjective sensory disorders associated with organic lesions. In the chapter entitled "Dysæsthesiæ and their Neural Correlates" (the title smells of brimstone and the black art!) the philosopher in the neurologist is at his best. "Dysæsthesiæ" includes all subjective disorders of sensation, such as "burning," "tingling," "deadness," which seem to arise spontaneously. After a brief preliminary discussion, including a short consideration of the nature of pain, the dysæsthesiæ associated with lesions at the various neural levels are described. Since these abnormalities are conscious sensations the afferent paths from the sites of the lesions to the "perceiving cortex" must be open, and the latter must be intact. Their pathogenesis may be attributed either to stimulation and excitation at the site of the lesion—in many ways the simplest theory, or to the withdrawal of the influence of a postulated inhibitory sensory system—a view which presents many theoretical difficulties as yet, but to which further evidence may bring more support. Another pathogenic factor may be lesions either of the sympathetic nervous system or of the vascular system. Cases of peri-arterial sympathectomy furnish evidence pointing to the modification of certain sensory disorders by operation on arterial nerve-plexuses. Thus under certain circumstances a neural origin, under others a vascular or sympathico-vascular origin underlies the manifestation of dysæsthesiæ in consciousness.

The presentation of these papers in permanent and accessible form is the more fitting inasmuch as the writer possesses, in a degree uncommon among medical authors of our time, a gift for putting his contributions into literary shape.

◆

THE COMMON COLD.

Everyone has had, is having, or shortly will have a common cold, and, if we follow the advice of Prof. Lovatt Evans given at the recent meeting of the British Association, we shall not seek to know why it is so—that, he says, is the province of the philosopher; what we want is a brief statement of the way of a cold, and this, in spite of almost universal personal experience, is what we lack. The natural history of diseases which strike occasionally and disappear for a time has in many cases been worked out with care. The common cold is so swift and prolific that, like the drosophila for problems in genetics, it might well serve as the type object of epidemiological research. The new conception of epidemic genesis recently set out by Dr. C. A. Gill, director of public health for the Punjab, in a book reviewed on another page, may stimulate inquiry into the way of a cold, for the gist of what he calls the quantum theory is that all epidemic manifestations are essentially dependent upon loss of equilibrium between infection and immunity—upon what Lovatt Evans would call maladaptation. And Gill's theory is all the more applicable to the common cold, for he attributes great prominence in the genesis of epidemics to meteorological conditions. During their passage from one human host to another, he writes, parasites are exposed directly or indirectly to the influence of meteorological conditions, a factor which may well be potent, even though the host as well as the parasite is susceptible to atmospheric changes. We are, as it happens, in possession of some recent information as to the extent to which disturbance of the body heat may be considered as the primary cause of commensal infection. The inquiry is by Dr. J. J. van Loghem, professor of hygiene in the University of Amsterdam, who has made a special study[1] of the borderline between parasitism and commensalism, the commensal organism being one that lives on the surface of the skin and mucous membranes and only causes disease under special circumstances which weaken the physiological defences. There are previous data bearing on the point. Greenwood and Young in this country have found temperature to be the meteorological factor most closely associated with the mortality from respiratory disease. Dr. van Loghem also quotes an analogous result from a study by Schade of the German Army in time of peace which showed a parallelism in the rise and fall of "disease through cold" (affections of the skin in consequence of freezing), and of respiratory diseases. The direct research into the minor respiratory diseases conducted by the Public Health Service of the United States has also shown the synchronous occurrence of these diseases in various parts of North America.

---

[1] Journal of Hygiene, vol. xxviii., No. 1.

Dr. van Loghem's own research in Holland lasted 37 weeks and the final data covered 6933 persons. His informants were mainly heads of families of the more intellectual classes. A weekly list of questions demanded for each member of the family simply a no (no new cold) or yes (caught cold), and in case of colds the further statement—nose cold, sore-throat (angina), hoarseness (laryngitis), cold with cough (bronchitis), or slight influenza. No inquiry was made about serious diseases. The weekly percentages of colds in seven geographical groups showed a roughly similar course as regards major variations, and this similarity became more evident when the data were put into two groups only—Amsterdam and the rest of Holland. Roughly the same course (with the exception of a high initial September peak in the colds) was found in the ten-daily average of the outdoor temperature, inverted so that the peaks were peaks of cold. This disparity the author explains by the fact that the nights were then very cold—a fact marked in the averages by the warmth of the days, thus indicating that not only a general drop but also a large variation in temperature in the 24 hours may go hand-in-hand with colds. Weekly deaths from pneumonia for the Netherlands also showed a course following roughly—though with a lag—the course of both the temperature and the "colds incidence" line, agreeing with the former more closely than the latter especially in the absence of the high September peak, but differing from both in having a very sharp rise in March and April. Mortality from "old age" in the Netherlands for the same period showed a similar parallelism with outdoor temperature, but unlike pneumonia had no March-April rise. The specific cause underlying this peak in the pneumonia deaths, however, was suggested by a corresponding peak in the influenza deaths for Holland. Of the five types of colds classified in the colds inquiry, coryza largely outweighed all the rest, the courses of coryza and bronchitis were almost exactly parallel, angina and laryngitis showed the same tendency but on a smaller scale. Influenza at first followed the colds and then took its own course, having its highest peak much later in the period, corresponding to the late peak noted in the mortality for the country both from influenza and pneumonia. From these results Dr. van Loghem concludes that during the period there were two important causes of pneumonia—disturbed thermo-regulation, more potent in the first part of the period, and influenza, more potent in the second. He thus places influenza in a different category from diseases resultant on catching cold or commensal infections such as cold, pneumonia (in part), and old age mortality, and describes it as "a parasitic infection which in a period of catching cold easily gets entangled with pneumonia." He concludes that an important part of the respiratory diseases is based on infection by commensal microbes which occurs after the physiological defences have been weakened by a disturbance of thermo-regulation, and that commensal infection may thus lead to parasitic infection to which healthy persons may fall victims by contagion. Dr. van Loghem then sought from his data evidence as to the contagiousness of colds. He argued that if colds were contagious small families should have a lower incidence than large families. On dividing his families into two groups according to size, he found the difference in incidence negligible. This part of his analysis carries less weight, for the average difference in family size is small, and might even with fairly high contagiousness be outweighed by opportunities for infection outside the family. Families even where there are small children are not isolated units, and contact with the outside world is generally too close for us to do more than agree with the author's first comment that nothing has been proved by this of the contagiousness of colds. To test the disturbance of the heat-regulating powers of the body by outside cooling Dr. van Loghem obtained the rectal temperature of 33 children at 3.30 A.M. and 4.30 P.M. for 26 days, and found some conformity between the former and the open-air temperature at midnight—not a very striking correlation if we are right in estimating it from the published graph at 0·19±0·13.

There is room for much more work on the lines of this study. His subjects had an average of over four colds per person in the 37 weeks—a frequency which, as we have said, makes it a hopeful subject for investigation. Such observations might be increased both in scope and in detail. Dr. van Loghem's views on the active and passive means of keeping up the body-heat level may be a little one-sided. The observed facts can tell us of the association of environmental factors such as temperature with the incidence of disease, but assuming a real basis of causation in this association, the manner of its working is not self-evident. The paradox that cold may work inversely by means of heat needs some consideration, and there is nothing in the Netherland results to contradict the conclusion to which the work of Leonard Hill leads, that cold weather may bring about a large crop of colds through people being more inclined to shut themselves up in warm stuffy rooms and to open fewer windows.

◆

A course will, as usual, be held at St. Mary's Hospital, London, during the week-end preceding the autumn session. The meetings will be in the library of the medical school and will be open to all medical practitioners without fee. They begin on Saturday, Oct. 6th, at 11 A.M., with a lecture by Dr. Reginald Miller on the Intestinal Child, after which Sir William Willcox will speak on Food Poisoning and Paratyphoid Infections (noon). Dr. A. Hope Gosse on Prognosis in Heart Disease (2.15 P.M.), and Mr. R. M. Handfield-Jones on Recent Advances in Everyday Surgery (3.15 P.M.). On Sunday the first lecture will be at 10.15 A.M. when Mr. Aleck Bourne will speak on the New Ovarian Hormones, followed at 11 A.M. by Dr. C. M. Wilson on Some Common Difficulties in Diagnosis, and at noon by Mr. Zachary Cope with a demonstration of clinical cases and pathological specimens. On Sunday afternoon there will be no lectures, but the course will be continued throughout Monday, Oct. 8th, Mr. Duncan Fitzwilliams starting at 11 A.M. with an account of the Use of Radium in Malignant Disease. Prof. C. A. Pannett will lecture, at noon, on Some Surgical Obsessions and Dr. John Ryle at 2.15 P.M. on the Nature and Relief of Some Common Gastric Symptoms. Mr. T. G. Stevens will conclude the series with an address, at 3.15 P.M., on Some Pitfalls in Obstetrics. Those who have attended former courses of this kind will need no recommendation to attend. The popularity of the lectures is a welcome indication of the need felt by practitioners to keep their knowledge up to date.

Annotations.

"Ne quid nimis."

WOMEN IN MEDICINE.

WHILE London University is considering the facilities provided in the London schools of medicine for the education of men and women students respectively, various women's organisations have set up a joint committee to promote equal opportunities for women with men in the medical and hospital services. The latter have now issued a leaflet setting out the facts as seen by them regarding (1) the training of women medical students in London, (2) equal opportunities of hospital appointments, and (3) women on hospital boards of management. It was of course during the war years, 1914–18, that women came into their own in the opportunities for making a medical career. For a time seven of the 12 medical schools of the University of London were co-educational and some of them apparently intended to remain so. This high tide has ebbed as might have been prophesied, and the periodicity of its flow is difficult to determine. There is a perhaps not unnatural tendency to regard the situation as having settled down, like the price of houses and the ratio of unemployment, to what may be regarded as normal conditions. But probably in all three respects it is too early to speak of a norm at all, although the entries of medical students of both sexes are not unlikely to fluctuate fairly close to the standard of 500 each for England and Scotland and 200 for Ireland. The women's memorandum, however, envisages a general tendency towards a steady increase in the demands for the services of medical women as time goes on. First and foremost, there is an increased demand for women to fill posts in child welfare and maternity clinics, school inspection, and the like, under local authorities. There is the probability—the memorandum regards it as a practical certainty—that within a few years national health insurance will be extended to cover dependent wives and children, or, if not, a health service covering these classes will be set up, and in either case there will be greater need for the advice of women doctors. Apart from these special occasions, the memorandum speaks of a steadily growing demand for women doctors spreading from the more to the less educated women as the latter begin to realise the possibility of employing doctors of their own sex. It is suggested that women are still often deterred by scruples of delicacy from submitting themselves to medical examination by a male practitioner until the time has gone by for the recognition of such serious diseases as cancer. The growth of population in and around London, and the increased demand for doctors in India and the Far East, are also regarded as likely to augment women's entry to the medical profession. Finally, there is the economic reason, very frankly stated in the memorandum, that the financial condition of the professional classes at the present time makes it especially desirable for them to seek careers for their daughters; and where should a more suitable career be found than in medicine? These are the reasons why, in the opinion of an influential body of women's organisations, the growing need of facilities for the medical education of women in London should not be overlooked.

OSSIFICATION.

FOR generations the problems of calcification and ossification have been the subject of inquiries and research. Anatomists, embryologists, physiologists, pathologists, and chemists have contributed views on some one or more of the questions concerned, and certain facts have emerged from the theories and fancies to gain general acceptance. It is usually held that calcification precedes ossification, whether cartilaginous preformation is present or not, and that the calcified area is destroyed in the course of the osteogenetic process. Osteoblasts and osteoclasts have also been in the picture for many years, the former being concerned in some way with the deposit of the bony material, while the large, usually multinucleated cells known as osteoclasts are held responsible for the removal of bone where necessary. It must be admitted that the powers claimed for these cellular bodies are not based on incontrovertible evidence, and some observers have not hesitated to deny them. For example, Drs. R. Leriche and A. Policard, who, after some ten years of research in collaboration, have produced their results in a book[1] which does not seem to have attracted the attention it merits, attempt to discredit the osteoblast and belittle the osteoclast. These authors have arrived at many conclusions which are not in accordance with commonly accepted ideas. For example, in discussing the preliminary stages of ossification, they suggest that the physiological value of the connective tissue basis of bone is in inverse ratio to its histological differentiation. The higher the degree of complexity of the pre-osseous framework the less dense is the bone formed. To illustrate this thesis, bone is aptly compared with reinforced concrete, the steel skeleton representing the connective tissue fibrils, while the cement corresponds to the calcified matter. They believe that there is no relation between osteogenesis and the presence of osteoblasts, which are held to be osteolytic elements, albeit of a feeble power. Their appearance is held to be a reaction on the part of the cellular elements to the pre-osseous changes occurring in their midst. The osteoclast is not, according to these workers, a cell of specific origin; it may arise from fibroblasts, osteoblasts, or endothelial cells. Its action is phagocytic; osteoclasts have been observed in the process of enclosing fine spicules of bone in areas where absorption is taking place. The view expressed by Kölliker that osteoclasts may change into osteoblasts finds no favour; disintegration and disappearance of these elements seems to Leriche and Policard to be a more likely fate. The resorption of bone is not, according to these observations, a cellular phenomenon, and the rôle of the osteoclast may be of minor significance. The process of halisteresis is considered from a biochemical aspect. As to the periosteum, Leriche and Policard range themselves with Macewen in holding that it does not possess any specific osteogenic function. It limits bone growth, but also by virtue of its proximity to the bone-forming elements it favours ossification. The authors describe an ingenious method of experimental production of bone in the skin in man, and discuss the mode of formation of bone in unusual regions. Finally, an attempt to apply to pathology and surgery the general laws of ossification is stimulating and suggestive. Nevertheless the work is not altogether convincing. Especially in regard to the osteoblasts and osteoclasts it is difficult to accept their conclusions. Most embryologists will hold that the status of osteoblasts and osteoclasts remains more or less unimpaired. The older view of the preliminary calcification, that it was a deposit of lime salts in a non-living or extra-cellular tissue or medium, an inter-cellular substance, has now given way to the better founded conception of the exoplasm, an outlying part of a cell, in which the deposit takes place. It is in this material that fibrils make their appearance before calcification; fibrillation, due probably to the linear arrangement of cytoplasmic granules with a covering of adsorbed colloidal material, is a function of living protoplasm. Calcification, then, occurs during the life of the area involved, but it is nevertheless a sign that this life is at a very low ebb. Ossification, on the other hand, is an indication of exuberant life, a sequence of new circulatory invasion, entailing of necessity the clearing away of the calcified debris which preceded its advent. Embryological examination shows very clearly this association of ossific centres with vascularity, and the way they destroy and replace the practically non-vascular calcified area. These matters were well brought out in THE LANCET of Sept. 8th by Prof. H. A. Harris writing on Bone Formation and the Osteoblast. Readers interested in the questions from a pathological or morphological standpoint will find this paper of considerable reference value. Dr. Harris says truly that we wait for the chemist to explain the colloidal processes which lead to the deposition of calcium in two tissues so fundamentally distinct as dying cartilage and living bone. It does not seem that the anatomist and the embryologist can advance much further without some widening of the horizon. The modern view of living substance compares it with a reversible colloid, and researches along the lines indicated by such a comparison, researches dealing with suspensions and emulsions and the effects on them of various salts, will without doubt open up new avenues along which the investigator of ossification will be able to progress. There will still remain a vital activity (in the form of cellular regulating processes) which will be outside the chemist's province, and it is in the elucidation of this process that the opportunity of the experimental embryologist will come.

CHILD WELFARE IN JAPAN.

WRITING from the laboratory of the University medical clinic at Kyoto, Dr. Teruko Minouchi describes[1] the development of infant and child welfare in Japan. She points out that the changes which have taken place in this country within the last 60 years, while they represent an enormous advance in energy and culture, seriously threaten the health of the people in several directions. A special feature in the industrial life of Japan is the greatly increased ratio of female to male workers, especially in the case of the textile trades which form the most important industry of the country. The ill-health of the women is increased by the fact that the girls begin to work while very young and undeveloped. The author briefly sketches the growth of infant welfare in Japan from its earliest beginning 1400 years ago down to the present day. In spite of this long period, however, the infant death-rate in Japan in 1924 was more than twice that of England and Wales, and three times that of the Netherlands. Dr. Minouchi is convinced that progress in maternity and child welfare will depend largely upon the development of the women's movement, and she urges that women should take a larger share in public life and in the general activity of the nation if any progress is to be made in social hygiene. Dr. Minouchi's paper was presented to the open meeting of the Medical Women's International Association recently held at Bologna.

CONTROL OF INVALIDITY.

NATIONAL attention is being ever more and more directed to the importance of invalidity, to the economic loss it entails through national insurance, and to the industrial inefficiency thereby created. Few investigations have thrown more light on the causes underlying sickness, whether due to illness or accident, than one made among coal-miners by Dr. H. M. Vernon and Dr. T. Bedford.[2] Nevertheless, the subject is difficult; and, although records were studied relating to 23,000 miners for periods of 21 months to six years, and although the authors can point to the extraordinary sensitiveness of the miner to his conditions of work and general environment, yet the inferences suggested by the facts are only cautiously advanced. Some deductions seem definite. The most valuable method of reducing absenteeism which among coal-miners is considerable is to improve the conditions of work; thus air movement within a narrow range is associated with a minimum of accidents and sickness, and at moderate variations to lower or higher velocities the rates rapidly rose. Air velocities of only 18 to 21 feet per minute were found, and are condemned as too low for efficient work or for safety in mines rich in gas. The cause of absenteeism most studied was accident, the frequency of which, so far as minor accidents are concerned, varies with underground temperature. The grading is remarkable; accidents causing less than ten days' disablement were 4·3 times more numerous at the highest than at the lowest temperatures; those causing 10–19 days' disablement were 2·0 times more numerous; those causing 20–59 days' disablement were 1·5 more numerous; but major accidents causing 60 days or more disablement were unaffected by temperature. Generally what holds good for accident frequency also holds good for sickness rates. Undue exercise increased absenteeism; men who walked from the pit shaft to the coal face, 2800 yards, showed 58 per cent. more than men who walked 1330 yards; similarly, men who lived 2–6 miles from their colliery showed 80 per cent. more voluntary absenteeism than those living 1–2 miles away. Seasonal fluctuations naturally affected surface workers more than underground men. The outstanding conclusion to be drawn is the delicate way in which the human organism reacts to its environment; by controlling the environment its reactions can be advantageously controlled whether the reaction result in a traumatic or infectious " accident."

THE CEREBRO-SPINAL FLUID IN SYPHILIS.

WRITING on the cytology of the cerebro-spinal fluid in syphilis, Paul Ravaut and Raoul Boulin[1] say that dried fixed films made after centrifugation leave such a large proportion of the cells disorganised as to be valueless, whilst a simple numerical count may give no hint of a serious underlying pathological process, persisting after the cell count has almost reached normal figures. After many trials they favour vital staining with methyl-green pyronine, the deposit after centrifugation being mixed with the stain and the cover-slip ringed. Such a preparation lasts about 24 hours. Living cells may be distinguished by the fact that they take longer to stain, sometimes even hours, the nucleus eventually becoming blue and the cytoplasm and nucleolus red or rose-coloured. As a result it is claimed that the following types of cell may be distinguished: unattached nuclei, lymphocytes, medium-sized mononuclears, polymorphonuclears, large mononuclears, and plasma cells. The two last types are always of great importance as indicating involvement of the parenchyma of the nervous system, as opposed to meningitis. In secondary syphilis, a count composed of lymphocytes and medium-sized mononuclears gives a favourable prognosis under treatment; but if large mononuclear cells and plasma cells are also present, they may persist in spite of treatment, giving warning, perhaps years ahead, of involvement of the nervous system. Tertiary cases they divide into four groups: those with no clinical involvement of the nervous system, those in which only the cerebral vessels are affected, tabetics and cases of general paralysis. In the first two groups the same rules apply as in secondary syphilis, but the significance of an abnormal fluid is greater. In an early tabes lymphocytes and middle-sized mononuclears often predominate with perhaps a few small plasma cells, or the latter may form the majority. An old or arrested case may show very few cells, most of them dead, and polymorphonuclears are rare. It is often impossible to tell a progressive from an arrested case by the cells present because, though quiescent in the meninges, the disease may be active in the parenchyma.

[2] A Study of Absenteeism in a Group of Ten Collieries. By H. M. Vernon and T. Bedford. Industrial Fatigue Research Board. Ref. No. 51. H.M. Stationery Office. 2s. 8*d*.

---

[1] Presse Méd., July 14th. This paper summarises one appearing in the Annales de Dermatologie et Syphilographie for last December.

General paralysis has more definite characteristics. The cells often show great vitality and diversity of type and it is only in these cases that the large and polynuclear plasma cells are found. Lymphocytes and medium-sized mononuclears still, however, often form the majority of the cells present. Ravaut and Boulin claim that the technique is simple, but it is clear that a considerable experience would be necessary before the different types of cells could be distinguished with certainty, the more so as moist preparations are necessary. Confirmation of the results is also clearly necessary and this can only be obtained, as the authors have found, by years of comparison with clinical findings. But the importance of the spinal fluid as a guide to prognosis in secondary syphilis is now becoming recognised; and the assistance promised by the present work should not be ignored where there is enough material at hand to allow mastery of the technical difficulties.

QUESTIONING THE PATIENT.

No one will dispute the importance of thorough physical examination before diagnosis, but the stress laid upon it tends to relegate history-taking to a second place. The main reasons for a relative neglect of this fundamental part of the examination are nervousness or incoherence on the part of the patient, a preconceived idea of the diagnosis either on his or the doctor's part, and, most important of all, lack of time. The time available for a consultation has its limits, and it can only be used to the best advantage if patient and physician are prepared to assist each other. We have just received the second edition of a little book[1] designed to meet these difficulties and prepare the patient for consultation. It opens with a short preface in which the duties of the patient to the physician are explained, and emphasises especially the need for early consultation, so that tendencies to disease may be recognised before they become incurable, and the desirability of giving an accurate account of the symptoms themselves rather than of deductions and theories. This advice is followed by lists of questions arranged under various headings such as general information, family history, nutritional and digestive disorders, and respiratory troubles, which the patient, according to his complaint, can prepare himself to answer, in order that when the actual consultation arrives nothing will be missed and answers will be clear and to the point. There is no doubt that if this book were used intelligently history-taking would be made easier and more speedy. But there are great disadvantages in putting a book of this kind in the hands of patients. The people who most need such a guide are exactly those who would be most confused by the possibility of having to answer a formidable array of questions, whilst the suggestive effect of studying queries like, "Have you a very sharp pain which starts from the region of the heart and goes towards the left arm?" might be very unfortunate. The book may be useful to the physician in re-emphasising the value of a careful history, but in the hands of patients it would certainly give rise to more mistakes than are traceable to the surreptitious leading questions which a medical man must introduce into his catechism.

MALARIA AND COMPROMISE.

The 33 members attending a session of the First Subcommission of the Malaria Commission of the League of Nations have issued a unanimous report on antimalaria methods.[2] The final aim of all measures directed towards the eradication of malaria is regarded as being an "integral bonification," which may perhaps be defined as the sum of economic, social, and hygienic betterment induced by development of the land and growth of civilisation. But by the very process of its attainment, bonification may temporarily increase malaria, so that in the meantime antilarval and other measures must be employed. Time is the essence of the contract for this as for all general antimalarial procedures, and unless adequate time be conceded adequate results will not be obtained. Time, too, is concerned in obtaining that "minimum effective degree of perfection" which must be reached before any individual antimalarial measure produces visible results. The most important of these is the treatment of the sick; it is the primary obligation, whose good results will, however, be apparent rather in the reduction of the severity of infection than of its incidence. In the choice of other intermediate methods which shall be employed in any particular local campaign, imitation of those which have already proved their value elsewhere is actually dangerous. Quite otherwise is the imitation of the confidence, energy, and perseverance which gave them their earlier success, and of the discernment which chose those measures which have proved applicable to each particular locality. In effect, this advice from the Subcommission implies the selection of an executive officer with wide knowledge and shrewd mind, who is allowed time in which his schemes may show their value. The report also emphasises how essential is the setting apart, in every country concerned, of special research workers; for very much still remains obscure in malaria, and antimalarial measures cannot reach their full effect till that shadow is enlightened.

HOUSING IN CITIES.

During the coming autumn session Parliament will have to review the position of the subsidy granted out of the national exchequer in order to expedite the supply of adequate housing for the existing population. The Minister of Health, who has the Rating and Local Government Bill on his hands, will no doubt be guided mainly by the experience of the public health authorities in the large urban areas concerned. Reports from medical officers of health of three industrial cities contain comments of moment on the local housing problems.

In Birmingham the City Corporation has since 1920 built 17,682 houses, the numbers for the years 1925–6–7 being 3066, 5159, and 4007 respectively. Dr. H. P. Newsholme remarks that while this steady progress is being made in the provision of new houses, the problem of housing continues to rank as one of the most urgent and fundamental questions confronting the city. Much is being done, through sanitary inspectors and in other ways, to improve the conditions, often deplorable, of the least satisfactory houses, but there is great need for more radical treatment of a large mass of mean houses spread through various portions of the city—houses which are dismal, dilapidated, insanitary, and lacking in elementary amenities. It is not possible, says Dr. Newsholme, to measure the loss to Birmingham arising from the effects of such surroundings, not only through their adverse effect on physical welfare, but far more fundamentally through their hindrance to any real fullness of life. The problem calls all the more strongly for a solution through the contrast between this old and insanitary property and the remarkable new housing estates which have sprung up so rapidly. It is to be hoped on the one hand that the proposals of the Government for facilitating slum treatment will mature quickly, and on the other that the rehousing scheme is approaching a stage at which the problem of the slums can be systematically attacked.

In Manchester a special report on housing was submitted by Dr. R. Veitch Clark to the City Council on Sept. 30th, 1927. Dr. Clark can give no real evidence of a reduction in overcrowding although there may be a tendency in that direction, and the increased proportion of cheaper houses in the present housing schemes is likely to hasten the tendency. There is no noticeable slackening in the demand for houses to let, and much the greatest demand is for the A type of house, probably owing to inability to pay higher rents. The report also gives an estimate that about 69 per cent. of the overcrowded families waiting for houses of the A2 and A3 type are able to pay the rents charged by the corporation. An estimate is put forward that the housing need for the relief of present overcrowding and for the normal increase of the population up to Dec. 31st, 1936, is 21,650, and that, in addition, 26,000 houses are required to meet the demolition of those now below a reasonable standard of fitness. During 1927 4461 houses were built, 2240 of which were municipal. Another estimate in the report is to the effect that about one-third of the "lodger overcrowding" is caused by single and married lodgers over 50, who are frequently in receipt of old age pensions or rental allowances from the guardians. The total of these rental allowances is put at £38,000 per annum, and it is suggested that the corporation might provide small houses in the form of flats consisting of a living room and bedroom or of a combined bed-living room for tenants of this type, and thus relieve much of the overcrowding without extra cost to the rates.

[2] League of Nations: Health Organisation. C.H./Malaria/121. London: Constable and Co.

In Sheffield, according to Dr. F. E. Wynne, the amount of overcrowding continues to be deplorable and houses unfit for habitation cannot be closed, because the tenants cannot be rehoused. During 1927 five unfit houses were closed and the tenants of three small areas, comprising 173 houses, were removed to one of the housing estates. There are 4000 families on the waiting-list for municipal houses, and only a very small number of the very numerous applications of a most pathetic description received at the office can be entertained. It is impossible to prevent undesirable conditions on the corporation estates arising from subletting. During the municipal year ended March 31st, 1928, 1897 new houses were certified, of which 723 were municipal. During 1925 and 1926 the new houses numbered 2178 and 2714 respectively. The Parliamentary return shows that since the subsidy was reduced in December, 1926, the cost of erecting houses of the parlour and non-parlour type has gone down quarter by quarter, and that for the quarter ended June 30th, 1928, the average reduction in cost for both types was £82. Further, subsidised houses are going up at the rate of 10,000 a month and building is proceeding at twice the pre-war rate. Little has been done as yet in slum clearance and nothing in the way of building houses within the reach of the poorer classes of wage-earners.

These three reports, then, concur in the view that we are now only approaching the most difficult part of the housing problem. All people of goodwill will share the hope that when Parliament tackles it all parties will unite in a whole-hearted effort to cope with a national emergency.

TREATMENT OF MIGRAINE WITH ERGOTAMINE TARTRATE.

THE most plausible explanation of migraine is that it is due to spasm and subsequent dilatation of cerebral arterioles. If this theory were correct and, further, if such vascular spasm were evoked by nervous impulses reaching the cerebral vessels by the sympathetic nerves, it might be hoped that migraine would be relieved by the administration of drugs possessing a paralytic effect upon the sympathetic nerve-endings. Such a possibility led Dr. Arnault Tzanck[1] to treat migraine with ergotamine tartrate, a drug which is credited with an inhibitory effect upon the sympathetic. Dr. Tzanck, in introducing his report on this treatment, comments on the ineffectiveness of numerous other therapeutic measures. The number of cases treated with ergotamine was small, but the results obtained were sufficiently encouraging to warrant its employment on a larger scale. The dose was 2·0 mg. of ergotamine tartrate daily by the mouth, an additional 2·0 mg. being given at the threat of an attack. After a time it was often found possible to reduce the dose to 1·0 mg. a day. Treated on these lines eight patients subject to typical recurrent attacks of migraine improved, the intervals between their attacks being lengthened from a few days to two or three months. It was sometimes possible to abort an attack by administering a dose as soon as the first symptoms appeared. Three other patients suffered from "a veritable status migrainosus," being hardly ever free from pain. Two of these were almost cured: the third abandoned the treatment. In a case of ophthalmic migraine the headache was almost completely relieved, but the ocular manifestations persisted, though in an attenuated form. Dr. Tzanck observed no ill-effects in patients taking as much as 60 mg. of ergotamine tartrate a month, but he recommends careful supervision on account of the reported occurrence of gangrene following the administration of this drug, an event which if true is difficult to reconcile with its reputation as a depressor of the sympathetic. Dr. Tzanck wisely refuses to draw any theoretical conclusions as to the cause of migraine from the success of ergotamine in its treatment.

SPLENIC TUMOURS DUE TO FUNGI.

ATTENTION was drawn in these columns[1] some months ago to the evidence produced by Emil-Weil, Chevalier, and Flandrin, in France, to the effect that many cases of splenomegaly clinically of the Banti type are really due to a mycotic infection. Evidence that tumours of the spleen apparently malignant, even to the extent of producing distant metastases, may also be due to a mycelial infection, is now brought forward by the same authors.[2] They describe the case of a young man who suffered from 1920 to 1923 from progressive enlargement of the spleen, at the end of which time the organ was removed and weighed 62 kg. He made a good recovery, but in the following year developed a tumour of the occipital region, fixed to the bone, which ultimately attained the size of an orange. This disappeared under treatment with X rays, but its disappearance was associated with the development of symptoms of intracranial tumour. Relief was gained by decompression but the symptoms returned and death ensued in 1926, three years after the splenectomy. Examination of the spleen showed it to be filled with dense, firm tumour masses, and macroscopically a confident diagnosis was made of the "pseudo-sarcoma" of Letulle and Jacquelin. Serial sections, however, showed the tumour masses to be actually united into one, and microscopy revealed the presence of a dense fibrous stroma and of well-formed blood-vessels, both incompatible with the diagnosis even of a "pseudo-sarcoma." The actual tumour consisted of masses of lymphoid cells, with scanty larger cells, having two or more nuclei; portions of it showed hæmorrhage, calcification, and a plentiful deposit of iron pigment, such as was described by Gamna in his "hæmosiderotic" splenomegaly. Further examination revealed in these hæmorrhagic areas structures of a filiform nature which the authors believe to be the mycelial elements of a fungus; in some cases terminal organs which might be sporangia were detected. These supposedly mycelial elements stained poorly with hæmatein and did not take any other of the ordinary microscopic dyes—but they stained well with ferrocyanide and hydrochloric acid, giving the blue reaction of iron. So long ago as 1913 Dr. A. G. Gibson[3] demonstrated the presence of myceloid elements in the spleens from certain cases of splenomegaly, and the present observations of Emil-Weil and collaborators, which bear upon the ætiology of Hodgkin's disease, should stimulate further research along the lines laid down by Gibson. The confirmation of his work so long after its performance, and by observers apparently unaware of his findings, must be regarded as highly significant.

SUPRARENAL APOPLEXY.

Dr. Felix Pearl and Dr. Harold Brunn,[1] of San Francisco, who describe a case in a man, aged 45, which has come under their observation, remark that hæmorrhage into the suprarenal gland, though not infrequently found in infancy, is a rare condition in the adult, only 20 instances of bilateral suprarenal apoplexy in adults having been reported since 1906. The ætiological factors suggested have been thrombosis, capillary emboli, congestive diseases, infections and toxins, diseases of the solar plexus, surface burns, and the hæmorrhagic diathesis. The cases have been classified by Arnaud into three types—peritoneal, asthenic, and nervous. Any combination of symptoms may form the clinical picture, but asthenia is the most constant and characteristic of all symptoms. Physical signs are usually of no assistance in locating the seat of the disease. There may be merely vague tenderness in the lumbar regions or epigastrium or abdominal distension as in the present writers' case. There is no pigmentation of the skin as in Addison's disease. The diagnosis has only once been definitely made before death, in a case reported by N. B. Foster in 1920, but the presence of severe abdominal symptoms, with few or no physical signs, in a patient who presents definite nervous manifestations, profound asthenia, and gradual decline of blood pressure, should suggest acute adrenal disease. The prognosis is hopeless in well-marked bilateral cases, but small hæmorrhages may be absorbed without sequelæ. Treatment of bilateral suprarenal apoplexy is usually unsuccessful. The best results are likely to be obtained by injection of normal saline, Ringer's solution, and extracts of adrenal cortex or whole suprarenal gland. Epinephrin is ineffectual. Although operation is of no benefit in well-marked bilateral cases, it may be the only hope where there is massive unilateral hæmorrhage and where death is likely to be due to severe hæmorrhage and shock rather than to suprarenal failure.

THE Royal College of Physicians of London will commemorate its benefactors on Thursday, Oct. 18th, when the Harveian Oration will be delivered by Sir Humphry Rolleston, at 4 P.M., in the large library. The annual sermon at the Church of St. Mary-le-Bow will be preached at 11 A.M. on the same day, and in the evening the commemoration dinner will be held in the College at 7.30 P.M.

OUR advertisement columns contain an official notice of the forthcoming election of two members to the General Medical Council, to represent the registered medical practitioners resident in England. A group of not less than 12 practitioners is entitled to nominate a candidate, and nominations must be delivered in proper form to the Registrar of the Council on or before Oct. 13th.

OPENING OF THE LONDON MEDICAL SCHOOLS.

ADDRESSES AND ANNUAL DINNERS.

Charing Cross Hospital.—Prizes will be distributed at the hospital on Thursday, Oct. 4th, at 3.30 P.M., by Dr. Thomas Watts Eden. The annual dinner will be held at Gatti's Restaurant on the same day at 7 for 7.30 P.M., with Sir Herbert Waterhouse in the chair.

Guy's Hospital.—The session will begin on Tuesday, Oct. 2nd, but there will not be an opening ceremony.

King's College Hospital.—An introductory address will be given at the Medical School at 2.30 P.M. on Wednesday, Oct. 3rd, by Mr. Ernest Barker, professor of political science, in the University of Cambridge. Sir William Watson-Cheyne, F.R.S., will preside. The annual dinner of past and present students will be held at 7.30 P.M. on Wednesday, Oct. 3rd, at the Trocadero Restaurant, Piccadilly-circus, W., with Dr. B. R. Turner in the chair.

London Hospital.—The old students' dinner is to be held at the Trocadero Restaurant on Thursday, Oct. 18th, at 7.30 P.M.

London (R.F.H.) School of Medicine for Women.—An introductory address will be given at the school at 3 P.M. on Monday, Oct. 1st, by Dr. Andrew Balfour, whose subject will be the Tropical Field, its Possibilities for Medical Women.

Middlesex Hospital.—Mr. A. E. Webb-Johnson will deliver an introductory address, entitled the Enemies of Man, at the Queen's Hall at 3 P.M. on Tuesday, Oct. 2nd, after which Prince Arthur of Connaught will distribute prizes and Princess Arthur will present the Fardon Memorial medals. The annual dinner will be held at the Savoy Hotel on the same day at 7.30 P.M., with Prince Arthur in the chair.

Pharmaceutical Society of Great Britain.—On Wednesday, Oct. 3rd, at 3 P.M., an inaugural sessional address will be given by Mr. Reginald R. Bennett, chairman of the British Pharmaceutical Conference. A presentation of the Pereira medal will be made. On the same day, at 6.45 for 7 P.M., the anniversary dinner will take place at the Hotel Victoria, Northumberland-avenue, W.C. 2.

Royal Dental Hospital.—The dinner of past and present students will be held at 6.30 for 7 P.M. on Saturday, Oct. 20th, at the Trocadero Restaurant. Mr. G. G. Campion will preside.

St. Bartholomew's Hospital.—The old students' annual dinner will be held in the Great Hall of the hospital at 7 for 7.30 P.M., on Monday, Oct. 1st, with Sir D'Arcy Power in the chair.

St. George's Hospital.—The prize distribution will be held in the Board Room of the hospital at 3 P.M. on Monday, Oct. 1st, when an inaugural address, entitled Hydrocephalus: A Study in Phylogeny and Pathology, will be delivered by Sir John Bland-Sutton The annual dinner will be held on the same day at the Hyde Park Hotel at 7.15 for 7.45 P.M. The chair will be taken by Dr. W. S. Fox.

St. Mary's Hospital.—The annual dinner of past and present students is to be held at the Trocadero Restaurant on Friday, Oct. 5th, at 7 P.M.

St. Thomas's Hospital.—The old students' dinner will be held at St. Thomas's House on Friday, Oct. 26th, with Mr. Edwin Francis White in the chair.

University College Medical School.—The session will open on Monday, Oct. 1st, when Sir Thomas Barlow, F.R.S., will give an introductory address in the Library at 4.30 P.M. The annual dinner of past and present students will take place at the Hotel Cecil on Friday, Oct. 12th, Surgeon Vice-Admiral Gaskell in the chair.

Westminster Hospital.—An inaugural address will be given in the Board Room of the hospital on Monday, Oct. 1st, at 3 P.M., by Mr. A. C. Powell, headmaster of Epsom College. Sir William Goschen will take the chair. The hospital dinner is to be held on the same day, at 7 P.M. for 7.30, at Gatti's Restaurant, Strand, W.C., Sir James Purves-Stewart presiding.

DONATIONS AND BEQUESTS.—A cheque for £1000 from an anonymous donor has been handed to the Glasgow Dental Hospital by a chartered accountant of the city.—Miss Martha Mills, of Nottingham, left £1000 to the Nottingham General Hospital for the endowment of a bed in memory of her brother-in-law, Morris Weisblum, and £100 each to Dr. Barnardo's Homes and the Nottingham General Hospital; £50 each to several other charities.—Mr. Miles Daniel Whitehead, of Kingstown, Co. Dublin, left £500 to the Drogheda Memorial Hospital at the Curragh, Co. Kildare, and £400 to Laura Hitchins, and the income for life from 800 shares in the Imperial Tobacco Co., with remainder to the Manchester Royal Infirmary if Laura Hitchins predeceased him.

PRESENTATION OF WILLIAM MACKENZIE MEDAL.—This medal, given for valuable contributions to ophthalmology, will be presented to Dr. A. Maitland Ramsay at the Glasgow Eye Infirmary, on Tuesday, Oct. 9th, at 8 P.M., when Dr. Ramsay will deliver an address on the Importance of General Methods in the Treatment of Eye Disease.

The Clinical Interpretation of Aids to Diagnosis.

A Series of Special Articles contributed by Invitation.

V.—THE INTERPRETATION OF REPORTS ON SPUTUM.

BY S. ROODHOUSE GLOYNE, M.D. LEEDS,
D.P.H. LOND.,
PATHOLOGIST TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS.

(2)* CELLULAR AND BACTERIAL CONTENT: UNUSUAL SUBSTANCES.

Cellular Content.

THE cells of the sputum are often difficult to differentiate, but when they can be identified they are helpful in diagnosis. The dominance of large squamous epithelial cells indicates a condition of pharyngitis or coryza. Polymorph cells in large quantities are, of course, found in any purulent sputum and are not diagnostic of any special disease. They can be found in small numbers in specimens of sputum which are not purulent. In uncomplicated phthisis they are, as a rule, not very conspicuous, and when they predominate point to secondary infections. Alveolar cells from the lung are not easy to distinguish; they predominate in pulmonary tuberculosis. Ciliated bronchial epithelium is most difficult to detect even with special methods of staining, owing to the fact that it readily degenerates when the ciliated processes become unrecognisable. Malignant cells cannot be recognised with any degree of certainty, though large cellular plaques of cells are often suspicious. It is sometimes stated that predominance of the lymphocyte is an early sign of pulmonary tuberculosis. In the writer's experience this is not so. A predominance of eosinophil cells is often found in true asthma. Saliva and mucus contain few cells.

The Bacterial Flora.

The tubercle bacillus, suitably stained by the accepted Ziehl-Neelsen technique, is easy to recognise when present in any considerable number. Difficulty arises when the bacilli are very scanty. In doubtful cases of pulmonary tuberculosis it is advisable to examine a fresh specimen of sputum daily for at least a week before being satisfied that they are not present. Much depends on selecting the typical "nummules" in the sputum for examination. If search by this method fails a concentration test may be made. Several drachms of sputum are mixed with an equal amount of 5–10 per cent. antiformin; the mixture is allowed to stand for 15 minutes or so until the sputum is disintegrated, and then centrifuged, washed with water, recentrifuged, and a film of the deposit stained by the usual method. Unfortunately the method cannot be applied to a large series of specimens at one time, as in the ordinary film examination for *B. tuberculosis*, and therefore time does not permit its use as a routine. The method is said to increase the positive findings for tubercle bacilli by about 1 per cent. A daily examination by the ordinary film method for a week is equally efficacious and less laborious where large numbers of specimens have to be dealt with. The presence of large numbers of tubercle bacilli does not necessarily signify an acute infection. Chronic cases in fairly good health often have many bacilli in their sputum. A report on the number of bacilli seen per field of the microscope is therefore not of great value. Moreover, the actual count is dependent on variable factors such as the thickness of the film. At one time much stress was laid on the presence of so-called involution forms of tubercle bacilli as an aid to treatment and prognosis. It is doubtful if this sign is of any value.

In uncomplicated phthisis the sputum contains very few organisms other than the tubercle bacillus, but in the late stages of the disease catarrhal infections may be superimposed, and then the secondary organisms are many and various. Non-pathogenic acid-fast organisms are sometimes met with in sputum, but they are generally readily distinguished from the tubercle bacilli by their shape, size, and arrangement, and by the fact that they are rarely alcohol-fast and do not resist treatment with antiformin. Such bacteria generally come from the nose or ear. In case of doubt recourse must be had to guinea-pig inoculation.

Three or four years ago pathologists were frequently asked to report on the type of pneumococcus in cases of pneumonia, prior to the administration of anti-pneumococcal serum, but of late the practice has much diminished—presumably clinicians are not satisfied with the results of the serum treatment. Three types of pneumococcus are recognisable by means of agglutinin or precipitin tests. Types I. and II. are most commonly found in uncomplicated pneumonia and type III. in the rapidly fatal cases. Hæmolytic streptococci are not uncommon in the purulent sputum of "influenzal" broncho-pneumonia and imply a serious prognosis. Organisms of the coliform group are common in the fœtid sputum of bronchiectasis and pulmonary abscess. *B. pyocyaneus* is found in the same condition.

In interpreting a report on the bacterial flora other than *B. tuberculosis*, it is frequently difficult to know what emphasis to place on the different findings. Much depends on the efficiency with which the patient has washed out his mouth before expectorating the sample. Sarcinæ, leptothrices, yeasts, and even *Staphylococcus albus* are of very little significance. The so-called diplo-streptococcus also is not as a rule of much significance. Pneumococci, streptococci, *M. catarrhalis*, *B. pneumoniæ* Friedländer, and *B. influenzæ* are of pathological significance. Any combination of them may be found together and they are all common during the catarrhal seasons of the year, irrespective of the anatomical situation of the lesion. A bacteriological report should state which of the species predominates. It is sometimes said that any species found to be intracellular is of special pathological significance. As stated above, a sputum crowded with organisms of all kinds, especially if the sputum be foul smelling, is very suspicious of bronchiectasis or pulmonary abscess. When "granules" are found in the sputum actinomycosis fungi should be searched for. This disease is characterised in the lung by its frequent association with "pointing" empyema and may follow operation for appendix abscess. Others of the higher bacteria—e.g., mucor and aspergillus—are also sometimes found in sputum associated with bronchitis. It must be remembered, however, that mucor especially may be an accidental contamination, and its presence should be confirmed by repeated examination. As a rule these cases give a history of some occupational risk or dusty trade.

Unusual Substances.

Curschmann's spirals and Charcot-Leyden crystals are, of course, associated with true spasmodic asthma; and *Entamœba histolytica* with tropical abscess rupturing through the diaphragm. The latter is characterised by "anchovy paste" sputum. When search for the entamœba is required, the specimen of sputum should be as fresh as possible. Fibrin is found in sputum where there is extensive lung tissue destruction, as in chronic phthisis, bronchiectasis, and pulmonary abscess; it is the one object of search which necessitates a large amount of sputum for examination (an ounce or more).

Sputum may contain unusual substances such as pieces of sloughing mucous membrane, calcified nodules, or foreign bodies. These should always be sent to the laboratory for identification.

The hooklets of hydatid disease may also be found in sputum. Although this disease is not common in this country, it does sometimes occur associated with hæmoptysis or signs of lung compression.

---

* Part (1) appeared in THE LANCET last week.

With regard to *animal inoculation tests*, now that pneumococcus typing tests—for which the mouse was generally used—are only occasionally made, the guinea-pig test for tubercle is the commonest inoculation test required. One of its disadvantages is the length of time which must elapse before a report can safely be made—i.e., about one month. In cases of urgency it is best to inoculate two animals and to kill one at the end of a fortnight, leaving the other to go on for a month or six weeks.

Special Articles.

SOME CONSTITUENTS OF DRIED YEAST AND YEAST EXTRACTS.

THEIR APPLICATION IN HUMAN NUTRITION.

By STANLEY G. WILLIMOTT, PH.D. CAMB. AND LIVERP., B.SC.;
AND
FRANK WOKES, B.SC., F.I.C.
(*From the Biochemical Laboratory, Cambridge.*)

IN a recent discussion in THE LANCET[1] on the relative food value of white and wholemeal flour the suggestion was made that the admitted deficiency of vitamin B in white flour might be made good by yeast. "Any lack of vitamin B in white flour is definitely remedied when the flour is made into bread by the addition of yeast."[2] No data, however, were offered concerning either the vitamin content of different yeasts or the amounts of these yeasts which are normally employed in bread-making. In the absence of this necessary information the suggestion has, not unnaturally, been severely criticised.

In the meantime, progress in improvement of the staple cereal food of the nation appears to have reached a deadlock. Reasons for this are not hard to find. Perhaps one of the strongest is the conservative attitude adopted by most people towards a suggested radical change in the largest part of their diet. Bread, on an average, constitutes at least two-fifths of the diet of the mass of the population. The questions of appearance, palatability, coarseness of texture (often due to the bran employed), digestibility and keeping qualities have also proved to be important determining factors. Finally, there is the economic problem. Wholemeal bread is still slightly dearer than white bread.

This position is unfortunate, as by the proper use of yeast all these objections can be overcome. Yeast is undoubtedly a cheap and potent source of vitamin B, and abundant supplies are readily available. As long ago as 1910 Schaumann[3] obtained from yeast an extract of high physiological activity, but he drew no satisfactory conclusions regarding the constituents to which this activity was due. In 1912 Sir F. Gowland Hopkins[4] showed that yeast contained a potent growth-promoting factor which, in the light of further knowledge, was presumably vitamin B. During the last few years yeast and yeast preparations have been increasingly employed as standard sources of vitamin B. From these facts the idea has naturally arisen of supplying to white flour the missing vitamin B by the use of a potent yeast. The question which remains to be decided is the proportion of yeast necessary to be added to ensure a palatable bread of adequate potency.

On the manufacturing side experiments are already being made. There are now being placed on the market a number of white flours to which dried yeast in different proportions has been added. The results given by these modified flours, taken in conjunction with the laboratory findings here recorded, will be of great value in human nutrition. Every busy practitioner must feel somewhat bewildered at the number and the claims of proprietary preparations, purporting to contain vitamin B, with which his consulting room is constantly flooded. In these circumstances impartial scientific data may be of service. An investigation was therefore undertaken into the possibility of employing dried yeast and yeast extracts to supply the constituents lost in the removal of the wheat germ by the usual milling processes of to-day. These constituents include vitamins, proteins, and various mineral salts. Amongst the latter, phosphates are perhaps of most interest on account of their relation to nerve nutrition, in which vitamin B (antineuritic factor) appears to play a part. In fact, so well recognised is this removal of minerals in modern milling processes that one classification of flours is based on their mineral content. The most highly refined white flour, for example, is generally found to contain less than 0·4 per cent. of minerals, an average seconds flour from 0·7 to 0·8 per cent., and a wholemeal 1·0 per cent. or more, as compared with 1·4 to 1·9 in the whole wheat berry.[5] Of the total minerals, roughly two-thirds consist of potassium phosphate.

Another staple cereal food, rice, also has its vitamins and its minerals, especially phosphates, removed by modern milling processes. Unpolished rice was found by Fraser and Stanton[6] to contain about twice as much phosphate as polished rice. In the earlier work on beri-beri the curative substance was believed to be either itself an organic phosphorus compound, or some other substance closely associated with such a compound. This view was officially adopted by the Far Eastern Association of Tropical Medicine. A resolution[7] was passed that rice containing less than 0·4 per cent. of phosphorus should be excluded by law from those countries in which this cereal formed the staple food grain. Later work,[8] however, disproved the suggestion that vitamin B is a phosphorous compound. But the association of vitamin B with phosphorous compounds in rice, wheat and other natural foodstuffs is still of great practical importance.

If the vitamin and minerals absent from white flour are to be adequately supplied by yeast preparations, these constituents must be present in sufficiently high concentration to furnish the necessary amounts of each factor when the yeast is added at a level practicable from the point of view of palatability, &c. The level at which fresh yeast is ordinarily added to flour in bread-making is variable, though always in the neighbourhood of 1 per cent.[9] The actual amount of yeast added depends upon the length of time the dough is to be fermented. Thus with 12 hours' fermentation the quantity of compressed yeast added just exceeds 0·1 per cent. of the weight of the flour, but with only one hour's fermentation the percentage of yeast employed rises to 1·4.[10] However, it is possible to add a suitable dried yeast to flour up to a level of 4 or 5 per cent., producing a flavour which is distinct but not disagreeable. Vienna bread, for example, which contains a large proportion of yeast, is noted for its palatability.

The proportion of dried yeast necessary to supply an adequate amount of vitamin B to white flour is about 3 or 4 per cent. of the flour used. Taking the average moisture content of fresh yeast as 70 to 80 per cent., this would be equivalent to approximately 15 per cent. of fresh yeast. Therefore the highest amount of fresh yeast known to be employed in bread-making—i.e., 1·4 per cent.—is only about one-tenth of what would be required to furnish sufficient vitamin B. These findings lend no support to the statement made by several investigators that "any lack of vitamin B in white flour is definitely remedied when the flour is made into bread by the addition of yeast,"[2] where fresh yeast is meant. On the other hand, our results show that it is possible to make good the deficiency by the proper use of dried yeast. In order to avoid undue fermentation by the large proportion of yeast, this must have been dried at a temperature sufficiently high to destroy the diastatic enzymes.

The fact that dried yeast has a distinctly bitter flavour has led to efforts to extract the vitamins and other valuable constituents from fresh yeast by treatment with suitable solvents which do not remove the bitter constituents so readily. The extracts thus obtained are exhibited in the liquid or semi-solid condition as a palatable adjunct to the diet. In such forms vitamin B is commonly prescribed to-day. The tendency of modern diets to be deficient in vitamin B [11] has afforded opportunity to manufacturers of such extracts to advocate their general use. Evidence has recently been put forward by Plimmer, Rosedale and Raymond [12] that the vitamin B potency of such extracts may vary as much as 200 or 300 per cent. Fresh brewers' yeast is known to have a high vitamin content. Therefore it appeared probable that this variation in vitamin activity was due, in part at least, to differences in the method of extraction employed. A consideration of these facts suggested the desirability of examining quantitatively samples of yeast and of extracts prepared from them. This necessitated ascertaining their content of vitamins by feeding experiment, and of mineral and other constituents by analysis.

Preparation of Yeast Extracts.

In preparing extracts of yeast for human consumption several points have to be considered. A solvent must be employed which will take out as much as possible of the vitamins and other desired constituents—e.g., phosphates—while leaving behind the unpalatable, bitter principles. (Vitamin B is now known to contain at least two factors, the antineuritic principle of Eijkman [13] or vitamin B, and the pellagra-preventive (P-P) factor of Goldberger [14] or vitamin B_2. Whenever the term vitamin B is used, both these factors are implied.) Vitamin B is known to be soluble in water, in aqueous solutions of certain salts, and in water-alcohol mixtures. By employing a suitable strength of alcohol (say, 75–80 per cent.) fairly complete extraction of the vitamin can be effected without dissolving any considerable proportion of the bitter principles.

On the commercial scale, where the expense of alcohol is an important consideration, satisfactory results can be obtained by heating the yeast with strong saline solutions under proper conditions. The exact conditions employed by different manufacturers are, of course, industrial secrets. Apparently the saline solutions employed vary widely in strength, from 2 to 10 per cent. or more, and the time of heating may be anything from half an hour to several hours. The destruction of the yeast enzymes without serious loss of vitamin potency is thus ensured. Finally, in view of the wide variation in composition of different batches of yeast, it is important to use raw material from carefully selected sources, and produced under properly controlled conditions. From recent work by Randoin and Lecoq [15] it appears probable that distillery yeast differs from brewers' yeast in not containing the antineuritic principle of Eijkman.

Perhaps the first yeast extract to be placed on the market was marmite. This preparation is a stiff, dark brown paste, containing about 27 per cent. of water, the same proportion of salts, and about a third its weight of nitrogenous matter (see Table I.). It can be rubbed down with water to form a dark brown liquid of a salty, bitter taste. It is noteworthy that this product contains a large proportion of salt (about 13 per cent.) compared with less than 0·2 per cent. in average samples of fresh yeast. Since its introduction marmite has been largely employed as a standard source of vitamin B both in clinical practice and in research. On account of variations in the activity of marmite, dried yeast is probably a more satisfactory standard for research work. For therapeutic use, on the other hand, an extract such as marmite is more convenient. Marmite was administered in large quantities as a prophylactic against beri-beri to the troops in Mesopotamia during the war. A tablet containing ¼ oz. of marmite was given once or twice a week to supplement the vitamin B content of the ration. In preparing these tablets some difficulty was experienced on account of the bitter taste. This was eventually overcome by admixture with suitable fat, such as bacon fat or cotton-seed oil.[16] In our own experiments it was decided to overcome the bitter taste of marmite, and also obtain greater accuracy of dosage, by making an alcoholic extract. 250 g. of fresh marmite, purchased on the open market, were extracted with 75 per cent. alcohol by mechanical shaking in a stoppered Winchester at room temperature for over three hours. The aqueous-alcoholic extract was then decanted off, and the alcohol removed by heating on the water bath at 80° C. for an hour, using broken pot to facilitate the distillation of the solvent. The work of Chick and Hume [17] shows that this treatment would destroy very little of the vitamin B present. When no more solvent distilled over, the dark-coloured aqueous extract remaining in the flask, containing the vitamin B, was filtered and made up to 250 c.cm. with distilled water. Thus 1 c.cm. of this extract was equivalent to 1 g. of marmite. It was almost free from the bitter taste of the original product.

It has recently been suggested by Plimmer [11] that the vitamin potency of marmite has diminished within the last few years, since a larger dose—i.e., 4 per cent. of the diet—is now required to produce the same curative effect as was previously obtained with only 2 per cent. Workers in other laboratories have experienced similar results (private communication). Since the earlier experiments were carried out, however, much more has been learnt of the necessity of balancing the vitamin B intake against various constituents of the diet (Funk,[18] Hartwell,[19] and Plimmer [20]). This knowledge has led to the introduction of more accurate methods of testing for the vitamin, and may be one of the causes of the apparent deterioration of the marmite. A further complication arises from the recent confirmatory work of Chick and Roscoe [21] that vitamin B contains at least two factors—viz., the antineuritic principle of Eijkman and the pellagra-preventive factor of Goldberger. Since both factors are necessary for the maintenance of health and growth (Chick and Roscoe), these criteria have been employed in our estimations of the vitamin B content of various extracts.

In addition to marmite, Plimmer [11] also tested five other samples of yeast extract and discovered a variation in vitamin B potency of 200 or 300 per cent. Some were weaker and others were stronger than marmite when tested on pigeons by the same procedure. Our own experience with rats having confirmed this wide variation in the content of the most important constituent, we considered it advisable to carry out experiments on the efficacy of industrial extraction methods. For this purpose it was necessary to obtain a standard supply of fresh yeast, prepare an extract from it under known conditions, and determine the amount of vitamin and other constituents both in the extract and in the residue. The data thus obtained should indicate the efficiency of the process for extracting the vitamins and other principles, and also afford some evidence on the significance of phosphates and other analysable constituents in yeast extracts. For the preparation of this experimental extract the raw material employed was a good quality brewers' yeast, obtained from a satisfactory source, in which strict analytical control was maintained over the purity of the product. Immediately after removal of the alcoholic liquor it was conveyed to the laboratory, and heated to 98° C. with a strong saline solution (about 5 per cent.) for several hours but not long enough to affect the vitamins. The extract was then cooled and filtered, using moderate pressure, and the filtrate, which was a brown liquid with a pleasant taste, was stored under refrigeration conditions during the investigation. Analysis of this experimental extract* showed that it contained only about one-third of the amount of nitrogenous derivatives found in commercial yeast extracts such as marmite. On the other hand, its water-content being double that of marmite, some reduction in vitamin potency might be anticipated. This reduction could have been obviated by concentration of the extract to a paste but, in view of the greater accuracy of liquid dosage, concentration was not attempted. The next step, therefore, was to ascertain by feeding experiments the comparative potency of the extracts in vitamin B.

---

* A yeast extract, prepared in a similar manner and presumably of the same composition, has recently been placed on the market under the title "Verra" by Mr. Hugh Mapleton, of Garston, Liverpool, to whom we are indebted for supply of materials and certain manufacturing facilities.

Feeding Experiments with Yeast Extracts.

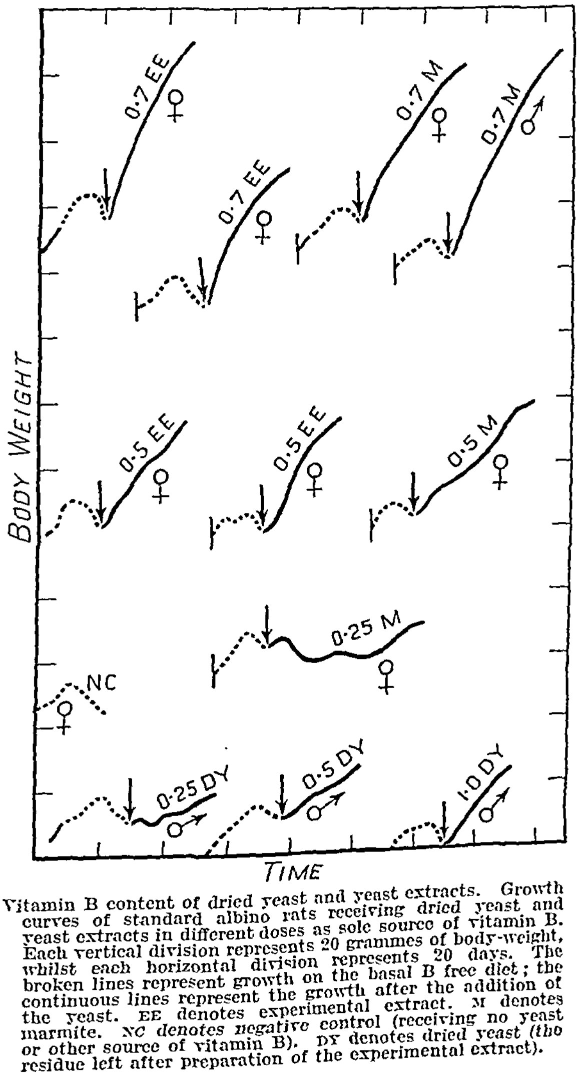
For an accurate assay of vitamin B it is essential that the basal diet shall be as free as possible from this vitamin. This can be ascertained by restricting a group of young standard rats to the basal diet whilst supplying vitamins A and D in the form of cod-liver oil. It is advisable not to attempt to supply vitamin C, because the usual sources of this vitamin are liable to be contaminated with vitamin B.[22] Moreover, it is well known that the absence of vitamin C does not appear to exert any prejudicial effect on the rat.[23] On such a vitamin B-free diet growth of all the rats should cease, and a steady decline in weight set in within two or three weeks. Precautions must be taken to prevent the animals gaining access to their fæces, which may serve as a source of the vitamin. The condition of the carbohydrate in the diet is of great importance, and constitutes a problem in itself. Recent work by Bacharach and Hartwell[24] indicates that on a diet lacking vitamin B the loss in weight appears more quickly when uncooked starch is employed.

The vitamin B deficient diet usually employed in Cambridge during recent years[25] has the following composition: raw potato starch, 40; sugar, 17; refined palm kernel oil, 15; purified caseinogen, 23; salt mixture, 5. This ration, with the addition of cod-liver oil, has usually been found to produce stoppage of growth within three weeks. In certain cases, however, irregular results have been obtained. Our most extreme case was one in which ten young albino rats after five weeks on the experimental diet were still increasing in weight, and showed an average growth increase of about half the normal. These abnormal results led to an examination of the diet for possible contamination with vitamin B. The caseinogen had been heated to above 120° C. for several hours and also had been well extracted with alcohol. It was therefore free from vitamin B. The palm kernel oil was also known by tests to be free from this vitamin. Since there is little storage of vitamin B in the body of the rat the discrepancy was traced by elimination to the potato starch. Potato starch has been used by many investigators as the source of carbohydrate in diets employed for the estimation of vitamin B. The Medical Research Council's Report on Accessory Food Factors,[22] for instance, states that starch is devoid of this vitamin. Nevertheless, our experience was that potato starch may contain sufficient vitamin B to affect seriously a vitamin assay. On replacing the potato starch of our synthetic diet by rice starch, without disturbing any other constituent, failure of growth in the normal period was at once secured (see Fig. 1) in this and other researches.[26]

A series of 12 standard albino rats (Wistar Institute strain) was then placed upon the improved vitamin B-free diet. In every case stoppage of growth had occurred within a fortnight, and before the end of the third week the weight was rapidly declining, and in several cases had reached the original level (see Fig. 1). The animals were now obviously in a poor physical condition, and in a few cases displayed premonitory symptoms of paralysis. The food intake was about 4 g. per head per day. At this point the yeast extracts were administered in doses ranging from 0·25 to 0·7 g., given separately to each animal in advance of the basal ration. One animal, which was continued on the vitamin B deficient diet as a negative control, died within a few days with definite symptoms of vitamin B deficiency. Considerable differences were observed between various animals in regard to the ease with which they accepted their doses of yeast extract. Small amounts of 0·25 g. were usually taken without difficulty, but a little sugar was found to assist the ingestion of larger doses. The marked loss of appetite is another difficulty and requires special precautions. During the actual consumption of the specified doses the animals occupied separate cages. In view of the apparent greater need of females for vitamin B[27] the experimental animals employed were mainly females. On the highest dose (0·7 g.) a male gave similar results to a female, allowing for the rather more rapid growth of the normal male. The initial weight of the animals has been shown by Osborne and Mendel[28] to have an important effect on the vitamin B requirement of rats. In the present experiments care was taken to place animals with similar initial weights on the same dose of the two extracts under test. Those with lowest initial weights were selected for the lower doses of the vitamin.

About a decade ago a number of workers found that an average dose of 0·25 g. of marmite was sufficient to restore normal growth in rats which were declining as a result of vitamin B deficiency. When, however, we tested this dose last year, either as original marmite or as the alcoholic extract, the growth response was very slight. Moreover, no significant difference in effect was observed between the original marmite or the alcoholic extract of it. (From this finding it was concluded that the method of extraction of vitamin B from marmite was reasonably efficient.) In Fig. 1 is given a typical result with this dose of 0·25 g., from which it will be seen that the animals' weight actually fell during the first two weeks of receiving the marmite. Nearly seven weeks of marmite dosage had elapsed before the animal regained and passed its initial weight. In this case recovery was finally achieved, but in several others,

FIG. 1.



Vitamin B content of dried yeast and yeast extracts. Growth curves of standard albino rats receiving dried yeast and yeast extracts in different doses as sole source of vitamin B. Each vertical division represents 20 grammes of body-weight, whilst each horizontal division represents 20 days. The broken lines represent growth on the basal B free diet; the continuous lines represent the growth after the addition of the yeast. EE denotes experimental extract. M denotes marmite. NC denotes negative control (receiving no yeast or other source of vitamin B). DY denotes dried yeast (the residue left after preparation of the experimental extract).

details of which have been omitted in order to save space, death supervened.

A dose of 0·25 g. of marmite having proved insufficient, the amount was now increased to 0·5 g., while two similar animals were put on the same dose of the experimental extract. The growth response was much better than with the 0·25 g. dose, and the experimental extract appeared to be at least as potent as the marmite, although containing only two-thirds the amount of total extractive matter. The rate of growth was still subnormal. A still higher dose of 0·7 g. was therefore tried, two animals being placed on marmite and two on the control extract. From Fig. 1 it will be seen that with this dose practically normal growth was secured with both the yeast extracts. The food intake was 8–9 g. per head per day. Possibly a dose between 0·5 and 0·7 g. might have proved adequate. From other experiments, we believe the minimum adequate dose to be not much below 0·6 g. These results might be taken to indicate that the vitamin B content of marmite has diminished to less than one-half of its original value during the last few years. Part of this apparent loss may be due to refinements in technique, and probably the figure suggested by Plimmer[11] of a 50 per cent. deterioration is more nearly correct.

Feeding Experiments with Dried Yeast.

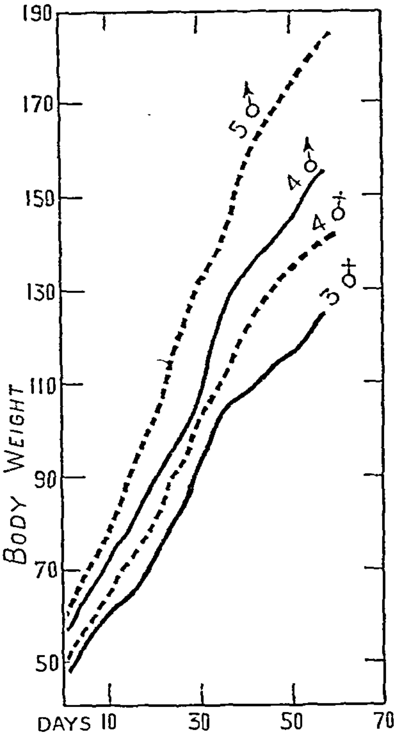
From the standpoints of industry and research alike, dried yeast is a most important source of vitamin B. The removal of the moisture produces, with proper precautions, a stable and highly concentrated product, very suitable for mixing with white flour in bread-making, to increase the vitamin B content; it has also been found the most satisfactory standard for assay work.[29] Experiments have shown that a good sample of dried yeast should restore normal growth when fed in doses of 0·3 to 0·5 g. to rats suffering from vitamin B deficiency. Taking the daily food intake as about 10 g. per head, this would mean from 3 to 5 per cent. of the diet. Some dried yeasts of unusually high potency may be effective in the proportion of 2 per cent.

The above experiments showed that it is possible to obtain from yeast an extract containing only 50 per cent. of solid matter, of which doses of about 0·6 g. are adequate. The next step was to determine how much, if any, vitamin B was left in the residue from which the extract had been prepared. For this purpose it was decided to remove all moisture from the residue, in order that it might be fed as a dry product. The residual sludge was dried by passage over steam-heated rollers in such a thin layer that less than one minute's exposure to the temperature of 100° C. sufficed to drive off practically the whole of the moisture. By this means any destruction of vitamin B was avoided. The product was in the form of thin light brown flakes, which were readily reduced to powder. Less than 1 per cent. of this powder failed to pass through a sieve of No. 40 mesh. Thorough mixing of the sieved powder ensured a product of uniform consistency, truly representative of the residue from which it had been obtained. The powder, when stored without any special precautions, underwent no noticeable deterioration in 12 months. Tests showed it to be free from diastatic enzymes. It was then fed to three rats suffering from vitamin B deficiency, in doses of 0·25, 0·5, and 1·0 g. respectively. The results, which are recorded in Fig. 1, indicate that 0·5 g. produced rather better growth response than 0·25 g. of marmite; 1·0 g. was about equal to 0·5 g. of the experimental extract. Allowing for the water content of the latter, the actual ratio of curative doses in the solid matter was therefore about 4 in the extract to 1 in the residue. Hence it would appear that the method of extraction employed had taken out roughly four-fifths of the total amount of vitamin B present in the raw material.

Nutritive Value of Yeast Protein.

In view of the high proportion of protein and other nitrogenous constituents in yeast, the question arises as to the possible value of these in nutrition, and the effects produced by their ingestion in large amounts. Various preparations of yeast have been used both for human and for animal food, and divergent opinions on their nutritive value are to be found in the literature. According to Berg,[30] the so-called "nutritive yeast," which was intended to be a rich source of protein for human consumption in Germany during the stringent times of the war, failed in its purpose. Others have reported that the protein of yeast is of low biological value. Hawk, Smith, and Holder[31] find that yeast protein cannot usefully exceed from 10 to 30 per cent. of the diet of man. If an excess of yeast is taken diarrhœa results. In view of these discrepant opinions, it was decided to test the dried yeast residue remaining over from the extraction process in the preparation of the experimental extract, and containing the larger part of the nitrogenous constituents of the original yeast. This was employed as the sole source of nitrogen, and was supplied in the unusually high concentration of 50 per cent. of the total ration, so that any possible toxic effect might be readily revealed.

FIG. 2.



Dried yeast as a source of protein. Growth curves of standard albino rats receiving dried yeast as sole source both of protein and of vitamin B. (Body-weight is shown in grammes.) Each curve is a composite one giving the average growth of a group of animals of the same sex. The continuous lines represent growth of the experimental groups receiving the whole of their protein in the form of dried yeast; the broken lines represent growth of control groups receiving their protein in the form of caseinogen. Apart from this difference, and the supply of vitamin B to the control groups as marmite, the diets were identical.

Seven albino rats of the same stock as previously used, and of about 52 g. initial weight, were restricted to the following diet:—

Dried yeast ..	.. 50	Cane sugar ..	.. 30
Palm kernel oil	.. 15	Salt mixture ..	.. 5

All the ingredients except the dried yeast had already been tested for their freedom from vitamin B. The dried yeast was thus the only source of this vitamin as well as of protein. As before, vitamins A and D were supplied in the form of cod-liver oil, while vitamin C was not provided. The bitter taste due to the high proportion of yeast was overcome by careful admixture with the fat, and by replacing the starch of the diet by sugar. In making up the diet, allowance was made for the carbohydrate carried by the dried yeast, so that the nutritive ratio of the original formula was not disturbed. The experimental conditions were the same as before.

After a few days the animals had become accustomed to the diet and the ration was readily consumed, the food intake rising gradually from 5 g. a day. All the animals grew at a steady though somewhat suboptimal rate. After eight weeks of experiment, the average increase in weight for the males was 100 g., and for the females 77 g., compared with 125 g. and 92 g. respectively for two other groups of animals on the complete ration containing caseinogen (see Fig. 2). The food intake had risen to 9 or 10 g., and all the animals appeared to be well nourished and had good coats and bright eyes, with no neuritic symptoms. Autopsies failed to reveal any pathological conditions.

It was concluded, therefore, that (1) the dried yeast constituted a satisfactory protein when fed at the level of 50 per cent. of the ration, (2) that it produced no deleterious effect when administered in quantities considerably larger than was necessary to supply sufficient vitamin B. No laxative effect was observed.

Analyses.

Chemical analyses were carried out on the same products as had been used in the feeding experiments, and on the raw materials from which these had been prepared. Total nitrogen was determined by the Kjeldahl-Gunning method. The factor 6·25 was used in estimating the protein. Fat was estimated by ether extraction in a Soxhlet apparatus, after careful removal of water at 100° C. Ashing was done in silica crucibles at low temperatures to avoid volatilisation of potash. Phosphorus was estimated according to the official directions published by the Board of Agriculture for the examination of feeding stuffs.

TABLE II.—*Vitamin B Content (Composite Factors) of Dried Yeast and Yeast Products.*

—	Moist yeast.[1]	Dried yeast.		Yeast extracts.	
		From marmite.[1]	From experimental extraction.	Marmite.[5]	Experimental extraction.
Minimum curative rat dose (g.)[2]	0·5–0·8	0·2	1·0	0·4–0·6	0·6
Minimum percentage in diet of rats[3]	5–8	2	10	4–6	6
Minimum percentage in human diet[4]	7–12	3	15	6–8	9

Notes.

1. Data given by Plimmer and other workers.
2. Minimum dose which will restore normal growth when supplied as sole source of vitamin B to standard rats of 40 to 60 g. weight suffering from vitamin B deficiency.
3. Assuming that food intake is about 10 g. per head per day.
4. Using Plimmer's figure[33] for vitamin B requirement of human beings—i.e., 1½ times that of the percentage requirement of rats.
5. Average results obtained in recent work by other investigators[24 34] and ourselves.

The results of these analyses are summarised in Table I., which also contains some data obtained by previous investigators on certain yeast products. Wide variations are shown in the composition of yeast preparations made by different methods. These may be due partly to differences in the raw material, and partly to differences in the methods of extraction employed. But in view of these wide variations in accurately analysable constituents, it is not surprising to find even greater difference in the vitamin B content of these yeast preparations, as shown in Table II.

Discussion.

It has already been pointed out by Cramer and Mottram[35] that the white and wholemeal bread problem has suffered much confusion from inaccurate statements on the one hand and the unproven claims of enthusiasts on the other. The facts that have been presented show that there is justification for this view. In the past, studies on the nutritive value of white and wholemeal bread appear to have centred round the questions of the relative protein content and the calorie value. Differences undoubtedly exist, but analysis shows that such differences are too slight to be of real importance. In recent discussions, the importance of the content of vitamin B (and other constituents) of bread, the staple cereal food, has been fully recognised on all sides. Divergence of opinion, however, is encountered on such questions as the adequacy of white bread in vitamin B and how best it may be fortified. Cramer and Mottram have clearly demonstrated that the modern milling processes used in the manufacture of white flour are responsible for a considerable loss of vitamin B amongst other constituents. This decline in nutritive value has been admitted by all serious students of the bread problem since the time of Liebig,[36] who stated that "the whiter the flour the less nutritive value it possesses." But, as previously pointed out, the suggestion has recently been made that any lack of vitamin B in white flour is rectified when the flour is made into bread by the added yeast. This contention has not been verified by the experimental facts. Cramer and Mottram have shown that the highest proportion of yeast normally employed in bread-making will not supply white bread with more than one-seventh of the amount of the vitamin found in good wholemeal bread.

A number of solutions of the problem have been proposed. During the war, for instance, Weill and Mouriquand[37] used an extract of bran in place of the bran itself in making bread. Greig and Curjel[38] employed wheat germ as a source of vitamin B, adding it to zwieback in the proportion of 15 per cent. Such bread was found to be a satisfactory means of protecting the English colonial army against beri-beri. This solution, apparently successful during the abnormal times of war, might not necessarily be satisfactory in peace. In ordinary wholemeal bread the proportion of germ varies from 1 to 2 per cent. This amount supplies only a small fraction of the vitamin B required. If wheat germ is to supply an adequate amount of this factor, it must be used in much higher proportion; for example, Hovis germ bread contains about 24 per cent. This method of enriching bread with its lost constituents is hardly a satisfactory solution. Wheat germ must first be detoxicated before it can be used in bread-making, and is more costly as a source of vitamin B than dried yeast. Moreover, it is economically unsound because, in order to provide this unusually high percentage of germ, a much larger quantity of flour (more than 12 times as much) must be robbed of the vital constituents in the germ.

Cramer and Mottram propose to solve the problem by replacing white by wholemeal bread. In practice, however, a number of difficulties at once arise. Amongst these are the questions of appearance, palatability, digestibility, texture, keeping qualities, price and, last but not least of the difficulties, the conservative attitude of the consumer. It is true that some of these obstacles can be overcome by fine grinding of wholemeal flour and improvements in the methods of baking. But a consideration which appears to have been overlooked by many investigatoıs is the extensive change in the existing milling plant which would be necessary. Serious difficulties arise when the attempt is made to produce a satisfactory wholemeal flour by the modern roller mills in general use to-day in the manufacture of white flour. The total replacement of white bread by wholemeal would probably involve the alteration, perhaps even the scrapping, of much expensive milling plant. Such a contingency would inevitably mean a considerable rise in the price of this staple foodstuff.

In view of these difficulties, a practicable *via media* is offered by the method of adding dried yeast in proper amount to ordinary white flour. An average dried yeast is several times more potent in vitamin B than the fresh yeast employed in bread making. Such a product, used in the proportion of 2 to 4 per cent. of the flour, would yield a bread containing as much vitamin B as is found in the finest wholemeal product (see Table II.). Moreover, from our own experience we can state that a white bread fortified by the addition of dried yeast can be quite palatable and in no way offend æsthetic susceptibilities. Many indeed would not realise that they were consuming anything but ordinary bread. Since dried yeast is a by-product in large industrial processes, supplies are readily and cheaply available. Finally, this method of supplying vitamin B, as well as phosphates and other valuable constituents missing from white flour, necessitates no expensive new plant, nor the scrapping of that already in operation.

Up to this point the use of dried yeast has been considered in a prophylactic capacity only. Often, however, the physician desires to administer larger quantities of vitamin B to make good, as rapidly as possible, a serious deficiency. In such cases yeast extracts appear to be very satisfactory because they can be easily administered in large and controlled doses. They should possess a high potency in vitamin B, varying only within small limits. Commercial extracts may vary in vitamin B potency by several hundred per cent., but our results have shown that a potent yeast extract can be made, under properly controlled conditions, by a simple inexpensive method. The product thus obtained was at least as active in vitamin B as the more expensive marmite. Being in a liquid form, it is very suitable for therapeutic and domestic use.

One or two important provisos should be made. The dried yeast which is to be employed in breadmaking should of course be examined for its constituents and specially tested for its content of vitamin B. Our own experiments indicate that the employment of dried yeast, even in high proportions, is free from the danger of introducing toxic constituents such as are found in wheat germ. Another consideration of the first importance is the growing practice of " bleaching " flour. Amongst the chemicals used for this purpose are ammonium persulphate, nitrogen peroxide, nitrogen trichloride, benzoyl peroxide, and chlorine. Apart from the probable inimical effects of these substances on health, which would be cumulative, their presence in bread would serve to lessen through oxidation the amount of active vitamin. From both points of view their use is both unnecessary and undesirable. The best immediate practical way of solving the bread problem, in the present situation, is to add dried yeast to flour.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 15TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 92 (last week, 123); scarlet fever, 1977; diphtheria, 1021; enteric fever, 122 (last week, 108); pneumonia, 540; puerperal fever, 45; puerperal pyrexia, 92; cerebro-spinal fever, 6; acute poliomyelitis, 17; acute polio-encephalitis, 3; encephalitis lethargica, 13; continued fever, 1; dysentery, 6; ophthalmia neonatorum, 109. No case of cholera, plague, or typhus fever was notified during the week. The notifications of small-pox are under 100 for the first time for more than two years.

The following counties each notified 3 or more cases of enteric fever:—London, 21; Chester, 3; Devon, 5; Essex, 6; Gloucester, 8; Huntingdon, 4 (St. Ives); Lancaster, 3; Norfolk, 5; Northumberland, 3; Southampton, 8; Sussex East, 6; Warwick, 3; Yorks, East Riding, 5 (Pocklington); Yorks, North Riding, 3; Monmouth, 3. The total of 122 includes 27 cases of paratyphoid fever, of which 12 were notified in London.

The number of cases in the Infectious Hospitals of the Metropolitan Asylums Board on Sept. 18th–19th was as follows:—Small-pox, under treatment 11, under observation 2; scarlet fever, 1647; diphtheria, 1466; enteric fever, 87; measles, 101; whooping-cough, 237; puerperal fever, 13 (plus 7 babies); encephalitis lethargica, 70; poliomyelitis, 2; "other diseases," 20. At St. Margaret's Hospital there were 17 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox (the last quarter has now been entirely clear), 2 (0) from enteric fever, 10 (1) from measles, 2 (1) from scarlet fever, 22 (6) from whooping-cough, 20 (5) from diphtheria, 125 (35) from diarrhœa and enteritis under two years, and 17 (5) from influenza. The figures in parentheses are those for London itself.

The fatal cases of enteric fever were reported from Plymouth and Bristol. Of the 9 fatal cases of measles outside London 3 each were reported from Liverpool and Newcastle-on-Tyne, Belfast reporting 10 in the same week. There was a further slight increase in the number of deaths from diarrhœa, of which Liverpool reported 15; West Ham, Birmingham, Manchester, Leeds, and Middlesbrough 5 each; Bristol and Hull, 4 each; while Glasgow, Dublin, and Belfast reported 14, 9, and 7.

The number of stillbirths registered during the week was 274 in the great towns (corresponding to a rate of 41* per 1000 births), including 55 in London.

---

* The rate was misprinted 89 for 39 last week.

POST-VACCINAL ENCEPHALITIS.

REPORT OF THE LEAGUE OF NATIONS COMMISSION.

AN important session of the Health Organisation of the League of Nations was held at Geneva from August 22nd to 25th. The report[1] of the proceedings has now reached us. Prof. Ricardo Jorge, Director-General of Public Health Services, Lisbon, presided, and those present were:—

Members of the Health Committee: Sir George Buchanan, Senior Medical Officer, Ministry of Health, London; Dr. H. Carrière, Director of the Federal Health Service, Berne; Dr. N. M. Josephus Jitta, President of the Health Council of the Netherlands, The Hague.

Experts: Prof. H. Aldershoff, Director of the State Serological Institute, Utrecht; Dr. F. R. Blaxall, Government Lymph Establishment, London; Prof. M. Camus, Director of the Superior Institute of Vaccine, Academy of Medicine, Paris; Prof. Dr. H. A. Gins, Robert Koch Institute, Berlin; Dr. H. Mervyn Gordon, St. Bartholomew's Hospital and College and Medical Research Council, London; Prof. A. Groth, Landesimpfanstalt, Munich; Prof. G. Sobernheim, Director of the Health Institute of the University, Berne.

The questions considered by the Commission were post-vaccinal encephalitis, and the preparation and preservation of vaccine lymph. The third subject on the agenda was the relationship between the different types of small-pox virus and those of certain human and animal pathogenic viruses, but it was decided to postpone discussion until the problem had been further examined.

A preliminary discussion on *post-vaccinal encephalitis* by a subcommission led to the framing of a report which was adopted by the Commission and is summarised below.

Terminology.—The term "post-vaccinal encephalitis" is used in the report for convenience, without necessarily implying that "post-vaccinal" is considered the equivalent of "propter-vaccinal." Some of the thousands, even millions, of persons who are successfully vaccinated in any given year must fall ill during this period in the ordinary chances of life, and they are no more immune from diseases specially affecting brain and nerves than any other persons. During recent years many countries have experienced a considerable prevalence of epidemic encephalitis (or encephalitis lethargica). The disease has no connexion with vaccination, but it may well be supposed that occasionally persons who have been recently vaccinated would be attacked by it as a matter of chance, like any others. The same consideration applies to chance coincidences between vaccination and attacks of epidemic poliomyelitis. Such rare coincidences, however, do not constitute the "post-vaccinal encephalitis" now under consideration. Encephalitis may occur as a complication of numerous infections, such as measles, or various forms of toxæmia, and it occurs, though rarely, as a complication of small-pox itself. It would be permissible clinically, and perhaps also pathologically, to group all such encephalitis under a single term, encephalitis *post-infectionem*. Vaccination is an infection. It is not implied that post-vaccinal encephalitis is not capable of being classed with, and attributed to, the same ultimate causes as "encephalitis *post-infectionem*," although there are practical reasons for considering it separately and by a separate name at the present time.

Cases in the Netherlands and in England and Wales.

The post-vaccinal encephalitis with which the report deals has become a problem of itself mainly in consequence of the events of the last few years in the Netherlands and England and Wales. In each of these countries the cases which have occurred have been sufficiently numerous and similar to require them to be considered collectively. Their occurrence has led to the realisation that a new, or at least a previously unsuspected or unrecognised, risk attaches to the practice of vaccination. This risk, when taken at its maximum value, is minute in proportion to the vast numbers of normal vaccinations to which the cases of post-vaccinal encephalitis correspond, and it is easy to exaggerate its importance. Nevertheless, it is one whose existence, in these two countries at any rate, has to be recognised, and its meaning considered. In fact, it has in the Netherlands been considered of sufficient gravity to cause the temporary suspension of the administrative measures by which the vaccination of children is secured, while in England the subject has already received the attention of two expert committees appointed by the Ministry of Health, the second of which (the Rolleston Committee) has now presented a comprehensive report,[2] embodying the information and conclusions arrived at by the first or Andrewes Committee, whose work was described to the Health Commission of the League of Nations in 1926.

In the Netherlands, 139 cases of disease of the central nervous system following vaccination were described during 1923 to 1927, of which 41 died. In England and Wales, taking the arbitrary periods dealt with respectively by the Andrewes and Rolleston Committees, 62 cases with 36 deaths occurred between Nov. 14th, 1922, and Nov. 1st, 1923, while a further group of 40 cases occurred between Jan. 1st, 1926, and Sept. 30th, 1927. Of these 40 cases, however, 15 were excluded by the Rolleston Committee on account of their doubtful nature, leaving for consideration 25 cases, of which 12 died, in the second period. The two combined, on this basis, gave a total of 87, of which 48 were fatal, for England and Wales during the two periods under investigation by these Committees.

The clinical characteristics of post-vaccinal encephalitis, as met with in both countries, are quoted from the Rolleston Committee report. Pathologically, the fatal cases have shown diffuse encephalomyelitis, the inflammation being mainly perivascular in type and often accompanied by œdema. The pathological changes in some instances resemble those found in acute disseminated sclerosis, and differ in essential respects from those met with in fatal epidemic encephalitis. The presence of the vaccinia virus in the brain tissue of certain of the fatal cases has also been definitely established. This fact, however, must be considered in the light of modern knowledge regarding the dissemination of this virus after vaccination. The brains were examined at a period after vaccination when it would be anticipated that the brains of many normal vaccinated persons, could they be tested, would equally yield the vaccinia virus.

"*Incubation period.*"—The period which usually elapses between vaccination and the onset of symptoms of encephalitis (the "incubation period") is from 9 to 13 days. The Rolleston Committee found that, out of 125 cases collected from the British and Continental sources, the onset was between the ninth and thirteenth day after vaccination in 94, and the most favoured day was the eleventh.

Age-incidence.—In both countries post-vaccinal encephalitis has occurred more rarely in infants under the age of two years than in older children and in adults.

During the four years 1924 to 1927 in the Netherlands 4 cases occurred among 126,124 vaccinations under the age of two years, as against 130 cases among 462,212 vaccinations between the ages of 3 and 12; in other words, 1 case to every 31,531 vaccinations at ages 0 to 2, and 1 case to every 3555 vaccinations at ages 3 to 12. The vaccination figures are based on the doses of lymph issued and not on the actual vaccinations performed; they are, therefore, an over- rather than an under-statement.

In England and Wales the predilection of the disease for older children has been equally notable, though figures comparable to the Dutch of vaccinations at ages are not obtainable. The vaccinations done by the public vaccinators in England and Wales under the vaccination law of the country are normally limited to the vaccination of infants under two years. But in the English series of 87 cases of post-vaccinal encephalitis referred to above, those under two years of age were only eight in number. During recent years, owing to the prevalence of small-pox, an exceptionally large number of school-children have been vaccinated who had escaped vaccination in infancy, and the

majority of the English post-vaccinal encephalitis cases have occurred among these school-children.

---

[1] Publications of the League of Nations. Health. 1928. III. 12. C.H. 739.

[2] See THE LANCET, August 4th, 1928, p. 233.

Method of vaccination: source of lymph.—Most of the post-vaccinal encephalitis cases in both countries have occurred in children whose vaccination, to judge from all ordinary signs and cutaneous reactions, has run a normal course. No single method of vaccinating has been exclusively concerned. The American practice of using minimal quantities of vaccine lymph has, up to the present, been so little followed, however, in the Netherlands or in England that it is not possible to ascertain whether in any case encephalitis has followed the use of this method.

Many different vaccine lymphs have been used to vaccinate the cases which developed encephalitis, and no one source of lymph has been proved to be more associated with the occurrence of the disease than another.

The *geographical distribution* of the cases in each country has been wide.

The cases have chiefly occurred in those regions and at those times when organised vaccination of the population was in progress. Nevertheless, it is noteworthy that, both in the Netherlands and in England and Wales, there have been large populous areas in which vaccination has been carried out on a large scale on persons of all ages during the past four or five years without the occurrence of any post-vaccinal encephalitis. On the other hand, in certain rural districts, sometimes in quite small villages or rural communes, local vaccination has been attended by a relatively excessive proportion of encephalitis cases. Striking illustrations of this circumstance have been supplied in the Dutch reports.

Originally in the Netherlands the local distribution of post-vaccinal encephalitis showed a notable degree of correspondence with the local distribution of known cases of epidemic encephalitis (encephalitis lethargica), but this correspondence has not been maintained in the later series of Dutch cases, and has never been established in any of the English series.

In no country other than the two under discussion has the occurrence of encephalitis been on any considerable scale, but cases of the same sort have been reported in 1922 from Portugal (1); in 1924 from Prague (8), from Switzerland (2), and Germany (3); in 1927 from Poland (2), and the United States (4); and in 1928 from British Guiana (1).

Research has so far failed to give any sufficient or generally accepted explanation of the cause or causes of post-vaccinal encephalitis. The questions whether the appearance of post-vaccinal encephalitis can be checked by the habitual use of smaller doses of vaccine, or by the adoption of different methods of vaccination, are being studied in the countries specially affected. It is hoped, however, that the proposals, in the second part of the report, for international expert coöperation in the study of the different viruses allied to vaccinia; of the effect of diluting vaccine lymph; of the use of antiseptics in lymph preparation, and so forth, may prove to be of use, directly or indirectly, to those who are doing research work on post-vaccinal encephalitis.

Cases in Other Countries.

From the international point of view, it is important that further inquiries should be made as to the existence of post-vaccinal encephalitis in countries other than the Netherlands and England and Wales. If, as it appears, the condition is one which occurs with the utmost rarity among infants vaccinated under the age of two years, and if also it is the fact that post-vaccinal encephalitis is similarly of the utmost rarity after revaccination of older children or adults, it is probable that there are many countries in which little or no post-vaccinal encephalitis is likely to occur. In these countries, the great majority of the population is vaccinated in infancy. But, on the other hand, there are certain countries in which, like the Netherlands, primary vaccination at school age is habitually practised, or in which, as in England, large numbers of children of school age or adults are vaccinated for the first time on account of the appearance of small-pox. It is in such instances that the establishment of the negative, after full inquiry and observation, would be of the greatest value as a control to the English and Dutch experience.

It is fallacious to expect these cases to be brought to the notice of the Central Health Authority merely through the ordinary channels of infectious disease notification. This fact may be attributed either to failure on the part of the practitioner to connect the subsequent illness with previous vaccination, or to the fact that the doctor in attendance on the case during the nervous illness is not the one who performed the vaccination. A further complication in the inquiry is the occurrence of transient cases, or cases with indefinite symptoms, which are readily considered by the practitioner to be due only to vaccination. The four cardinal symptoms of the disease (temperature, vomiting, headache, and drowsiness) may each or all occur in course of normal vaccination in a young child.

The possible fallacies of a negative return from either a country or districts in a country are therefore very great, and a statement that cases of post-vaccinal encephalitis do not occur in a given locality can only be of value if made after most careful inquiry on the spot by a competent investigator, who has access to doctors, hospitals, schools, and all other sources of information in the area. Inquiries are to be made with a view to indicating a limited number of countries or regions which would be appropriate for such investigations.

Conclusions.

The facts and considerations which have been before the Small-pox and Vaccination Commission at its present session seem to permit the following conclusions:—

(*a*) The foremost of these is the rarity of cases of post-vaccinal encephalitis, even in the countries specially affected, by contrast with the number of vaccinations. We are in fact concerned with a minimal proportion of them. (*b*) Apparently the matter is not one in which mere coincidence between vaccination and encephalitis can be invoked; in other words, we are not dealing with a merely fortuitous occurrence. (*c*) In our present state of knowledge we must conclude that post-vaccinal encephalitis is a different disease from encephalitis lethargica. The conditions under which post-vaccinal encephalitis has manifested itself in the Netherlands and in England and Wales tend to show that children between 3 and 13 years of age are particularly susceptible, whilst infancy and adult ages are almost wholly exempt. All observations point to the conclusion that the appearance of encephalitis is not connected either with particular strains of lymph or with particular accidents of lymph preparation. (*d*) Passing to the ætiologico-pathological side of the problem, it would appear in our present state of knowledge that the virus of vaccinia of itself cannot be considered responsible for the supervention of encephalitis. Rather it has to be supposed that some unknown factor exists—perhaps bacterial or a filter-passing virus, or a latent virus—which, by means of a reciprocal reaction, determines the occurrence of the accidents in question.

None of the facts considered in this report lead the Commission to the conclusion that there is reason for discontinuing the use of vaccination, which remains the most powerful weapon against small-pox that we possess.

In view of the circumstances associated with the occurrence of nervous complications which, as explained in the first part of this report, are in any case of extreme rarity, the Commission draws attention to the advantage which may result from practising primary vaccination during early infancy rather than at later ages of childhood.

HALF A MILLION FOR HOSPITALS.—To celebrate his seventy-eighth birthday in December next, Mr. Bernhard Baron, the cigarette manufacturer, has created a trust and endowed it with £575,000 four per cent. Consolidated Loan, to be called "The Bernhard Baron Charitable Trust for Hospitals and Asylums for Orphans and Crippled Children." The trust is to endure for 20 years, and the trustees are to apply annually as nearly as possible an equal proportion of the capital and income to the prescribed purposes. Twenty-five per cent. of the money is to be distributed among institutions under Jewish control. Lord Reading is the chairman of the trustees.

POST-VACCINAL ENCEPHALITIS.

REPORT OF THE LEAGUE OF NATIONS COMMISSION.

AN important session of the Health Organisation of the League of Nations was held at Geneva from August 22nd to 25th. The report[1] of the proceedings has now reached us. Prof. Ricardo Jorge, Director-General of Public Health Services, Lisbon, presided, and those present were :—

Members of the Health Committee : Sir George Buchanan, Senior Medical Officer, Ministry of Health, London ; Dr. H. Carrière, Director of the Federal Health Service, Berne ; Dr. N M. Josephus Jitta, President of the Health Council of the Netherlands, The Hague.

Experts : Prof. H. Aldershoff, Director of the State Serological Institute, Utrecht ; Dr. F. R. Blaxall, Government Lymph Establishment, London ; Prof. M. Camus, Director of the Superior Institute of Vaccine, Academy of Medicine, Paris ; Prof. Dr. H. A. Gins, Robert Koch Institute, Berlin ; Dr. H. Mervyn Gordon, St. Bartholomew's Hospital and College and Medical Research Council, London ; Prof. A. Groth, Landesimpfanstalt, Munich ; Prof. G. Sobernheim, Director of the Health Institute of the University, Berne.

The questions considered by the Commission were post-vaccinal encephalitis, and the preparation and preservation of vaccine lymph. The third subject on the agenda was the relationship between the different types of small-pox virus and those of certain human and animal pathogenic viruses, but it was decided to postpone discussion until the problem had been further examined.

A preliminary discussion on *post-vaccinal encephalitis* by a subcommission led to the framing of a report which was adopted by the Commission and is summarised below.

Terminology.—The term "post-vaccinal encephalitis" is used in the report for convenience, without necessarily implying that "post-vaccinal" is considered the equivalent of "propter-vaccinal." Some of the thousands, even millions, of persons who are successfully vaccinated in any given year must fall ill during this period in the ordinary chances of life, and they are no more immune from diseases specially affecting brain and nerves than any other persons. During recent years many countries have experienced a considerable prevalence of epidemic encephalitis (or encephalitis lethargica). The disease has no connexion with vaccination, but it may well be supposed that occasionally persons who have been recently vaccinated would be attacked by it as a matter of chance, like any others. The same consideration applies to chance coincidences between vaccination and attacks of epidemic poliomyelitis. Such rare coincidences, however, do not constitute the "post-vaccinal encephalitis" now under consideration. Encephalitis may occur as a complication of numerous infections, such as measles, or various forms of toxæmia, and it occurs, though rarely, as a complication of small-pox itself. It would be permissible clinically, and perhaps also pathologically, to group all such encephalitis under a single term, encephalitis *post-infectionem*. Vaccination is an infection. It is not implied that post-vaccinal encephalitis is not capable of being classed with, and attributed to, the same ultimate causes as "encephalitis *post-infectionem*," although there are practical reasons for considering it separately and by a separate name at the present time.

Cases in the Netherlands and in England and Wales.

The post-vaccinal encephalitis with which the report deals has become a problem of itself mainly in consequence of the events of the last few years in the Netherlands and England and Wales. In each of these countries the cases which have occurred have been sufficiently numerous and similar to require them to be considered collectively. Their occurrence has led to the realisation that a new, or at least a previously unsuspected or unrecognised, risk attaches to the practice of vaccination. This risk, when taken at its maximum value, is minute in proportion to the vast numbers of normal vaccinations to which the cases of post-vaccinal encephalitis correspond, and it is easy to exaggerate its importance. Nevertheless, it is one whose existence, in these two countries at any rate, has to be recognised, and its meaning considered. In fact, it has in the Netherlands been considered of sufficient gravity to cause the temporary suspension of the administrative measures by which the vaccination of children is secured, while in England the subject has already received the attention of two expert committees appointed by the Ministry of Health, the second of which (the Rolleston Committee) has now presented a comprehensive report,[2] embodying the information and conclusions arrived at by the first or Andrewes Committee, whose work was described to the Health Commission of the League of Nations in 1926.

In the Netherlands, 139 cases of disease of the central nervous system following vaccination were described during 1923 to 1927, of which 41 died. In England and Wales, taking the arbitrary periods dealt with respectively by the Andrewes and Rolleston Committees, 62 cases with 36 deaths occurred between Nov. 14th, 1922, and Nov. 1st, 1923, while a further group of 40 cases occurred between Jan. 1st, 1926, and Sept. 30th, 1927. Of these 40 cases, however, 15 were excluded by the Rolleston Committee on account of their doubtful nature, leaving for consideration 25 cases, of which 12 died, in the second period. The two combined, on this basis, gave a total of 87, of which 48 were fatal, for England and Wales during the two periods under investigation by these Committees.

The clinical characteristics of post-vaccinal encephalitis, as met with in both countries, are quoted from the Rolleston Committee report. Pathologically, the fatal cases have shown diffuse encephalomyelitis, the inflammation being mainly perivascular in type and often accompanied by œdema. The pathological changes in some instances resemble those found in acute disseminated sclerosis, and differ in essential respects from those met with in fatal epidemic encephalitis. The presence of the vaccinia virus in the brain tissue of certain of the fatal cases has also been definitely established. This fact, however, must be considered in the light of modern knowledge regarding the dissemination of this virus after vaccination. The brains were examined at a period after vaccination when it would be anticipated that the brains of many normal vaccinated persons, could they be tested, would equally yield the vaccinia virus.

"*Incubation period.*"—The period which usually elapses between vaccination and the onset of symptoms of encephalitis (the "incubation period") is from 9 to 13 days. The Rolleston Committee found that, out of 125 cases collected from the British and Continental sources, the onset was between the ninth and thirteenth day after vaccination in 94, and the most favoured day was the eleventh.

Age-incidence.—In both countries post-vaccinal encephalitis has occurred more rarely in infants under the age of two years than in older children and in adults.

During the four years 1924 to 1927 in the Netherlands 4 cases occurred among 126,124 vaccinations under the age of two years, as against 130 cases among 462,212 vaccinations between the ages of 3 and 12 ; in other words, 1 case to every 31,531 vaccinations at ages 0 to 2, and 1 case to every 3555 vaccinations at ages 3 to 12. The vaccination figures are based on the doses of lymph issued and not on the actual vaccinations performed ; they are, therefore, an over- rather than an under-statement.

Twenty-five per cent. of the money is to be distributed among institutions under Jewish control. Lord Reading is the chairman of the trustees.

POST-VACCINAL ENCEPHALITIS.

REPORT OF THE LEAGUE OF NATIONS COMMISSION.

AN important session of the Health Organisation of the League of Nations was held at Geneva from August 22nd to 25th. The report[1] of the proceedings has now reached us. Prof. Ricardo Jorge, Director-General of Public Health Services, Lisbon, presided, and those present were:—

Members of the Health Committee: Sir George Buchanan, Senior Medical Officer, Ministry of Health, London; Dr. H. Carrière, Director of the Federal Health Service, Berne; Dr. N. M. Josephus Jitta, President of the Health Council of the Netherlands, The Hague.

Experts: Prof. H. Aldershoff, Director of the State Serological Institute, Utrecht; Dr. F. R. Blaxall, Government Lymph Establishment, London; Prof. M. Camus, Director of the Superior Institute of Vaccine, Academy of Medicine, Paris; Prof. Dr. H. A. Gins, Robert Koch Institute, Berlin; Dr. H. Mervyn Gordon, St. Bartholomew's Hospital and College and Medical Research Council, London; Prof. A. Groth, Landesimpfanstalt, Munich; Prof. G. Sobernheim, Director of the Health Institute of the University, Berne.

The questions considered by the Commission were post-vaccinal encephalitis, and the preparation and preservation of vaccine lymph. The third subject on the agenda was the relationship between the different types of small-pox virus and those of certain human and animal pathogenic viruses, but it was decided to postpone discussion until the problem had been further examined.

A preliminary discussion on *post-vaccinal encephalitis* by a subcommission led to the framing of a report which was adopted by the Commission and is summarised below.

Terminology.—The term "post-vaccinal encephalitis" is used in the report for convenience, without necessarily implying that "post-vaccinal" is considered the equivalent of "propter-vaccinal." Some of the thousands, even millions, of persons who are successfully vaccinated in any given year must fall ill during this period in the ordinary chances of life, and they are no more immune from diseases specially affecting brain and nerves than any other persons. During recent years many countries have experienced a considerable prevalence of epidemic encephalitis (or encephalitis lethargica). The disease has no connexion with vaccination, but it may well be supposed that occasionally persons who have been recently vaccinated would be attacked by it as a matter of chance, like any others. The same consideration applies to chance coincidences between vaccination and attacks of epidemic poliomyelitis. Such rare coincidences, however, do not constitute the "post-vaccinal encephalitis" now under consideration. Encephalitis may occur as a complication of numerous infections, such as measles, or various forms of toxæmia, and it occurs, though rarely, as a complication of small-pox itself. It would be permissible clinically, and perhaps also pathologically, to group all such encephalitis under a single term, encephalitis *post-infectionem*. Vaccination is an infection. It is not implied that post-vaccinal encephalitis is not capable of being classed with, and attributed to, the same ultimate causes as "encephalitis *post-infectionem*," although there are practical reasons for considering it separately and by a separate name at the present time.

Cases in the Netherlands and in England and Wales.

The post-vaccinal encephalitis with which the report deals has become a problem of itself mainly in consequence of the events of the last few years in the Netherlands and England and Wales. In each of these countries the cases which have occurred have been sufficiently numerous and similar to require them to be considered collectively. Their occurrence has led to the realisation that a new, or at least a previously unsuspected or unrecognised, risk attaches to the practice of vaccination. This risk, when taken at its maximum value, is minute in proportion to the vast numbers of normal vaccinations to which the cases of post-vaccinal encephalitis correspond, and it is easy to exaggerate its importance. Nevertheless, it is one whose existence, in these two countries at any rate, has to be recognised, and its meaning considered. In fact, it has in the Netherlands been considered of sufficient gravity to cause the temporary suspension of the administrative measures by which the vaccination of children is secured, while in England the subject has already received the attention of two expert committees appointed by the Ministry of Health, the second of which (the Rolleston Committee) has now presented a comprehensive report,[2] embodying the information and conclusions arrived at by the first or Andrewes Committee, whose work was described to the Health Commission of the League of Nations in 1926.

In the Netherlands, 139 cases of disease of the central nervous system following vaccination were described during 1923 to 1927, of which 41 died. In England and Wales, taking the arbitrary periods dealt with respectively by the Andrewes and Rolleston Committees, 62 cases with 36 deaths occurred between Nov. 14th, 1922, and Nov. 1st, 1923, while a further group of 40 cases occurred between Jan. 1st, 1926, and Sept. 30th, 1927. Of these 40 cases, however, 15 were excluded by the Rolleston Committee on account of their doubtful nature, leaving for consideration 25 cases, of which 12 died, in the second period. The two combined, on this basis, gave a total of 87, of which 48 were fatal, for England and Wales during the two periods under investigation by these Committees.

The clinical characteristics of post-vaccinal encephalitis, as met with in both countries, are quoted from the Rolleston Committee report. Pathologically, the fatal cases have shown diffuse encephalomyelitis, the inflammation being mainly perivascular in type and often accompanied by œdema. The pathological changes in some instances resemble those found in acute disseminated sclerosis, and differ in essential respects from those met with in fatal epidemic encephalitis. The presence of the vaccinia virus in the brain tissue of certain of the fatal cases has also been definitely established. This fact, however, must be considered in the light of modern knowledge regarding the dissemination of this virus after vaccination. The brains were examined at a period after vaccination when it would be anticipated that the brains of many normal vaccinated persons, could they be tested, would equally yield the vaccinia virus.

"*Incubation period.*"—The period which usually elapses between vaccination and the onset of symptoms of encephalitis (the "incubation period") is from 9 to 13 days. The Rolleston Committee found that, out of 125 cases collected from the British and Continental sources, the onset was between the ninth and thirteenth day after vaccination in 94, and the most favoured day was the eleventh.

Age-incidence.—In both countries post-vaccinal encephalitis has occurred more rarely in infants under the age of two years than in older children and in adults.

During the four years 1924 to 1927 in the Netherlands 4 cases occurred among 126,124 vaccinations under the age of two years, as against 130 cases among 462,212 vaccinations between the ages of 3 and 12; in other words, 1 case to every 31,531 vaccinations at ages 0 to 2, and 1 case to every 3555 vaccinations at ages 3 to 12. The vaccination figures are based on the doses of lymph issued and not on the actual vaccinations performed; they are, therefore, an over- rather than an under-statement.

In England and Wales the predilection of the disease for older children has been equally notable, though figures comparable to the Dutch of vaccinations at ages are not obtainable. The vaccinations done by the public vaccinators in England and Wales under the vaccination law of the country are normally limited to the vaccination of infants under two years. But in the English series of 87 cases of post-vaccinal encephalitis referred to above, those under two years of age were only eight in number. During recent years, owing to the prevalence of small-pox, an exceptionally large number of school-children have been vaccinated who had escaped vaccination in infancy, and the

majority of the English post-vaccinal encephalitis cases have occurred among these school-children.

---

[1] Publications of the League of Nations. Health. 1928. III. 12. C.H. 739.

[2] See THE LANCET, August 4th, 1928, p. 233.

Method of vaccination: source of lymph.—Most of the post-vaccinal encephalitis cases in both countries have occurred in children whose vaccination, to judge from all ordinary signs and cutaneous reactions, has run a normal course. No single method of vaccinating has been exclusively concerned. The American practice of using minimal quantities of vaccine lymph has, up to the present, been so little followed, however, in the Netherlands or in England that it is not possible to ascertain whether in any case encephalitis has followed the use of this method.

Many different vaccine lymphs have been used to vaccinate the cases which developed encephalitis, and no one source of lymph has been proved to be more associated with the occurrence of the disease than another.

The *geographical distribution* of the cases in each country has been wide.

The cases have chiefly occurred in those regions and at those times when organised vaccination of the population was in progress. Nevertheless, it is noteworthy that, both in the Netherlands and in England and Wales, there have been large populous areas in which vaccination has been carried out on a large scale on persons of all ages during the past four or five years without the occurrence of any post-vaccinal encephalitis. On the other hand, in certain rural districts, sometimes in quite small villages or rural communes, local vaccination has been attended by a relatively excessive proportion of encephalitis cases. Striking illustrations of this circumstance have been supplied in the Dutch reports.

Originally in the Netherlands the local distribution of post-vaccinal encephalitis showed a notable degree of correspondence with the local distribution of known cases of epidemic encephalitis (encephalitis lethargica), but this correspondence has not been maintained in the later series of Dutch cases, and has never been established in any of the English series.

In no country other than the two under discussion has the occurrence of encephalitis been on any considerable scale, but cases of the same sort have been reported in 1922 from Portugal (1); in 1924 from Prague (8), from Switzerland (2), and Germany (3); in 1927 from Poland (2), and the United States (4); and in 1928 from British Guiana (1).

Research has so far failed to give any sufficient or generally accepted explanation of the cause or causes of post-vaccinal encephalitis. The questions whether the appearance of post-vaccinal encephalitis can be checked by the habitual use of smaller doses of vaccine, or by the adoption of different methods of vaccination, are being studied in the countries specially affected. It is hoped, however, that the proposals, in the second part of the report, for international expert coöperation in the study of the different viruses allied to vaccinia; of the effect of diluting vaccine lymph; of the use of antiseptics in lymph preparation, and so forth, may prove to be of use, directly or indirectly, to those who are doing research work on post-vaccinal encephalitis.

Cases in Other Countries.

From the international point of view, it is important that further inquiries should be made as to the existence of post-vaccinal encephalitis in countries other than the Netherlands and England and Wales. If, as it appears, the condition is one which occurs with the utmost rarity among infants vaccinated under the age of two years, and if also it is the fact that post-vaccinal encephalitis is similarly of the utmost rarity after revaccination of older children or adults, it is probable that there are many countries in which little or no post-vaccinal encephalitis is likely to occur. In these countries, the great majority of the population is vaccinated in infancy. But, on the other hand, there are certain countries in which, like the Netherlands, primary vaccination at school age is habitually practised, or in which, as in England, large numbers of children of school age or adults are vaccinated for the first time on account of the appearance of small-pox. It is in such instances that the establishment of the negative, after full inquiry and observation, would be of the greatest value as a control to the English and Dutch experience.

It is fallacious to expect these cases to be brought to the notice of the Central Health Authority merely through the ordinary channels of infectious disease notification. This fact may be attributed either to failure on the part of the practitioner to connect the subsequent illness with previous vaccination, or to the fact that the doctor in attendance on the case during the nervous illness is not the one who performed the vaccination. A further complication in the inquiry is the occurrence of transient cases, or cases with indefinite symptoms, which are readily considered by the practitioner to be due only to vaccination. The four cardinal symptoms of the disease (temperature, vomiting, headache, and drowsiness) may each or all occur in course of normal vaccination in a young child.

The possible fallacies of a negative return from either a country or districts in a country are therefore very great, and a statement that cases of post-vaccinal encephalitis do not occur in a given locality can only be of value if made after most careful inquiry on the spot by a competent investigator, who has access to doctors, hospitals, schools, and all other sources of information in the area. Inquiries are to be made with a view to indicating a limited number of countries or regions which would be appropriate for such investigations.

Conclusions.

The facts and considerations which have been before the Small-pox and Vaccination Commission at its present session seem to permit the following conclusions:—

(*a*) The foremost of these is the rarity of cases of post-vaccinal encephalitis, even in the countries specially affected, by contrast with the number of vaccinations. We are in fact concerned with a minimal proportion of them. (*b*) Apparently the matter is not one in which mere coincidence between vaccination and encephalitis can be invoked; in other words, we are not dealing with a merely fortuitous occurrence. (*c*) In our present state of knowledge we must conclude that post-vaccinal encephalitis is a different disease from encephalitis lethargica. The conditions under which post-vaccinal encephalitis has manifested itself in the Netherlands and in England and Wales tend to show that children between 3 and 13 years of age are particularly susceptible, whilst infancy and adult ages are almost wholly exempt. All observations point to the conclusion that the appearance of encephalitis is not connected either with particular strains of lymph or with particular accidents of lymph preparation. (*d*) Passing to the ætiologico-pathological side of the problem, it would appear in our present state of knowledge that the virus of vaccinia of itself cannot be considered responsible for the supervention of encephalitis. Rather it has to be supposed that some unknown factor exists—perhaps bacterial or a filter-passing virus, or a latent virus—which, by means of a reciprocal reaction, determines the occurrence of the accidents in question.

None of the facts considered in this report lead the Commission to the conclusion that there is reason for discontinuing the use of vaccination, which remains the most powerful weapon against small-pox that we possess.

In view of the circumstances associated with the occurrence of nervous complications which, as explained in the first part of this report, are in any case of extreme rarity, the Commission draws attention to the advantage which may result from practising primary vaccination during early infancy rather than at later ages of childhood.

HALF A MILLION FOR HOSPITALS.—To celebrate his seventy-eighth birthday in December next, Mr. Bernhard Baron, the cigarette manufacturer, has created a trust and endowed it with £575,000 four per cent. Consolidated Loan, to be called "The Bernhard Baron Charitable Trust for Hospitals and Asylums for Orphans and Crippled Children." The trust is to endure for 20 years, and the trustees are to apply annually as nearly as possible an equal proportion of the capital and income to the prescribed purposes. Twenty-five per cent. of the money is to be distributed among institutions under Jewish control. Lord Reading is the chairman of the trustees.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Predestination to Medical Study.

AT the opening of the new home of the Cologne Medical Society, Prof. Moritz read a paper on the qualities which predestine men and women to take up medical work. He agreed with the views of the late Prof. Garré, of Bonn, who discerned two types among mankind—the auditive and the visual. The latter have an open eye for the world of phenomena, whereas those of the auditive type form their views from the written or spoken word. Prof. Moritz said he had written, on the one hand, to nearly all the medical professors at the German universities, and, on the other, to professors of theoretical sciences such as history, philosophy, archæology, and mathematics, asking them to let him know what had been their favourite subjects at school. He wanted to know whether in their matriculation examination they had got high marks in natural science, whether they had shown interest in physical experiments, or whether, as a sign of an auditive disposition, they had easily learnt their lessons by heart. The answers showed that the medical professors when schoolboys belonged rather to the visual type than to the other, whilst the professors of theoretical sciences had an auditive make-up. The medical men had done well in physics and chemistry, and had shown a taste for experiment, collecting, and observation. As only 8 per cent. of the medical men did not belong to that type, Prof. Moritz concluded that the born naturalist and medical man early shows his predilection for visible phenomena and for experiments, and this later helps in his medical training.

Scarlet Fever and the Potato.

A Berlin medical man, Dr. Benda, the author of essays on the influence of weather and social conditions on the incidence of scarlet fever, has now been studying the possible relation between scarlet fever and the consumption of potatoes. The disease first became known, he points out, at the time when the potato was originally imported into Europe—namely, in the middle of the sixteenth century—and it remained very rare until the beginning of the nineteenth century when potatoes began to be consumed in larger quantities. In Prussia at the present day, he finds, 68·6 per cent. of the potatoes come from the six eastern provinces, and only 31·4 per cent. from the western provinces, and he thinks it significant that on the average the eastern provinces have a scarlet fever mortality of 2·56 per 10,000, as compared with 1·14 in the west. In the individual provinces he has noted that good potato harvests coincide with an increase in the mortality from scarlet fever, and he is of opinion that the consumption of this vegetable favours the development of scarlet fever, although other factors, such as the weather and the density and social standing of the population, should not be overlooked. In support of this view he points out that in countries where potatoes are cultivated very little or not at all scarlet fever is very rare, and these facts make him suggest that the virus may be present in the tubers. A similar theory has been elaborated in connexion with certain epidemics which have broken out in barracks, asylums, and other institutions after the consumption of potatoes, and which were originally ascribed to solanin poisoning. They are now regarded in some quarters as possibly due to the presence in the potatoes of the toxins of *Bacillus coli*, *B. proteus*, and other micro-organisms.

Chimney-sweeps' Cancer.

Chimney-sweeps' cancer has completely died out in Germany, according to an article written by the secretary of the Chimney-sweeps' Association. Nevertheless, this disease is still mentioned in recent works on occupational diseases, and is included in the schedule to the recent law on compensation for professional diseases, together with lead, mercury, and other forms of poisoning. The writer is of opinion that the progress of hygiene, especially improvement in washing facilities, has contributed to the disappearance of the disease. In England, he says, chimney-sweeps' cancer still exists, but perhaps this is because the soot from English coal is more irritating to the skin than German soot.

Legal Responsibility for the Mistakes of Locum Tenents.

The question whether a medical practitioner may be held responsible for malpraxis by his locum tenent has lately been decided in the affirmative by the High Court of Leipzig. A medical man had been absent on a holiday and had appointed a locum tenent with a fixed salary on condition that he should attend the patients designated to him by his employer's wife. A patient had telephoned to the doctor's house to say that he had broken his arm, and wanted attention. The defendant's wife answered that he would come at once, but eventually sent the locum tenent. As the treatment given was alleged to have had damaging results, the patient brought an action against the medical man because he had suffered at the hands of his representative. After a long law-suit the High Court found for the plaintiff, on the ground that the locum tenent had acted as the agent of the defendant, and the latter as principal must be held responsible for the mistakes made. The defendant had pleaded that the locum tenent, as a medical man, was completely independent in his treatment, but this argument was not approved by the court.

Scarcity of Bodies for Dissection.

Human bodies destined for anatomical studies are somewhat scarce in certain universities. The laws and regulations on the subject differ in the various German states, but as a rule the bodies of unknown persons and of criminals who have died in penitentiaries are taken to the anatomical institutes. In the case of prisoners this does not happen if the relatives declare themselves ready to pay the expenses of burial. The anatomical institute of the University of Jena has now published an appeal to the public to send bodies for dissection; they say that the corpses are not mutilated, students being instructed to spare the feelings of the relatives. It is pointed out that many great men—for instance, the late Prof. Häckel—have left their bodies to the institute, and there is no reason why other people should not follow their example. The offer is made that where the body is sent for dissection, cremation will be done free of charge, a religious service will be held if desired, and the ashes will be sent to the family.

Periodica Medica.

The Association of the German Medical Press has issued a catalogue of medical journals, reviews, and other periodicals with the abbreviations to be used in citations. This catalogue, which is entitled Periodica Medica, includes the full and abbreviated names of 1800 periodicals, and it will now be enlarged by adding the more important journals of the profession abroad. The work has been carried out by Dr. Kunze, librarian of the former Army Medical College.

Enteric Fever in Potsdam.

An epidemic of enteric fever has broken out in Potsdam and its neighbourhood. By careful investigation it has been ascertained that it started in a milkshop where an employee had suffered from so-called influenza but was eventually found to have had enteric fever. Fifty cases have been reported with three deaths. The milkshop was, of course, closed, and the milkman and the other patients isolated in hospital. The epidemic has since made no progress, and it is hoped that no new cases will occur.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

The Dublin Hospitals.

A DISCUSSION concerning the financial condition of the Dublin voluntary hospitals has been carried on in the *Irish Times* during the past week. It began with an unsigned contribution from a correspondent who had made a careful study of the income and expenditure of five of the smaller general hospitals for quinquennial periods before the war and recently. The five hospitals studied have an aggregate of about 600 beds. The total expenditure for the years 1909–13 was £192,000; for the years 1922–26, £367,000. Some of the expenditure was for new buildings or structural alterations, but the correspondent points out that with the advance of medical and surgical technique such changes become frequently necessary, and the expense may properly be classed as ordinary. The annual expenditure has varied little from 1922 to 1926. The income comes from various sources—pay-patients, subscriptions, dividends from invested funds, grants from the Hospital Sunday Fund, the Corporation of Dublin, the Government, and some payments for special services. Some of these sources are discussed in detail. The payments from patients have increased twelvefold from the one quinquennial period to the other. In 1909–13 a sum of £10,315 was collected from patients; in 1922–26 the amount was £120,258. It may be assumed, therefore, that as far as the hospital itself is concerned hospital abuse in the old sense has disappeared. But there is a tendency for a new abuse to appear. This lies in the fact that there is often a difficulty in obtaining a place for a patient who is not able to contribute to the cost of his maintenance.

Paying Patients.

The correspondent next draws attention to the fact that the recognition in the hospitals of a class of pay-patients has led to a change in the relation of the members of the staff to the patients. Formerly members of the staff invariably gave their services gratuitously to all their hospital patients. Now, in some hospitals, it is becoming the custom for members of the staff to accept fees from those who can afford to pay. It is suggested that this custom may lead in time to the disappearance of nursing homes and the concentration of all patients in general hospitals or in homes attached thereto. The amount of money raised in subscriptions increased from £64,000 in 1909–13 to £76,000 in 1922–26. There was, however, a decline in the case of some hospitals, and the increase is in part due to special appeals in recent years. But, as the correspondent drily remarks, "special appeals are among the recognised methods of obtaining hospital funds." The income from investments has increased from £9000 to £10,000: or, in other words, the actual investments have been increased by about £20,000. The combined overdraft of the five hospitals is about £40,000. The correspondent thinks that if this could be wiped out these hospitals could carry on satisfactorily on the present basis, and approximately balance their budgets. In conclusion, he states that there are not more hospital beds in proportion to the population in Dublin than in other centres, and that every hospital has a waiting-list.

A Plea for State Aid.

This communication has been followed by the publication of interviews with several hospital physicians and surgeons. Sir William Taylor puts in a plea for State aid, though he does not desire State control. He suggests that amalgamation of the smaller hospitals would be advantageous to the public, but it would require a capital sum of roughly £700,000. Sir Thomas Myles suggests that the demand on the Dublin hospitals might be considerably lessened if the country hospitals were fitted to do work of a wider range than at present. Nowadays most of the country hospitals have a staff of only one surgeon, so that work must needs be very limited in scope. Mr. Horace Law draws attention to the tax on hospitals constituted by industrial accidents and by the increasing number of motor accidents. He suggests that workmen should contribute to the hospitals through their trade-unions. Sir John Lumsden, while recognising the necessity of accepting payment for maintenance from patients, emphasises the need for making sure that the poor are not excluded. Every voluntary hospital should reserve a number of free beds. Mr. Louis Cassidy suggests the adoption of a scheme of combined marketing, and puts in a plea for provision for research work in the hospitals. Sir William Wheeler thinks that several of the hospital buildings have outlived their usefulness, and are far behind what might be expected in a university city. He urges that children should be removed from the city hospitals to country air.

Medical Certification for National Health Insurance.

Medical certification of insured persons for sickness benefit has had severe criticism at a recent meeting of the Executive Committee of the Approved Societies' Association. Attention was drawn to figures obtained from the National Health Insurance Commission as to the results of the work of the medical referees in the year 1927. It appeared that 13,395 applications had been made to the Commission to provide a second opinion. Of these, 409 were rejected as unsuitably elected and 581 presented final certificates before examination took place. Of the remainder, 4410 failed to attend for examination, about half of them declaring off benefit and the other half ignoring the summons. The remaining 7993 were examined by the medical referees. In regard to 3200 (40 per cent.) the referees found the claimants not incapable of work, while 4793 (60 per cent.) were found incapable and entitled to benefit. The society officials appear to think that these figures disclosed serious laxity in the issue of certificates. Before arriving at such a conclusion it would be necessary to know what proportion these certificates bore to the total number issued. It is wrong to assume that all who declined to attend for examination by the referee did so because they had been acting in fraud. Many sick people will go without benefit rather than take trouble to get it, and many go to work when they should not. That 60 per cent. of the cases thought doubtful by the society officials which actually came to examination by the referee should have been upheld by him is evidence of fairly accurate certification. It was suggested by the secretary of one society that certificates were sometimes issued without examination. If this is done it is liable to the severest professional censure.

Proposed Change of Unit for Distribution of Payment.

While the approved societies are criticising the system of medical certification from one point of view, the National Health Insurance Commission is proposing to make an alteration which is likely to render the system more open to abuse. When the present system was adopted about 13 years ago it was arranged that the dispensary district should be the unit of distribution of payment. A sum equal to the number of insured persons living in the district multiplied by the agreed capitation rate was assigned to each district, and this pool was then distributed according to the work done to the several practitioners who furnished certificates in that district. The Commission now proposes to substitute the county for the dispensary district as the pool unit, on the grounds that the smaller unit leads to widely divergent rates of remuneration, and that the difficulty and expense of obtaining accurate figures of the number of insured persons in the dispensary districts is very great.

Large or Small Units.

It is somewhat surprising that with 13 years' working of the system the Commissioners and the societies have been unable to get a satisfactory register, showing the dispensary district in which each insured person resides, compiled. If such a register were prepared the other objections fall to the ground. The Commission has invited all medical certifiers to agree to the proposed change, but, on the other hand, the chairman and secretaries of the Irish Medical Committee have asked certifiers to take no steps until the local medical committees and the Irish Medical Committee have considered the matter. It has to be recognised that the substitution of a large pool area for a small one abolishes important checks on excessive certification. In a dispensary district pool the great bulk of the pool—probably 80 or 90 per cent.—is likely to go to the dispensary doctor in any event. He is unlikely, therefore, to be tempted to issue certificates in excessive numbers. Moreover, where only a few men share in a pool they act as checks on each other, and it would be difficult for one of them to secure an undue share without rousing the suspicion of the others. In a large area such as a county these checks disappear. An unprincipled certifier, if such there be, has the way open to him to act unfairly by the pool by issuing excessive numbers of certificates.

BUDAPEST.

(FROM OUR OWN CORRESPONDENT.)

Increase of Bastardy.

Dr. Lajos Neményi has been propounding to the Royal Medical Society the question whether the community would not benefit if the same opportunities for development were given to illegitimate children as to those who are born in wedlock. He does not regard the illegitimate birth-rate as any index of the state of morality. This rate has been rising generally in the years since the war, and in Hungary the proportion of illegitimate children in 1925 reached the relatively high figure of 8·2 per cent. Last year nearly 5 per cent. of the pupils at the State auxiliary schools in Budapest were illegitimate. Examination of the patients in the State asylum at Angyalföld shows that general paralysis of the insane is much commoner among women of this class, which is not surprising in view of the inferiority of the education and discipline which they usually receive as girls. Other forms of mental disease do not seem to occur especially often among the illegitimate, and they do not appear to be degenerate by heredity.

Conservative Treatment of Surgical Tuberculosis by Zinc Sulphate.

A preliminary account has been published by Dr. Nikolaus Hedry of his extensive experiments with zinc sulphate in various forms of surgical tuberculosis—e.g., abscesses, caries, fistulæ, and coxitis. After referring to the increase of surgical tuberculosis due to deplorable economic conditions since the war, he goes on to speak of conservative treatment by sunlight, ultra-violet rays, and heat rays. None of these, however, has proved so helpful as zinc sulphate, which he has been experimenting with since the spring of 1926. A 10 per cent. glycerinated solution is employed, and with this it is possible to get complete sterility in abscesses. The infected tissues shrink under the astringent action of zinc, and no harmful incidental effects have been observed in the course of the treatment, apart from a slight inflammation which accompanies the changes in the tissues. In rare cases the patients have complained of shivering and pains, but these were of short duration. Besides many other lesions, six tuberculous fistulæ were treated by irrigation with 1–5 per cent. sulphate of zinc solution, followed by the application of 15–20 per cent. sticks. In three cases the fistulæ were completely closed, and in two there was a considerable improvement; the remaining one showed no benefit. According to Hedry, the particular advantages of the method are as follows. Sulphate of zinc is highly antiseptic, even in high dilution; it is an efficacious astringent, and has a specially stimulating action upon tuberculous tissues, whereby cold abscesses are transformed into warm ones. Its use causes no untoward consequences in the neighbouring healthy areas, even when a strong solution is employed, and no cumulative after-effects have been noted during the two years during which the method has been adopted on a large scale.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

To be Surg.-Lts.: M. A. Graham-Yooll, J. G. Paley, E. W. Graham, R. G. E. Richmond, H. P. Williams, and H. S. Marks.

Surg. Lt.-Comdr. S. R. Johnston to *Caradoc*, for duty during trials.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Sub.-Lt. D. S. Buchanan to be Surg. Lt.

Proby. Surg. Sub-Lt. T. C. Larkworthy promoted to Proby. Surg. Lt. and appointed to R.N. Hospl., Haslar, for 28 days' training.

Lt.-Comdr. J. H. Anning to *Pangbourne*, for disposal for training.

Proby. Surg. Sub-Lt. J. D. J. Freeman to *Renown*, for training.

ROYAL ARMY MEDICAL CORPS.

Col. N. J. C. Rutherford retires on ret. pay.

Lt.-Col. and Bt. Col. P. H. Henderson to be Col., vice Col. A. Chopping, to ret. pay.

Lt.-Col. B. F. Wingate retires on retd. pay.

The undermentioned Lt.-Cols., having reached the age limit for compulsory retirement, retire on retd. pay: G. J. Houghton (and is granted the rank of Col.), and C. H. Carr.

The undermentioned Majs. to be Lt.-Cols.: G. B. F. Churchill, F. E. Roberts, and E. G. R. Lithgow.

Maj. T. W. O. Sexton, Reg. Army Res. of Off., relinquishes his appt. under Art. 507 (b) Royal Warrant for Pay and Promotion, 1926.

Lt. C. L. Day is restd. to the estabt.

ARMY DENTAL CORPS.

To be Lts. (on prob.): H. L. Foulkes-Roberts, T. R. Wall, J. A. O'Connor, and H. S. Golding.

ARMY RESERVE OF OFFICERS.

Maj. A. F. L. Shields, from R.A.M.C., T.A., to be Maj.

SUPPLEMENTARY RESERVE OF OFFICERS.

Lt. H. L. Oldershaw to be Capt.

TERRITORIAL ARMY.

Lt. A. A. Eagger (late Gordons) to be Lt.

ROYAL AIR FORCE.

Flight Lt. J. Hutchieson is granted a permanent commission in this rank.

RESERVE OF AIR FORCE OFFICERS.

Flying Officer E. D. Gray relinquishes his commission on completion of service.

INDIAN MEDICAL SERVICE.

Col. H. Boulton to be Maj.-Gen.

Lt.-Col. J. Fuller-Good to be Col.

Majs. to be Lt.-Cols.: W. D. Keyworth, B. Gale, H. H. King, R. E. Flowerdew, and A. J. Symes.

Capt. to be Maj.: H. H. Elliot.

Lt. Bhagwant Singh Nat to be Capt. (provl.).

Temp. Capt. Bhanu Datta Sharma relinquishes his tempy. commn.

NORTH PERSIAN FORCES MEMORIAL MEDAL.

Dr. W. H. Dye, Colonial Medical Services, has been awarded the North Persian Forces Memorial Medal for the year 1927 for his paper, The Relative Importance of Man and Beast in Human Trypanosomiasis, published in the Transactions of the Royal Society of Tropical Medicine and Hygiene (1927 vol. xxi). The medal is awarded annually for the paper on tropical medicine or hygiene that has attained a standard of merit published in any journal during the preceding 12 months by a medical officer, of under 12 years' service, of the Royal Navy, Royal Army Medical Corps, Royal Air Force, Indian Medical Service, or of the Colonial Medical Service.

OBTAINING A SPECIMEN OF SPUTUM.

To the Editor of THE LANCET.

SIR,—In his practical and authoritative article last week (p. 614) Dr. S. R. Gloyne states that it is not uncommon for saliva and stomach contents to be sent to the laboratory as sputum. A negative report may under such circumstances be accepted as valid, when a reliable specimen might be found to contain tubercle bacilli. The issues at stake are of such vital importance that I may be permitted to draw attention to some methods that I have employed for the purpose of obtaining a trustworthy sample.

1. *Coaxing* is often effective and may be practised while gently holding the patient's head down over a basin and urging him to "clear his chest and shoot the phlegm out into the basin," while at the same time giving a good cough one's self for him to imitate.

2. *Inhalation of mustard-oil vapour* is of the greatest value. A few drops of the oil in a six-ounce bottle are slightly warmed over a lamp and the patient is asked to have a good sniff or two from the mouth of the bottle. This rarely fails to induce a cough-reflex, especially if there is any inflammatory or tuberculous affection of the larynx. With this I have often obtained a "positive" report when repeated previous ones had been "negative."

3. *Intralaryngeal injection* of a few drops of warm 1 per cent. solution of bicarbonate of soda with a trace of solution of peroxide of hydrogen, as used for cleansing the larynx, may succeed when the mustard inhalation fails.

4. *Trans-nasal instillation* of similar drops may serve the same purpose and requires no "special" technique. The patient sits with his head thrown back and his mouth open. He is instructed to keep on panting and not to swallow while a few drops of the solution are poured into the nose by means of a simple glass syringe. Sufficient is likely to find its way into the larynx to excite a cough and induce free expectoration. This is a method of great value for the introduction of antiseptic oil into the larynx and trachea.

5. *The laryngeal mirror* may serve for the reception of a patch of sputum if the patient coughs while it is in situ.

6. *Potassium iodide*, in small doses, administered for a few days if not otherwise contra-indicated, will often increase the expectoration and bring up the latent bacilli.

It is obviously in the less advanced cases that these methods are called for.

I am, Sir, yours faithfully,

London, Sept. 25th, 1928. JAMES DUNDAS-GRANT.

A CASE RESEMBLING ADDISON'S DISEASE TREATED WITH PITUITARY EXTRACT.

To the Editor of THE LANCET.

SIR,—I can now report the sequel of this case, published in THE LANCET (1928, i., 79). After having derived great apparent benefit from pituitary extract, the patient left this district for South Wales, taking with her a supply of the pituitary tabloids. A fortnight after the supply was exhausted—so I am informed through a relative—she died. I have seen a copy of the death certificate which states "Tuberculosis of the Suprarenal Capsules," not confirmed by autopsy. This is all the information I have been able to obtain, but it appears to confirm the fact that great benefit may be conferred in Addison's disease by administration of pituitary extract.

I am, Sir, yours faithfully,

Merioneth, Sept. 19th, 1928. E. C. B. IBOTSON, M.D.

DEATHS UNDER ANÆSTHETICS FOR DENTAL OPERATIONS.

To the Editor of THE LANCET.

SIR,—Under this heading you called attention last week to an inquiry by the *Dental Surgeon* designed to reduce still further the number of deaths during dental operations. To my mind a lower percentage of deaths in this type of operation must be looked for along the lines of an improved technique on the part of the anæsthetist. If the following three incontrovertible facts are borne in mind it will be seen how large a responsibility rests with the administrator, and how important it is that he should be sufficiently expert to deal adequately with what may prove to be a very difficult administration :—

1. The operation though previously estimated to be of a trivial character and requiring the maintenance of anæsthesia for only a few minutes, frequently devolves itself into a much more arduous affair, requiring a tranquil anæsthetic period of possibly half an hour.

2. In so many cases a partial or even complete obstruction of the upper air passages occurs at some stage of the operation, and in the vast majority this obstruction is brought about by: (*a*) the gradual and increasing collection of blood at the back of the throat; (*b*) the necessary manipulations of the operator's fingers in the mouth pressing back the tongue; (*c*) the extraction of a difficult tooth in the lower jaw, entailing as it so often does undue depression of the chin. The dental surgeon is fully conversant with conditions (*a*), (*b*), and (*c*), and has been rather brought to believe that a "rush policy" answers best—i.e., to continue operating until the last possible moment, knowing from unhappy experience that should he be compelled to desist the chances are extremely remote that more favourable conditions will supervene, as upon his resumption a restless patient may still further increase his difficulties.

3. The method of administration chosen frequently necessitates the reapplication of a closed ether inhaler or the dropping of chloroform on an open mask, owing to the patient's partial return to consciousness. In either case the process of reinduction in an oftentimes restless and cyanotic subject choked with his own blood is fraught with danger, and is to be condemned.

It seems to me, therefore, that the lessening of the anæsthetic risk must be looked for along the lines of a better understanding and firmer handling of the issues involved in the above three factors. With regard to (1) all dental operations in which a general anæsthetic is required should automatically (from the anæsthetist's point of view) be relegated to the same class as other major operations performed upon the mouth and which, by their nature, are likely to give rise to interference with the upper air passages. Only by a frank recognition of this point shall we be able to obtain the same pre-operative routine care and attention in the preparation of the patient as obtains in the other cases under this category. All the well-known arguments cited in favour of preliminary hypodermic medication with morphine and atropine apply with especial force in prolonged anæsthesia for dental operations, and the exhibition of these drugs should be part of the routine treatment.

With regard to (2) and (3) I have employed the following technique with a reasonable freedom from anxiety and with no fatality in well over 1000 cases of multiple extractions: induction by gas-ether or ethyl-chloride-ether sequence with a Clover's inhaler. After induction has been completed, usually in two or three minutes, a further three minutes or so is never wasted in continuing with the closed apparatus, until a condition of "stable anæsthetic equilibrium" has been established. A change-over can now be quickly made to a Shipway's inhaler; the Shipway has been previously connected up with an oxygen cylinder, and the oxygen flow so regulated as to drive over sufficient anæsthetic vapour as previous experience has deemed sufficient to maintain anæsthesia. The narrow efferent rubber tube of the Shipway is wriggled well back to the posterior nares and retained in place by a metal clip attaching it to the ala nasi. Anæsthesia can now be prolonged indefinitely by the judicious administration through the nasal tube of either pure ether, ether-chloroform, or even pure chloroform without altering the uniform flow of oxygen. Cyanosis should rarely take place owing to the relatively large proportion of oxygen passing over; this latter factor enables a temporary obstruction of respiration to occur without any change of colour on the part of the patient. The operator need never be hurried by the thought of the patient's impending return to consciousness, and in consequence is not so reluctant to allow the anæsthetist to keep the operating field reasonably free from blood, with undoubted advantage both to himself and the patient.

One last word: It cannot be too strongly emphasised that no extraction should be continued with in the presence of an even moderate degree of duskiness; all operative interference should be postponed until the normal colour has been restored.

I am, Sir, yours faithfully,

ARTHUR V. BOYALL.

Minehead, Somerset, Sept. 24th, 1928.

THE LATER RESULTS OF PARTIAL GASTRECTOMY FOR GASTRIC AND DUODENAL ULCER.

To the Editor of THE LANCET.

SIR,—Mr. Flint criticises me for saying that "in our experience gastro-enterostomy is the commonest gastric disorder to-day" in view of the fact that I had given figures showing that duodenal ulcer was a still more common condition. But surely duodenal ulcer is a disease of the duodenum and not of the stomach. I have had many cases of gastro-jejunostomy undone in the absence of anastomotic ulcer in order to overcome more or less severe symptoms resulting from the disordered function caused by the operation, which had generally, though not always, been performed for an ulcer. I may add that in several cases the secondary operation was performed by a distinguished Leeds colleague of Mr. Flint.

There is now abundant evidence that duodenal ulcers rarely, if ever, develop in the absence of what I have called the hypersthenic gastric diathesis. This condition is still present after a duodenal ulcer has healed, whether as a result of medical treatment, a gastro-jejunostomy or partial gastrectomy. It is for this reason that none of these measures is likely to lead to *permanent* freedom from symptoms unless the patient follows a suitable régime for the rest of his life. Mr. Lake is asking for trouble if he allows his patients to eat ordinary food, even after six months. That is why I suggested that he would find the last results of his operations very different from what he calls the "late results"—i.e., the results after an interval of only one to five years. I have seen several cases of secondary ulceration after partial gastrectomy and have collected over a hundred from the literature.

Mr. Lake asks what I could suggest as an alternative to gastrectomy for "those cases in acute agony who have already had a succession of medical treatments with almost immediate recurrence." My answer is that there should be no such cases. The acute agony should disappear within 48 hours of beginning treatment, and if this is continued till the ulcer has really healed and not simply until the symptoms have disappeared, if all septic foci are eliminated, and if a proper régime is followed afterwards, the risk of recurrences is small. When they do occur they are far more amenable to treatment than the disasters which may follow gastric operations. Moreover, the mortality is nil, compared with Mr. Lake's mortality of 10 per cent. after partial gastrectomy for ulcer.

It is true that men and women of the labouring class do not come to New Lodge Clinic, but they come to Guy's as often as to Charing Cross. If Mr. Lake will send me his next three cases of the kind to Guy's, I should greatly value the opportunity of demonstrating to him my alternative to partial gastrectomy.

I am, Sir, yours faithfully,

ARTHUR F. HURST.

New Lodge Clinic, Windsor Forest, Sept. 24th, 1928.

THE NATURE OF THE ROUS TUMOUR.

To the Editor of THE LANCET.

SIR,—A leading article last week states that "the essential *similarity* between the reaction of the Rous tumour to irradiation and that of true mammalian new growths is evidence in support of the fundamental similarity of these two types of neoplasms." Surely the experiments referred to in this article show some striking *dissimilarities*. Mottram irradiated small Rous tumours in fowls with doses which he calculated would cause their ultimate disappearance. When the tumours had begun to regress, they were removed and dried in vacuo, but when reinoculated into fowls produced tumours. Could any true mammalian new growth have stood such treatment?

Although we gave Rous tumours in vitro five times the dose of X rays lethal to mouse, rat, and human tumours of various types, it had no apparent effect on the subsequent growth; surely this points to some dissimilarity in the Rous tumour. Mottram found that a small nodule of Rous tumour in a fowl could be made to disappear if it was exposed to a certain dose of irradiation, while we found that a dose of X rays lethal to other tumours had apparently no effect on an established Rous tumour in a chicken. Under the conditions of Mottram's experiment the surrounding normal tissues would get a dose of irradiation not very different from the tumour cells; under our conditions they would get only a small fraction of this dose.

In the *British Journal of Radiology* (1927, xxxii, 289) we published experiments showing the deterrent effect which suitable doses of X rays on the skin of the rat had on subsequent tumour-growth, when the tumour cells received no irradiation whatever.

We are, Sir, yours faithfully,

S. RUSS,
G. M. SCOTT.

The Middlesex Hospital, W., Sept. 24th, 1928.

IMPORTATION OF DRUGS AND CHEMICALS.—Under Section 10 (5) of the Finance Act, 1926, the Treasury may by order exempt from the duty imposed by the Safeguarding of Industries Act, 1921, any article which is not made in any part of His Majesty's Dominions in quantities which are substantial having regard to its consumption in the United Kingdom, provided that there is "no reasonable probability that the article will within a reasonable period be made in His Majesty's Dominions in such substantial quantities." The Board of Trade has under consideration the renewal of the exemption which has been accorded to the following substances and articles: R. acetone; acetone (fermentation); synthetic acetone; anhydrous hydrocyanic acid; lactic acid which satisfies the requirements of the British Pharmacopœia; oxalic acid; amidopyrin (pyramidon, dimethyl-amidoantipyrine); ammonium perchlorate; barbitone (veronal; malonal; malourea; diethyl barbituric acid; diethylmalonylurea; hypnogen, deba); bromural (dormigene); crude cocaine; dial (acid diallyl barbituric); didial (ethyl morphine diallyl barbiturate); elbon (cinnamoyl para oxyphenyl urea); ethylene bromide; ethylene glycol (glycol; alcohol ethylene); eukodal; furfurol; glycol ethers; guaiacol carbonate (duotal); hydroquinone; integrators (planimeter type); R. lead acetate; lead tetraethyl; lipoidin; lithium carbonate; lithium hydroxide; metaldehyde; methyl chloride; methyl sulphonal (diethylsulphonemethylethylmethane, trional); nickel hydroxide; papaverine; phenacetin (acetparaphenetidine); phenazone (antipyrine; phenyldimethylpyrazolone; analgesin; anodynine; dimethyl oxychinizin; phytin; piperazine (diethylene-diamine; dispermin); planimeters; R. potassium chlorate; potassium guaiacol sulphonate (thiocol); R. potassium hydroxide (R. potassium caustic; R. potassium hydrate); R. potassium permanganate; pyramidon-veronal; quinine ethyl-carbonate; radium compounds; resorcin (resorcinol); salol (phenyl salicylate); styracol (guaiacol cinnamate); sulphonal; synthalin; urea (carbamide); and vanadium-silica compounds specially prepared for use as catalysts for sulphuric acid manufacture. Any communications with respect to these matters should be addressed to the Principal Assistant Secretary, Industries and Manufactures Department, Board of Trade, Great George-street, London, S.W. 1, before Oct. 18th.

Obituary.

ROBERT KNOX, M.D. EDIN., M.R.C.P. LOND., D.M.R.E. CAMB.

By writing, by organisation, and by example Dr. Robert Knox played an important part in the development of radiology in this country. His death, which occurred in London on Sept. 21st, will be generally regretted by the profession, and especially by those who knew him as a colleague and friend.

DR. KNOX.

Born at Leith in 1868, he received the same name as his father. He was sent to the University of Edinburgh, and graduated there in medicine when 24 years of age. After acting for a time as demonstrator of anatomy in the New School of Medicine at Edinburgh he came south to Guy's Hospital, taking the English conjoint diploma in 1893. A year or two later he settled in general practice at Highgate, but continued his hospital work at the Great Northern Hospital where he first held appointments in the pathological and medical out-patient departments. He began to study radiology within a few years of Rontgen's discovery, and gradually radiological work began to absorb more and more of his time and interest. His first radiological or rather "electrical" appointment was to the Great Northern Hospital, and in 1909 he began his long series of contributions to the literature of the subject. In 1912 he was appointed director of the electrical and radiotherapeutic department of the Cancer Hospital, and began to specialise at Harley-street as a radiologist. In the following year he succeeded Dr. (afterwards Sir) Archibald Reid as radiologist to King's College Hospital. Soon afterwards he followed Dr. F. H. Low as honorary secretary of the Rontgen Society, being also elected to the Council of the Electrotherapeutic Section of the Royal Society of Medicine. Knox was a ready and rapid writer with a good sense of proportion and an eye to effective illustration. His text-book, "Radiography, X Ray Therapeutics, and Radium Therapy," which appeared in 1915 within one cover, was the first comprehensive treatment of the whole subject by a British author. It was an immediate success, which was justified by Dr. Knox's scrupulous care in keeping later editions of the book in touch with every new development. His other literary work included the chapter on Radium Therapy in Eden and Lockyer's Gynæcology and papers in many periodicals, whilst for years past he has been editor of the *British Journal of Radiology* and its predecessor.

His chief radiological researches were done at the Cancer Hospital, Fulham. In the laboratories attached to this department some new device was always being worked at; in radio-diagnosis he was especially interested in developing means whereby accurate information of the heart's movements might be got, and he did a great deal to encourage serial radiography. On the radio-therapeutic side he made a definite attempt to reduce the damage to the skin which may occur when depth doses are administered, and here again by his method of rotational focus a step forward was made. An account of some recent work on the reactions of normal and pathological tissues, carried out in association with the British Empire Cancer Campaign, was given to the Second International Congress of Radiology, held at Stockholm last July.

Dr. Knox helped to found the British Association of Radiology and Physiotherapy, and with Sir Archibald Reid was also the founder of the British Institute of Radiology. He was president of the former and also of the Rontgen Society, and when the Rontgen Society was recently amalgamated with the Institute he was able to give much help to those responsible for the change. Dr. George Batten, who followed Knox as president of the Rontgen Society and the Section of Electrotherapeutics of the Royal Society of Medicine, writes of him that he was a ruling spirit, if not *the* ruling spirit, in these associations. "The Council and members," writes Dr. Batten, "as well as his colleagues at the hospitals, quickly learnt to appreciate Robert Knox for his broadmindedness, thoroughness, and ballast, and we all learnt to love this quiet, modest, efficient man.' He brought to bear on every problem of patient or policy a friendly dignity which produced calm and good results."

Another colleague writes of him that he was always ready to recognise the help received from his staff, members of which, attracted by his personality, often gave their services without payment.

Abroad Knox was probably the best-known British radiologist, and he was elected to honorary membership of several foreign societies, including the American Roentgen Ray and Radium Society. It is not too much to say that it was owing to his initiative that the first International Congress of Radiology was held in London in 1925. During the war he was in charge of the X ray department of the 4th London General Hospital, holding a Territorial commission, and for many years was honorary radiologist to the Queen Alexandra Hospital, Millbank. He had recently been acting in an advisory capacity to the War Office and to the Ministry of Health.

He leaves a widow, Dr. Alice Vance Knox, a daughter, and a son Robert, who is studying medicine at St. Bartholomew's Hospital.

ARCHIBALD DUNBAR WALKER, M.D. EDIN.

We have to announce that Dr. Dunbar Walker, who was for more than 43 years in active practice in the London area, died at his home in Hampstead on Sept. 21st, at the age of 81. His father was a surgeon in the service of the East India Company, and Dr. Walker was born in India. He received his medical education at the University of Edinburgh, where he graduated in 1861 and gained his doctor's degree in 1871. Soon after qualifying he went out to Palestine to undertake medical mission work, spending also some time in Egypt. On his return to this country he took up general practice in Ladbroke-grove, being appointed medical officer to the North Kensington and Kensal-town Provident Dispensary. After 25 years in this district he moved to Notting Hill, where he remained actively at work for another 18 years. Dr. Walker was the author of "Egypt as a Health Resort" and "The Parents' Medical Note Book," besides a number of contributions to the medical press. His sister was Dr. Eliza Walker Dunbar, who long practised in Clifton and died two years ago, and his son is Lieut.-Colonel N. Dunbar Walker, R.A.M.C., another member of the family who sustains its medical tradition.

ALICE DEBORAH HICKLING, M.B.E., L.R.C.P. EDIN.

Mrs. Hickling, who has died at Hong-Kong, was a daughter of the Rev. James Sibree and was born in the Madagascar mission field in 1876. She entered Walthamstow Hall, Sevenoaks, as a young child, and ent up to Oxford in 1894, qualifying from the London School of Medicine for Women in 1901 with the Scottish conjoint diploma. After some two years' experience as resident medical officer at the Sanatorium for Consumption at Clare, in Suffolk, she went out to Hong-Kong to join the staff of the Alice Memorial Maternity Hospital. Shortly afterwards she became Government inspector of midwives in the colony, a post which she held for 20 years. During the war she was medical officer to the Voluntary Aid Detachment in Hong-Kong, and for the last 12 years of her life had been medical officer to the Victoria Nursing Division there. For her services to the colony, in these and other capacities, she was made a Member of the Order of the British Empire, and she was also an honorary serving sister of the Order of St. John of Jerusalem. Dr. Hickling served from 1918 to 1920 as acting medical officer of health for Hong-Kong, and in 1923 was appointed Government assistant medical officer in charge of native hospitals. She married Mr. C. C. Hickling, son of the Rev. James Hickling.

Medical News.

London Medical Exhibition.—From Monday, Oct. 1st, till Friday, Oct. 5th, from noon till 6 P.M., at the Central Hall, Westminster, the London Medical Exhibition will be open to members of the medical profession, and any medical man who has not received a card of admission can obtain one on application to the Secretary, 194–200, Bishopsgate, or at the Central Hall during the exhibition week. This exhibition grows in importance and magnitude every year, and it is expected that the forthcoming display of the latest results of research and of aids to medical and surgical treatment will be the largest yet held. Organised by the management of the Seventeenth International Congress of Medicine, 1913, and of the Fifth Clinical Congress of Surgeons, 1914, it aims at presenting a comprehensive survey of drugs and surgical appliances of practical value to the practitioner, while it also enables him to keep in touch with the latest developments of medical and surgical achievement. A large reception room and a refreshment room with orchestra are provided for the use of visitors.

Royal Sanitary Institute.—The Fortieth Congress and Health Exhibition of the Institute will be held at Sheffield from July 13th to 20th, 1929.

Sir John William Thomson-Walker, F.R.C.S., has been appointed a Deputy-Lieutenant for the County of London.

University of London.—A course of lectures on Smoke Pollution of the Air and Public Health will be given at University College, Gower-street, London, W.C., by Dr. John Owens, at 5.30 P.M., on Nov. 2nd, 9th, and 14th.

University of London Medical Graduates Society.—It is proposed to hold a dinner for members of this society in London towards the end of October, and it is expected that a dinner for members in Birmingham and one for members in Leeds will be held in November. All medical graduates of the University of London are eligible for membership, and nearly 300 life members have so far been enrolled. Applications should be sent to the hon. secretaries of the society at 11, Chandos-street, London, W.1.

Royal Institute of Public Health.—The Harben lectures for 1928 will be delivered at 4 P.M. on Oct. 23rd, 26th, and 30th, in the Lecture Theatre of the Institute, 37, Russell-square, W.C., by Dr. Arthur T. Henderson, lecturer in medicine in McGill University, Montreal, whose subject will be Studies in Asthma and Related Diseases. No tickets of admission will be required. A course of lectures on Industrial Diseases will be held at the Institute in the near future.

German Campaign against Rheumatism.—The third meeting of the Deutsche Gesellschaft für Rheumabekämpfung will be held under the chairmanship of Prof. Dietrich, at Berlin, from Nov. 4th to 7th. The subject of discussion will be the Clinical Features of Rheumatic Diseases, and there will be lecture-demonstrations at various clinics on the relation of these diseases to the different branches of medicine. The address of the society is Fraunhoferstrasse 16, Charlottenburg, Germany.

Medical Research Council: New Offic From Oct. 1st the administrative offices of the M Research Council, hitherto at York-buildings, Ad will be at 38, Old Queen-street, Westminster, London, S. (Telephone, Victoria 5027). The offices of the Indu Fatigue Research Board will also be at the new addr

Large Bequest to Manchester Royal Infirma This hospital has benefited to the amount of £36,000 b a bequest by the late Mr. John Whewell Simpson, Keswick, a director of the Bleachers' Association. Th the largest individual legacy which it has received more than 50 years.

Salisbury Infirmary League.—The members of the Salisbury and District Infirmary and Hospital Le has increased so rapidly that it has been decided to in porate it as a limited company without capital tr without profit. When the League was reorganised in spring of 1922 there were 46 centres of collection and collectors; there are now 280 centres of collection, collectors, and over 50,000 members. In 1914 the Le handed £76 to the infirmary; last year it paid over £

Welsh National Medical School.—We no in The Lancet of July 28th last that students prep for degrees and diplomas other than those given by University of Wales, could not be accepted for cou instruction in the final subjects. Considerable eco hardship is being caused to students in their fourth who might not have taken up the study of medicine they not felt assured that they could pursue it while li at their homes. Moreover, it may not be easy to vacancies at medical schools for students who done their preliminary work elsewhere. The situatio arisen quite independently of the dispute as to the status of the Welsh National Medical School, which is settled in so far that a draft charter establishing it separate school of the University has been adopted by parties concerned and submitted to the Privy Co Unfortunately for the prosperity of the school, how certain members of the staff of the Cardiff Royal Infir have resigned their position as clinical teachers, diminishing the number of beds available for instr to such an extent that the University of London and Conjoint Board have been compelled to withdraw recog of the school as a teaching centre. Joint represent of the case for the students has been made by the p concerned to the Board of the Royal Infirmary with effect. Opposition to the unit system is the alleged c of the resignations.

Medical Diary.

Information to be included in this column should rea in proper form on Tuesday, and cannot appear if it r us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street,

Tuesday, Oct. 2nd.—8.30 P.M., Orthopædics. dential Address, Mr. Naughton Dunn: The S of Muscles and Tendons in Relation to In Paralysis. (To be followed by discussion.)

Wednesday.—5 P.M., History of Medicine. Remar the President, Dr. Herbert Spencer. Paper D'Arcy Power: The Beginnings of the Renais of English Surgery. Members are invited to objects of historical interest for exhibition a meetings of this Section.

Thursday.—8.30 P.M.: Urology. Dr. Oswald Sw Lowsley (New York): Perineal Prostatectomy cinematograph demonstration). Members of th tion of Surgery are specially invited to attend.

LECTURES, ADDRESSES, DEMONSTRATIONS,

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lin Inn-fields, W.C.

Friday, Oct. 19th.—5 P.M., Sir Arthur Keith: Pr in Human Anatomy which arise out of the id cation of a skull attributed to Lord Darnley—D stration, illustrated by specimens.

FELLOWSHIP OF MEDICINE AND POST-GRAD MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, Oct. 1st, to Saturday, Oct. 6th.—BE Royal Hospital, St. George's-fields, S.E. and Sat. at 11 A.M.: Lecture-Demonstrati Psychological Medicine. Royal Free Hos Gray's Inn-road, W.C.—Lecture-Demonstrati Dr. C. B. Heald on Wed., on Treatment by E Therapy, at 5.15 P.M.

T LONDON POST-GRADUATE COLLEGE, West ndon Hospital, Hammersmith, W.

MONDAY, Oct. 1st.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Mr. Simmonds: Surgical Out-patients.

TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases (Demonstration). 2 P.M., Dr. Shaw: Medical Out-patients. 2 P.M., Mr. Sinclair: Surgical Out-patients.

WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2 P.M., Mr. Tyrrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Dr. Ironside: Medical Out-patients. 2 P.M., Mr. Bishop Harman: Eye Department.

FRIDAY.—10 A.M., Dr. Pritchard: Medical Wards. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.

SATURDAY.—9 A.M., Mr. Vlasto: Operation on Throat, Nose and Ear. 9.30 A.M., Dr. Burnford: Bacterial Therapy Department. 10 A.M., Dr. Owen: Medical Diseases of Children.

Daily 10 A.M. to 5 P.M., Saturdays 10 A.M. to 12 noon. Medical and Surgical In-patients and Out-patients. Operations, Special Departments, Anæsthetic Course.

TH-EAST LONDON POST-GRADUATE COLLEGE, nce of Wales's General Hospital, Tottenham, N.

MONDAY, Oct. 1st.—2.20 to 5 P.M.: Medical, Surgical, and *Gynæcological Clinics. Operations.*

TUESDAY.—2.30 to 5 P.M.: Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M.: Medical, Skin and Eye Clinics. Operations.

THURSDAY.—11.30 A.M.: Dental Clinics. 2.30 to 5 P.M.: Medical, Surgical, and Ear, Nose and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M.: Throat, Nose and Ear Clinics. 2.30 to 5 P.M.: Surgical, Medical, and Children's Diseases. Clinics. Operations.

PITAL FOR SICK CHILDREN, Great Ormond-street, .C.

THURSDAY, Oct. 4th.—4 P.M., Dr. Cockayne: Cretinism.

AL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Oct. 2nd.—3.15 P.M.: Sir Thomas Horder: Some Functional Diseases of the Heart and Their Treatment.

TRAL LONDON THROAT, NOSE AND EAR HOSPITAL, y's Inn-road, W.C.

MONDAY, Oct. 1st.—1.30 P.M.: Examination of the Pharynx.

WEDNESDAY, Oct. 3rd.—1.30 P.M.: Examination of the Larynx.

DON SCHOOL OF DERMATOLOGY, St. John's Hospital, Leicester-square, W.C.

THURSDAY, Oct. 4th, at 5 P.M., Dr. J. H. Stowers: Introductory.

T LONDON HOSPITAL FOR CHILDREN, Shadwell, E.

WEDNESDAY, Oct. 3rd.—4 P.M.: Clinical Demonstration. Free to Medical Practitioners.

CHESTER ROYAL INFIRMARY POST-GRADUATE URSE.

TUESDAY, Oct. 2nd.—4.15 P.M., Dr. R. S. Paterson: X Ray Work in Diseases of the Urinary Tract.

FRIDAY.—4.15 P.M., Dr. C. H. Melland: Diagnosis, Prognosis, and Treatment of Pernicious Anæmia.

OATS HOSPITAL POST-GRADUATE LECTURES, l-street, Manchester.

THURSDAY, Oct. 4th.—3.45 P.M., Dr. W. J. S. Reid: Diseases of Sympathetic Nervous System.

Appointments.

MIS. G. R. SEAGER, M.B., B.Chir. Camb., has been appointed Surgeon to the Southampton Borough Police Force.

broke Hospital, S.W.: THOMPSON, JOHN H., M.B. Lond., F.R.C.S. Eng., Resident Medical Officer; MORPHY, P. D., M.C., M.B. Glasg., House Surgeon.

Charlotte's Maternity Hospital: HEGGS, G. B. M., M.R.C.S., L.R.C.P. Lond., Senior Resident Medical Officer; COX, A. RAYMOND, M.R.C.S., L.R.C.P. Lond., Assistant Resident Medical Officer.

ing Surgeons under the Factory and Workshop Acts: WALKER, J. A., M.B., B.S. Lond. (Poole); MILLAR, G., M.B., Ch.B. Edin. (Crook, Durham).

Vacancies.

or further information refer to the advertisement columns.

Hospital for Children, 1, Clapham-road, S.W.—H.S. Also Asst. H.P. Each at rate of £100.

Addenbrooke's Hospital.—H.S. At rate of £130.

Royal Infirmary.—Hon. Asst. Surg. to Ear, Nose and Throat Dept.

Derbyshire Royal Infirmary.—Asst. H.S. and Cas. O. At rate of £150.

Doncaster Royal Infirma

Gloucester, Standish Hous M.O. £250.

Greenwich Metropolitan Borough.—M.O. Welfare Work. £600.

Hampstead, General and North-West London H hill, N.W.—H.S. Also Cas. M.O. and Cas. S at rate of £100.

Hampstead Hospital for Children, College Crescent, N. M.O. At rate of £100.

Hospital for Consumption, &c., Brompton, S.W.—H.P. At rate of £50.

Hospital of St. John and St. Elizabeth, 60, Grove End-road, W.—Res. H.S. At rate of £75.

Ilford Emergency Hospital, Essex.—Jun. H.S. £90.

Jersey General Hospital and Poor-law Infirmary.—Res. M.O. £200.

Lanark, Infectious Diseases Hospital and Tuberculosis Sanatorium, Roadmeetings, Carluke.—Res. Phys. £350.

Leeds City.—Asst. M.O. for Maternity and Child Welfare. £600.

Lincoln County Hospital.—Jun. H.S. At rate of £150.

Liverpool, Eye and Ear Infirmary, Myrtle-street.—H.S. £100. Also Hon. Asst. Surgeon to Ear, Nose and Throat Department.

L.C.C. Mental Hospital Service.—Eighth Asst. M.O. £300.

London Temperance Hospital, Hampstead-road, N.W.—Res. M.O. At rate of £175. Cas. O. At rate of £120. Also H.P. At rate of £100.

Macclesfield General Infirmary.—Res. H.S. £180.

Manchester, St. Mary's Hospitals.—Four H.S.'s. Each at rate of £50.

Mauritius, Port Louis.—M.O.H. £900.

Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Sen. Res. M.O. At rate of £140.

Northampton General Hospital.—Asst. H.S. to Ear, Nose and Throat Dept. At rate of £150.

Norwich, Norfolk and Norwich Hospital.—H.S. and Cas. O. Each £120.

Nottingham, General Hospital.—H.P. At rate of £150.

Nuneaton Borough.—Asst. M.O.H. £600.

Paddington Green Children's Hospital, W.—H.S. At rate of £150.

Prince of Wales's General Hospital, Tottenham, N.—H.S., Special H.S., and H.P. Each at rate of £120. Also Jun. H.S. and Jun. H.P. Each at rate of £90.

Queen's Hospital for Children, Hackney-road, E.—Physician-in-Charge Skin Department.

Royal Chest Hospital, City-road, E.C.—Res. M.O. Also H.P. At rate of £150 and £100 respectively.

Royal Free Hospital School of Medicine for Women, W.C.—Res. Asst. Pathologist. £150.

Royal National Orthopædic Hospital, 234, Gt. Portland-street, W. Four Surg. Regs. Each £105.

St. Andrew's Hospital, Dollis-hill, N.W.—Sen. and Jun. Res. M.O.'s. At rate of £150 and £120 respectively.

St. John's Hospital, Lewisham, S.E.—Res. Cas. O. At rate of £100.

St. Mark's Hospital for Cancer, &c., City-road, E.C.—H.S. At rate of £75.

Shanghai Municipal Council, Public Health Dept.—Second Asst. Commissioner of Public Health (Hospitals). £650.

Southampton, Royal South Hants and Southampton Hospital.—Jun. H.S. Also Cas. O. At rate of £130 and £120 respectively.

Southern Rhodesia Medical Service.—Govt. M.O. £500 to £600.

Stoke-on-Trent, North Staffordshire Infirmary, Hartshill.—Hon. Asst. Aural Surgeon.

Ventnor, Royal National Hospital for Consumption, &c., Isle of Wight.—Jun. Res. M.O. At rate of £300.

Warrington, County Mental Hospital, Winwick.—Asst. M.O. £350.

Wolverhampton, Wolverhampton and Staffordshire Hospital.—Two Asst. H.S.'s. Each at rate of £125.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Chaddesley Corbett and Halesowen (Worcestershire), Plymstock (Devon), and Hirwain (Glam.).

Births, Marriages, and Deaths.

MARRIAGES.

BINNS—O'SULLIVAN.—On Sept. 19th, at Haverstock-hill, N.W., Raymond Thomas Binns, M.B., B.S., to Anna Mary O'Sullivan.

HALE-WHITE—GOSDEN.—On Sept. 20th, at St. Anne's Church, Eastbourne. Dr. Reginald Hale-White, to Vera, daughter of Mr. and Mrs. John Gosden, of Eastbourne.

MCLAGGAN—ADAMS.—On Sept. 22nd, 1928, at Hampstead, John Douglas McLaggan, F.R.C.S., to Elsa Violet Adams, M.B., B.S.

DEATHS.

BUCHANAN.—On Sept. 23rd, at Westcliff-mansions, Eastbourne, Robert John Bertran Buchanan, late Captain R.A.M.C., aged 48.

KNOX.—Suddenly on Sept. 21st, 1928, in his 61st year, Robert Knox, M.D., C.M., M.R.C.P., M.I.E.E., of 38, Harley-street, and 15, South-grove, Highgate, N.6.

WALKER.—On Sept. 21st, at Maresfield-gardens, N.W., Dr. A. Dunbar Walker, M.D., aged 81.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

ALESCENCE.

clinical skill comes when the patient towards active life after a illness. An American institution, the torium for C ion, White Plains, N.Y., has tackled this th characteristic enthusiasm and ingenuity.[1] Mem es of land provide ample space for the 300 patients, the staff consists of two resident physicians, a small nursing corps, and a supervisor of recreation. The contrast between this organised convalescence and the practice at English homes is a striking one. The Director gives golf the highest place among re-educational games. Patients start on simple short courses, with holes ranging in length from 10 to 70 yards, and use solid rubber practice balls and any old clubs available which they keep in order themselves at negligible cost. Those on crutches and those who cannot bend are helped by companions, and the exercise well-nigh fulfils the ideal: outdoor exercise of the entire body, intense interest, wholesome competition and self-grading of exertion. In this institution walking is organised to a fine art. Patients proceed, in the words of the pamphlet, "from crutch and cane hobbling to extended speed hiking," from strolling to meals or the canteen or entertainment hall to walking as far as a distant arbour or hammock and finally to nature-study or shopping expeditions. The trouble with walking is that in this age it is not considered an interesting occupation, but no such objection is raised to dancing. Patients who cannot walk well can achieve the quiet gliding movements of modern dancing, and rest periods can be ensured by providing entertainment items between dances. The number of middle-aged and elderly people who renew a certain measure of youth by modified participation in the dances is surprising. To the sound of clinking metal alone is ascribed some of the value of quoit-throwing, which is a safe, all-round, intermittent exercise. Football sounds strenuous, but a football lying about will often tempt a crutched patient to propel it cautiously with one foot. Fives, played with old tennis balls on shortened distances, can be very valuable if the patients are carefully watched for overstrain. If a captive ball is to be used, where expense is an object, thick wooden paddles should replace the racquets, and an old tennis ball be covered with a sturdy canvas or leather cover. Tennis played over a sagging net, with some relaxation of the rules, can be a very satisfying recreation for convalescents. Mankind has played with a ball from the dawn of history and very often the first step forward that an introspective convalescent can be persuaded to take is to handle, squeeze, toss, bounce, or kick a ball. Unrestricted ball play, no matter how bizarre, should be possible for every convalescent. Bowls has been played from a wheelchair at White Plains, and crocquet is also suitable for crippled patients. We are accustomed to think of putting the weight and throwing the hammer as exercises for brawny giants at athletic gatherings, but if light apparatus is kept prominently in view nearly every man will pick up a piece from time to time and test himself cautiously. The winter season is a more serious matter in New York than it is in this country, but the director notes that the convalescent shrinks far more from wind than from cold, and that he should be urged out to walk and play in sheltered courts. Semi-invalids who are shut indoors rapidly develop mild depressions and irritabilities, and, if they must be kept in, ample indoor exercise must be available. Billiards, dancing, gymnasium, and table games are easily provided. It is interesting to learn that gambling has been sternly repressed at the Burke Foundation, not from any moral prejudice, but because it proved anti-convalescent. The player for money grows strained, restless, irritable, quarrelsome, uncoöperative, and adopts bad postures. Those in charge of convalescents should read this little book. The organising of graded exercise may not be easy if the patient is not in an institution where he can compete with others in like state, but his doctor could often arrange for competition of suitable severity to be provided by his friends.

MEDICAL PHOTOGRAPHY.

Messrs. KODAK, Ltd., Kingsway, W.C., announce the establishment of a special department for photography, subdivided into the three sections of radiography, clinical photography, and medical and surgical cinematography. A pamphlet, entitled X Ray News, deals with the use of the intensifying screen in radiography, sketching the development of this valuable apparatus. The Rheinberg filters for clinical microscopy, described in some detail, are designed to show the section illuminated in one colour against a background of another. The method is a refinement which should have its use in cases where staining is difficult or unsatisfactory.

ULTRA-VIOLET APPARATUS.

THE MEDICAL SUPPLY ASSOCIATION, Ltd., of 167-Gray's Inn-road, London, W.C., have placed on market under the name of Medisun a small mercury designed as a source of ultra-violet radiation of intensity with a corresponding current consumption. quartz burner is placed in a deep metal hood supported wide aluminium base containing the series resistance, whole instrument being small and portable. The burner made in two forms for use on direct or alternating and since, in the latter case, a special transformer is the price is increased from £10 to £18. The direct instrument consumes about 1 ampère and hence is economical in running costs. The alternating type considerably more current, from 2·5 to 4·5 ampè to the voltage of the supply. Like all mercury arcs, Medisun uses more current on starting up, but not the range of an ordinary house lighting circuit. The of the radiation generated by this small lamp is identical with that of the large quartz mercury arcs.

The catalogue of the COX CAVENDISH ELECTRICAL (105, Great Portland-street, London, W.) contains, a list of apparatus supplied for ultra-violet a number of short extracts from books and describing what may be achieved by its use, and a graphy for further reference. The apparatus is of range, including mercury, carbon, cored-carbon, and arcs of various types and standard makes (Hanovia, H Cox Cavendish). An interesting piece of mechanism is Water Steriliser (Hewitic) which employs radiation from a quartz mercury lamp and will, it is sterilise water at the rate of 140 gallons per hour. small ultra-violet lamps for use in the home are including (on a separate leaflet) a small mercury lamp. radiation from such a lamp will be rich in the shorter lengths and for that reason more effective in skilled than the carbon or cored arcs, but it should be borne in that the dangers of blistering the skin and damaging eyesight have been proportionately increased. The a necessity of wearing efficient goggles is not yet realised public, and no opportunity should be missed of em the point.

A catalogue published by Messrs. WATSON of Sunic Ho Kingsway, is a concise but representative list of lamps accessories for ultra-violet therapy. It contains, besides actual specifications, mush useful information for practitioner who wishes to select suitable apparatus. S matters as cost of running, repairs, and the use of are treated fully. A short section is devoted to radiation, and a few instruments for measuring radiation are included.

X RAY APPARATUS.

Messrs. WATSON issue also a small booklet with this describing the Muller Hot Cathode Tube for which they agents in this country. The cathode of this tube electrically heated filament which generates the carrying the current. It is claimed that the Muller tube not often break down owing to perforation of the glass, si the residual gas in the tube is helium which allows higher pressure than normal. In some of the tubes descri the filament is so arranged as to project a line focus on anode which is much blunter than in the usual type of tu Viewed from the direction of the principal X ray be the line focus is seen end on and is thereby reduced to dimensions of a spot. The intensity of the X rays genera remains unchanged but the heating effect of the discharg distributed over a larger area. Line focus tubes are m both in air-cooled and in water-cooled types for vari strengths of current. Tubes of this type require special in adjustment as a rotation in the holder results in apparent broadening of the focus and consequent loss detail.

Another catalogue of the same firm describes vari interesting types of apparatus designed to accommodate Metalix tube for diagnostic work. In the combined co and screening stand one tube can be used for all positi over and under couch and for upright screening at a w range of focal distance. Adjustment of the tube can made swiftly without disturbing the patient, and there a saving in cost and weight without sacrifice of safety. copy of this catalogue will be sent post free on applicati.

BRADFORD MUNICIPAL GENERAL HOSPITAL.—the annual distribution of prizes and certificates, the med superintendent, Mr. B. Holroyd Slater, spoke of the gr increase in the work. Quite recently, he said, there w so many operations to be performed that the staff w working continuously in the theatre from 8.30 one morn until 2.30 the following morning. The nurses, he add were living under "miserable conditions."
